At our institution, when we compare total pancreatectomy to the Whipple operation for ductal adenocarcinoma, and I emphasize we are talking about ductal adenocarcinoma, in a series of 89 patients with a total and 101 patients with a Whipple, we find an operative mortality rate of 4% for the Whipple, 11% for the total, 3-year survival rate, which is identical, (9%), and a 5-year survival rate that is close to being identical at 6% and 4%, respectively. The mean survival was a dismal 12 months after total pancreatectomy and 16.5 months after the Whipple procedure.

I close, though, with a ray of hope and ask both of the presenters their opinion regarding adjuvant radiotherapy after resection for cure.

(Slide) As you will see in this slide, in a statistically insignificant number of patients with ductal adenocarcinoma who had the Whipple, the total, or distal pancreatectomy followed by radiotherapy, the mean survival was 44 months, and the 5-year survival was 3 of 9 patients, which is 33%.

DR. G. ROBERT MASON (Irvine, California): I would like to congratulate the authors of the Hopkins service on their excellent activity and their excellent results, and in following the marvelous tradition of I. Ridgeway Trimble. As you probably recall, Dr. Trimble was not only one of the first who contributed to the operative procedures for resection, but also for reconstruction, dealing more successfully with the pancreatic remnant by reanastomosing it to the enteric tract.

This has, nonetheless, continued to be one of the major areas of problem for surgeons over the years, and I note that Dr. Cameron also continues to have the pancreatic remnant cause complications not only for fistula but also for abscess and hemorrhage as its major problems.

We have chosen to deal with this in a consecutive series of 25 patients by performing pancreatogastrostomy, and if you would wonder what that is, we will show you a slide or two.

(Slide) Pancreatogastrostomy is performed by a direct mucosal anastomosis to the posterior aspects of the stomach with an incision in the seromuscular layer and a suture of the capsule to the seromuscular layer.

(Slide) This then results in a rather simple enteric anastomosis of the pancreatic duct and stomach, and we have done this both with antrectomy and with pylorus preservation.

(Slide) In animal experiments this has served well as a patent anastomosis for up to 3 months as studied histologically. This has resulted in no morbidity from this particular anastomosis, and in the series of 25 consecutive patients, no mortality for the series of patients.

We have attributed part of our success to pancreatogastrostomy, and we have attributed part of our success to the fact that we are emphasizing the matter of assessing pre- and postoperative nutrition, the use of H2 blockers, the use of critical care monitoring, and the use of percutaneous drainage of fluid collections.

In the success rate that Dr. Cameron notes in his operative procedures, I would wonder if these latter items have contributed also to his success as they certainly were not available in the earlier years of his series.

DR. MARTIN S. LITWIN (New Orleans, Louisiana): I am pleased to have the opportunity to discuss these two excellent papers.

The treatment of adenocarcinoma of the pancreas is one of the last great surgical therapeutic frontiers. It provides surgeons with the opportunity to care for a disease that remains a therapeutic enigma. For those of you who work in this area, you know that Dr. Bernard's conclusion is a correct one; *i.e.*, practice does, indeed, make perfect, but it is perhaps a little more difficult to practice here than in other areas simply because of the deep-seated location of the disease. There is no doubt in my mind that the seat of the soul is in the pancreas. Cardiovascular surgeons deal with life in their hands, but general surgeons who operate on the pancreas deal with the soul.

In the last few years the technique of total intravenous hyperalimentation has allowed us to improve considerably operative morbidity and mortality for these patients. One of the most difficult tasks that a surgeon has when dealing with a patient who has adenocarcinoma of the pancreas is to do nothing until the patient has been adequately prepared for surgery with adequate nutrition. Intravenous hyperalimentation in the preoperative period for a minimum of 5–7 days and continuing into the postoperative period has allowed us to approach figures for morbidity and mortality similar to those presented by Dr. Cameron this morning.

The use of intravenous hyperalimentation allows a debilitated patient to be restored toward a state of positive nitrogen balance. In the postoperative period his ability to heal suture lines and to fight infections is vastly improved, and pancreatic fistulas have become almost unknown.

I would like to pose a question for both Drs. Block and Cameron. Were any of your patients treated with intravenous hyperalimentation before surgery, and if so, how did those compare with others who were not so treated?

DR. GEORGE L. NARDI (Boston, Massachusetts): I enjoy these hearty perennials on the pros and cons of surgery for pancreatic cancer, and I rise to make a couple of comments. I have no slides. I just wanted to tell of an experience of 20 years ago when I was reviewing mortality and survival in this type of surgery.

It disturbed me, being at the Massachusetts General Hospital, to see that the Lahey and Mayo Clinics both had much better results than we did. Their mortality was one third and their 5-year survival, 2 or 3 times what ours was.

I found a simple answer. We had about 16 surgeons doing our Whipple operations, whereas they had four and two, and there was a straight line correlation. We also found that our operability or resectability was 20% and theirs was less than 10%. It was apparent that mortality correlates with the number of surgeons doing the procedure and survival correlates with selection of patients.

I ask Dr. Cameron his operability or selection rate.

The last comment to set the record straight: there was an old paesano of mine named Codivilla who did a pancreatic resection back before the turn of the century for sarcoma. The patient survived nicely for 21 days, but unfortunately, died of sepsis.

DR. JOHN BRAASCH (Burlington, Massachusetts): I have enjoyed these two papers. They might represent the Ying and the Yang of the subject or the highball and the lowball, and I believe it is fair to make Dr. Cameron fair game because he is the highball. Let us look at his two major premises. First his excellent morbidity and the mortality. I believe that that has been confirmed from a number of institutions in this country and abroad. For instance, Ron Tompkins at UCLA has reported his low mortality. The Mayo Clinic has, as have we at the Lahey Clinic. Now Dr. Cameron and the MGH have from this country. There are two groups in Germany who have likewise had very low morbidity and mortality after the Whipple procedure.

The second area in which we might examine Dr. Cameron's results is that of the actuarial survival.

(Slide) I have always been suspicious of actuarial survivals and especially I was suspicious of the figures that I presented 1 year ago. This is the slide that I used.

Since these data were accumulated for the slide, we have had another 1.5 years of follow-up, and there has been a dropoff in survival of bile duct adenocarcinomas. That is going to end up, it looks like, at a 5-year survival rate of around 45% instead of about 65%.

Ampullary carcinomas are going to drop off, and it looks like it is going to be 50–60% instead of 70%. However, in a small series of adenocarcinomas of the pancreas, our two survivors (20%) out of this rather small group are still living at 61 months and 84 months without evidence of disease. These have been re-evaluated, and these, indeed, are adenocarcinomas, both node negative and are the usual kind that you see.

Finally, I would like to leave one more thought with you as has been suggested by other discussants. One question is: should we be training all general surgeons to do this procedure, and secondly, if we do train them, should they all be allowed to do the procedure if they choose?

DR. ALEXANDER J. WALT (Detroit, Michigan): John Braasch has just superseded me. I was going to comment that for most general surgeons, performing a Whipple in their surgical lifetime has long represented something of a trophy to be achieved, a surgical scalp. Dr. Axelrod, the health commissioner, probably had the information about the results in New York State yesterday. We have the results of two large series presented here today. The AARP will have the same results tomorrow and the science writers the day thereafter. Knowledge of such data carries at least two important implications. Firstly, do we now feel strongly enough in light of all these data to advocate the regionalization of the Whipple operation since it carries this high mortality and overall poor results, especially in institutions where there is little experience and where there is no opportunity for a significant experience to be acquired? Secondly, as individual chiefs of surgery in our various hospitals, do we have the will and the support to restrict the privilege for this operation to a small group of surgeons who have proven their ability to do the operation safely and well and to whom we will channel a sufficient number of cases to ensure high quality in the care of the patient?

DR. JOHN L. CAMERON (Closing discussion): I thank the many discussants for their comments and questions.

We, as I believe everyone else, when we first saw our data were suspicious that perhaps we were calling lesions carcinoma of the head of the pancreas that were more favorable distal bile duct or ampullary lesions. Therefore, we took our six 5-year survivors among those 32 patients with carcinoma of the head of the pancreas who were treated 5 or more years ago and had them re-reviewed by a pathologist at Hopkins who had not been involved in their initial signout. Pathologists are no different than surgeons. This pathologist would have loved to have found that these had been mistakingly signed out as carcinoma of the head of the pancreas, but on re-review they were all confirmed to be carcinoma of the head of the pancreas. I believe Dr. van Heerden's comments are appropriate and we would be happy to have these six patients reviewed by outside pathologists.

We, as many others, are somewhat suspicious of actuarial survival data. However, when we look at our 32 patients with cancer of the head of the pancreas who were operated on 5 or more years ago, there are six 5-year survivors for an actual 5-year survival rate of 19%, which is similar to our actuarial 5-year survival rate for all 50 patients of 18%. Therefore, we are convinced that the survival is real and that all patients indeed did survive carcinoma of the head of the pancreas.

The studies from the University of Chicago and the one from Hopkins are really not comparable. Whenever you look at something over four decades, it is always difficult for me to understand what the figures mean, and I believe that the two studies cannot be compared. I believe they were not looking for recent trends, which is what we were looking for. I believe they have the data to look at the same aspects of the disease and its management that we have, and perhaps they will or have already done it.

In answer to Dr. Warshaw, up until several years ago, we were restricting the Whipple to patients 70 years of age or less. But because everybody was surviving, we felt perhaps we were not extending it to enough patients, so now there really is no age limit among the patients we have done. We have one patient who is 84 and another who is 90. The 90-year-old patient was treated just a couple of weeks ago and recently left the hospital.

The presence of positive nodes was used to exclude a patient from being a candidate for a Whipple procedure for carcinoma of the head of the pancreas. However, we have one 5-year survivor who had two positive nodes; therefore, we would not exclude such a patient from a Whipple procedure today.

I believe there are some patients with carcinoma of the head of the pancreas who should not be operated on, but have their biliary tree decompressed with an endoprosthesis placed either endoscopically or percutaneously. In those patients with other diseases and illnesses that are unable to tolerate a Whipple, I believe we have nothing to offer them over a biliary decompression, which can be done nonoperatively. In addition, in those patients with widespread disease, I believe we offer them very little with operative intervention.

I believe one extension of our study is: should this operation ever be done as a palliative procedure? That has been looked at in the past, but it was looked at when one of every four patients we operated on would die. Now that it can be done with little hospital morbidity and mortality, I believe we have to at least consider whether or not it should be offered to a patient as a palliative procedure.

I believe Dr. van Heerden brings up a good point in terms of adjuvant therapy for patients with carcinoma of the head of the pancreas, and I believe that is the area where future hope rests for even improved survival. The GI Tumor Study Group reported their data in 1985 and in a series of about 40 patients, in the one half that were treated with adjuvant radiotherapy and chemotherapy, mean survival doubled and there was a 5-year survival rate of 15%. Our patients who survive a Whipple procedure and are discharged from the hospital with carcinoma of the head of the pancreas also receive adjuvant radiotherapy and chemotherapy.

In answer to Dr. Mason, we had 12 fistulas among our 88 patients. However, unlike other series, none of the 12 patients with pancreatic cutaneous fistulas died. Also, the fistulas did correlate with wound infections, postoperative sepsis, or the development of an intra-abdominal abscess. Therefore, for unclear reasons they were not the life-threatening complication in our series as in others. Eleven of the 12 closed spontaneously. Only one patient had to be operated on for a persistent fistula.

Few of our patients had preoperative TPN. One of the reasons the review extended back to 1969 was because that was when we first had a TPN team in our hospital and, therefore, it was available during the entire period. Many of the patients in whom complications developed after operation had TPN administered, but not before operation.

In answer to Dr. Nardi, we are not certain what our resection rate is now, but that also seems to have increased significantly, and we have the impression that it is now about 30%. We have the numerator, how many Whipples we have done during the last 20 years, and we are now looking up the denominator to see what the resectability rate is.

Again in answer to Dr. Braasch, actuarial survivals are somewhat of a risk when you rely on them too heavily. But both the real and actuarial survival rates are 18 and 19% for carcinoma of the head of the pancreas.

Dr. George E. Block (Closing discussion): It is my privilege to close Dr. Connolly's and Dr. Dawson's presentation, and I thank all the discussants for their wide-ranging and spirited discussion.

It is tempting to look at the two presentations on cancer of the pancreas today and immediately try to compare them. Although they are not really comparable, one might gather from the presentations that the surgeons in Chicago do not know how to treat the disease and that the surgeons in Baltimore do not know what disease they are treating. Such conclusions are obviously unfair.

It is worthwhile to emphasize that based on a critical review of our own experience, ony 4% of our patients had an ampullary carcinoma. Approximately one third of the patients in Dr. Cameron's series had periampullary or ampullary carcinoma. The survival rates from ampullary carcinoma in the two institutions are comparable, indicating that we are doing similar "cancer operations."

As far as the question of palliation is concerned, it is a nonsequitur. If we accept a 15% cure rate, a 5% cure rate, a 2% cure rate, or 0.2% cure rate, then by definition the operation is palliative. We must look at the operation for ductal carcinoma of the pancreas just as we do at resections for cancer of the esophagus. The majority of the operations are palliative.

To answer some of the discussants specifically, as time goes by our resectability level stays the same, about 14%. Our aggressiveness, however, decreases.

Since the advent of percutaneous decompression, many of my colleagues and I have adopted a philosophy that not all patients with cancer of the pancreas have to die with a scar on their abdomen. By using such diagnostic modalities as CT scanning, NMR, etc., we now can choose slightly better, but not perfectly, those patients who will obviously not benefit from operation.

Concerning radiation, our experience with postoperative radiation has not been favorable. The effect of intraoperative irradiation of these patients has yet to be determined.

Our experience does parallel Dr. Axelrod's experience in New York. As far as Dr. Litwin's comments are concerned, I do not believe we looked at TPN because this study goes back into the 1940s. From my own experience, however, I do not believe that we can achieve anabolism in 5 days. I would rather use parenteral alimentation in the postoperative period to carry these patients over a period of prolonged starvation. Although this does seem to help, we do not have objective data.

I certainly agree with Dr. Braasch's and Dr. Walt's suggestions that this is not an "every man" operation. I do not know if I can embrace the regionalization concept, however. From our experience it appears that today the majority of pancreatic resections in Chicago are attempted by surgeons familiar and skilled in the procedure. From Dr. Moossa's contributions and our own experience, our recent operative mortality rate approaches that of Dr. Braasch and Dr. Cameron.

We have not yet reached the 5% mortality rate, but we are hovering around 7% and it does improve with the learning curve of the surgeon.

In one final note I emphasize that the point of our paper is that the histologic diagnosis is the crux here and that we did not use actuarial survival. We determined actual survival. All of these patients were followed until death or 5 years or more.

I am a bit confused by actuarial survival. Therefore I asked our statistician before I came here to review the concept of actuarial survival with me. He told me that I would not understand it, but to clarify he explained that according to actuarial survival, Andy Warhol is still alive.

Angiostatic Steroids

Method of Discovery and Mechanism of Action

JUDAH FOLKMAN, M.D. and DONALD E. INGBER, M.D., PH.D.

From the Department of Surgery, Children's Hospital, Department of Pathology, Brigham and Women's Hospital, and Departments of Surgery and Pathology, Harvard Medical School, Boston, Massachusetts

A new class of steroids has been found that inhibits angiogenesis in the presence of nonanticoagulant heparin. Tetrahydrocortisol is the most potent of the naturally occurring angiostatic steroids. It is a metabolite of cortisone that circulates in the blood, appears in the urine, and was previously believed to be biologically inactive. Both the plasma form and the urinary form are antiangiogenic. The mechanism of action of these steroids depends on their ability to specifically alter basement membrane turnover in growing capillary blood vessels. These steroids represent a prototype of angiogenesis inhibitors that may find potential therapeutic use as adjuncts to anticancer therapy, and in diseases dominated by abnormal neovascularization, *i.e.*, angiogenesis-dependent diseases.

ENDOTHELIAL CELLS, which line the entire vascular system, are relatively quiescent compared with other cell types. Intestinal mucosal cells, for example, undergo billions of cell divisions every day, and the entire lining of the intestine is replaced or "turned over" in 3 days. The turnover time of bone marrow cells is approximately 5 days. In contrast, the turnover time of vascular endothelial cells is measured in years.[1] During the growth of new capillary blood vessels, however, vascular endothelial cells are capable of rapid proliferation with turnover times of a few days. When this process of angiogenesis occurs normally or physiologically, it seems to be almost unique to females. Physiologic angiogenesis occurs during ovulation, after menstruation, and during development of the placenta. Angiogenesis is rarely observed in males unless it is of pathologic origin. Thus, a male may live an entire lifetime without angiogenesis unless he is wounded or a disease develops dominated by neovascularization.

Pathologic Angiogenesis

It is becoming clear that unabated capillary blood vessel growth can be the basis of devastating diseases that occur in both males and females. These diseases, previously believed to be unrelated, can now be considered "angiogenesis-dependent diseases," and can be found in almost every branch of medicine and surgery. They generally share two characteristics in common: (1) an abnormality of capillary blood vessel growth as a principal pathologic feature, and (2) the possibility that therapeutic control of the abnormal capillary growth would ameliorate or eliminate other manifestations of the disease. Diabetic retinopathy, retrolental fibroplasia, and neovascular glaucoma are some examples of pathologic neovascularization. In fact, neovascularization is one of the most common causes of blindness worldwide. Excessive neovascularization can also damage other tissues. Cartilage in the arthritic joint may be destroyed by neovascularization. Rapidly growing hemangiomas often disfigure babies. Excessive neovascularization in the skin is a dominant feature of psoriasis.

The most persistent and intense angiogenesis is associated with tumor growth.[2,3] There is accumulating evidence that progressive tumor growth is dependent on angiogenesis and that an increase in tumor cell population depends on new capillary blood vessels that converge on the tumor.[4,5]

Tumor angiogenesis seems to be initiated by diffusible angiogenic factors released by the tumors themselves[3] as well as by cells such as macrophages,[6] which tumors

Submitted for publication: April 24, 1987.

recruit.[6–8] At least four angiogenic factors have been isolated from both tumors and normal tissues. These four factors have been completely purified, the amino acid sequence of their proteins determined, and their genes cloned (for review see reference 2).

Angiogenesis Inhibitors

In 1972, we proposed the idea that "antiangiogenesis" could be a potential therapeutic approach against solid tumors.[9] No angiogenesis inhibitors were known at that time, however.

The first angiogenesis inhibitor was discovered in cartilage,[10–13] but has not been completely purified nor is it available in sufficient quantity for antitumor testing in animals. Protamine was also shown to be an angiogenesis inhibitor,[14] but toxicity increased with prolonged administration. Recently, we described a new class of steroids that have the inhibition of angiogenesis[15–17] as their principal function.

The elucidation of this new steroid activity resulted from a previous inquiry about the role of heparin in angiogenesis. We observed a 40-fold increase in mast cells at the site of a tumor implant in the chick embryo, just before new capillary sprouts converged on the tumor.[18] Increased mast cells also had been found in human hemangiomas during the proliferative phase of these vascular tumors.[19] Mast cell heparin stimulated locomotion[20] of endothelial cells *in vitro*[21] and significantly increased the rate of tumor-stimulated capillary growth *in vivo*.[14] On the basis of these results, heparin was used in the chick embryo chorioallantoic membrane bioassay for angiogenic factors because it reduced the time required for a positive angiogenic response from 3 days to 1 day.[14,22,23] The "heparin-enhanced" chick embryo bioassay set the stage for the discovery of steroids that could inhibit angiogenesis.

The chick embryo chorioallantoic membrane has served as a useful bioassay for angiogenic activity during the past decade.[24,25] Originally, a window was made in the eggshell, and angiogenic factors dissolved in a pellet of methylcellulose were applied to a 9-day chorioallantoic membrane. A positive angiogenic response was recorded if new capillaries and small venules converged on the implanted pellet in a spokewheel pattern. (This bioassay was subsequently improved by removing the embryo from its shell on day 3 and using the 6-day chorioallantoic membrane as the testing site for angiogenic substances.[5,26] A problem with the former method was that eggshell particles occasionally fell on the chorioallantoic membrane and caused inflammatory neovascularization. Pretreatment of the chorioallantoic membrane with cortisone or hydrocortisone abolished the inflammatory reaction. Fortunately, these steroids did not suppress angiogenesis induced by tumor extracts.

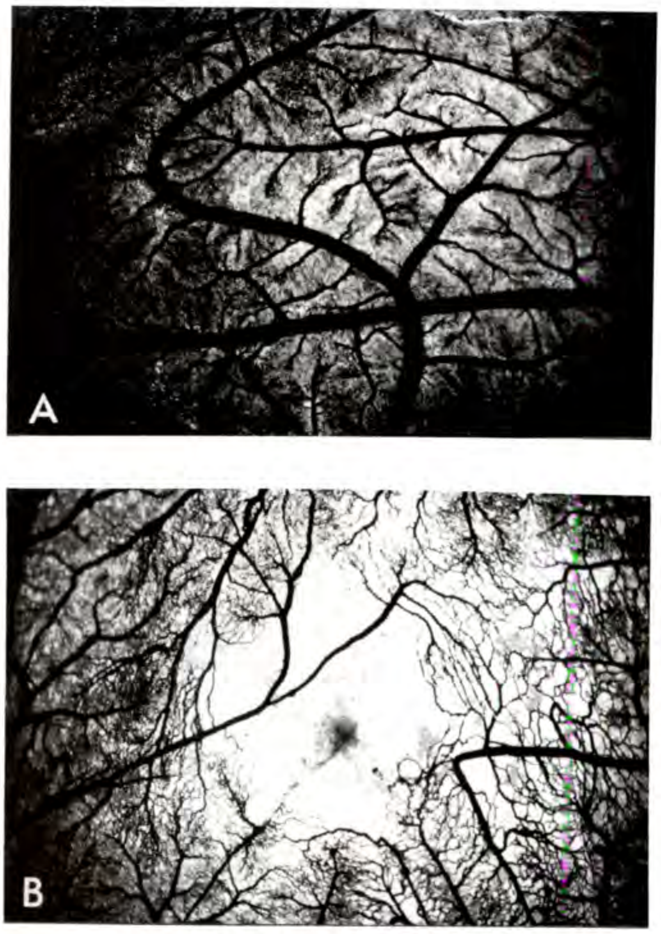
A New Class of Angiogenesis-inhibiting Steroids

Tumor angiogenesis was inhibited, however, when cortisone and heparin were applied together.[15] Furthermore, an avascular zone appeared in the chorioallantoic membrane surrounding the methylcellulose pellet containing the heparin–steroid mixture. Histologic sections showed that growing capillaries had actually regressed, leaving a hole in the membrane covered only by a layer of ectoderm and endoderm. Nongrowing capillaries and larger vessels were not effected. This unexpected antiangiogenic activity was independent of the anticoagulant activity of heparin. Nonanticoagulant fragments of heparin produced by enzymatic cleavage[15] or chemical synthesis[16] were more potent than whole heparin. It was thus possible to construct dose-dilution curves to determine the optimal concentrations of heparin and steroid (Figs. 1 and 2). As the concentration of hydrocortisone was increased beyond an optimum level (*e.g.*, 50–60 μg/10 μL), antiangiogenic activity diminished, generating a bell-shaped curve (Fig. 2).

In our first report of this new phenomenon[15] we were puzzled by an apparent paradox. Dexamethasone plus heparin had little or no antiangiogenic activity when tested at the concentrations where cortisone and hydrocortisone (in the presence of heparin) were maximally effective. Yet, dexamethasone is a synthetic analogue of hydrocortisone with approximately 25–30 times its glucocorticoid (anti-inflammatory) activity. During the year after this report, we completed dose-dilution curves for a variety of other natural corticosteroids. We noticed that they also produced bell-shaped curves, *i.e.*, the highest antiangiogenic activity for a given steroid often occurred at a lower concentration than the highest concentration tested.[16,27]

When dexamethasone was re-examined at concentrations far below effective doses for hydrocortisone, there was a sharp peak of antiangiogenic activity at 2 μg (with heparin), almost 1/25th the optimum dose for hydrocortisone. Dexamethasone, however, showed no antiangiogenic activity from 3–200 μg. In fact, concentrations above 100 μg were toxic, and 200 μg of dexamethasone killed all embryos. The eventual solution to the paradox lay in the fact that dexamethasone produced its own bell-shaped curve of antiangiogenic activity with an optimum dose of 2 μg instead of the 50–60 μg optimum level for hydrocortisone.

Before this paradox was solved, we had begun to explore an alternate possibility. The apparent lack of an-



FIGS. 1A and B. Normal (*A*) and angiostatic steroid-treated (*B*) CAMs injected intravascularly with India ink/Liposyn mixture (see below) on day 8. *A.* Normal 8-day CAM contains a continuous vascular network beneath its surface ectoderm. *B.* CAM exposed to a methylcellulose sustained-release polymer containing 6a-fluoro-17,21-dihydroxy-16b-methyl-pregna-4,9,(11)-diene-3,20-dione (Upjohn, Kalamazoo, MI) (50 μg) and heparin (50 μg) for 2 days. Note the avascular zone within the center of the view, which is free of capillaries, although a larger vessel remains intact. The semiopaque methycellulose disc can be seen in the central portion of the zone. These avascular zones were used to generate dose-dilution curves for heparin–steroid combinations (see Fig. 2). India ink was injected through a 33-gauge needle into the major artery supplying the chorioallantoic membrane of chick embryos. A mixture of India ink 1:6 with a lipid emulsion (10% Liposyn II, Abbott Laboratories, North Chicago, IL), gave the most uniform distribution of ink into the finest capillaries. The chorioallantoic membranes were then fixed with formalin and photographed from above.

tiangiogenic activity by the potent glucocorticoid dexamethasone suggested that the antiangiogenic activity of hydrocortisone and cortisone (in the presence of heparin) could be independent of glucocorticoid activity. This hypothesis was tested by substituting 11alpha-hydrocortisone (epicortisol) for hydrocortisone (Fig. 3). Epicortisol is the biologically inactive stereoisomer of hydrocortisone.[28] The alpha position of the 11-hydroxyl group eliminates glucocorticoid and mineralocorticoid activity. Epicortisol inhibited angiogenesis and caused capillary regression (in the presence of heparin) as had hydrocortisone, although epicortisol was slightly less active than hydrocortisone on a molar basis.[16,27] At this writing, inhibition of angiogenesis is the only known biological activity of epicortisol.

Structure–Activity Relationships of Steroids that Inhibit Angiogenesis

A search was initiated for other corticosteroids in which antiangiogenic activity might be dissociated from glucocorticoid and/or mineralocorticoid activity. More than 100 corticoids and related compounds were tested for antiangiogenic activity. Each steroid was dissolved or suspended in the presence and absence of heparin, in 10 μL of methylcellulose (0.45% in distilled H_2O) and pipetted onto a Teflon rod of 2-mm diameter.[16] The droplet was air-dried (in a laminar flow hood) to a disk of 2-mm diameter and implanted on the 6-day chorioallantoic membrane of the shell-less chick embryo cultured in a humidified incubator at 37 C and 3% CO_2. An optimum heparin concentration was found to be 50 μg. A dose-dilution curve was generated for each steroid (1–200 μg) in the presence of heparin. Each steroid was also tested alone at the optimum and maximum doses. At least 20 embryos were examined for each steroid concentration. The endpoint for angiogenesis inhibition was an avascular zone of 4-mm diameter or larger 48 hours after implantation of the methylcellulose pellet. A mixture of hydrocortisone-21-phosphate (Sigma, St. Louis, MO), 60 μg/10 μL, plus heparin (Hepar Inc., Franklin, OH), 50 μg/10 μL, was used as a positive control.

An antiangiogenic index was determined as the percentage of embryos with avascular zones (4-mm or

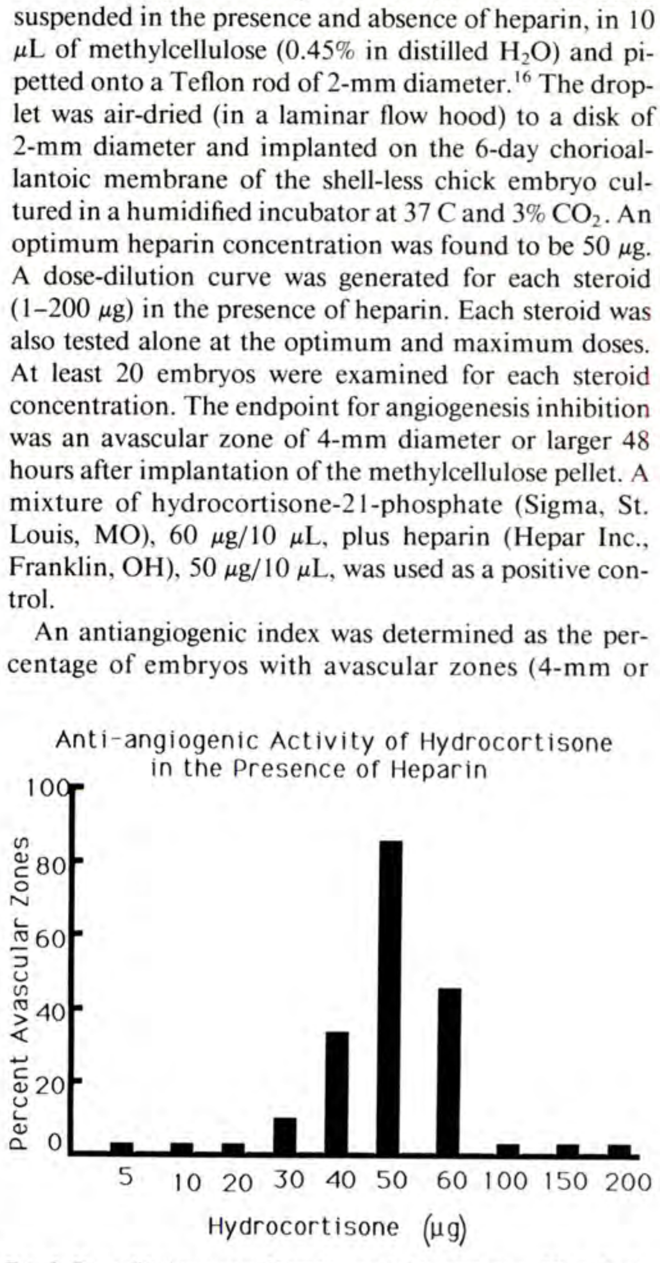


FIG. 2. Dose-dilution curve. Heparin was held constant at 50 μg. Each bar represents 20 embryos.

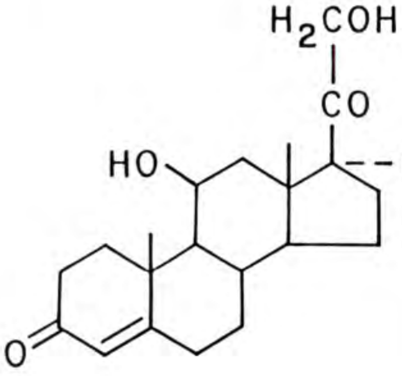
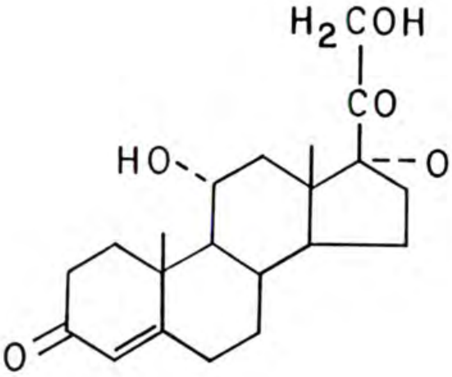


HYDROCORTISONE



11a-EPIHYDROCORTISOL

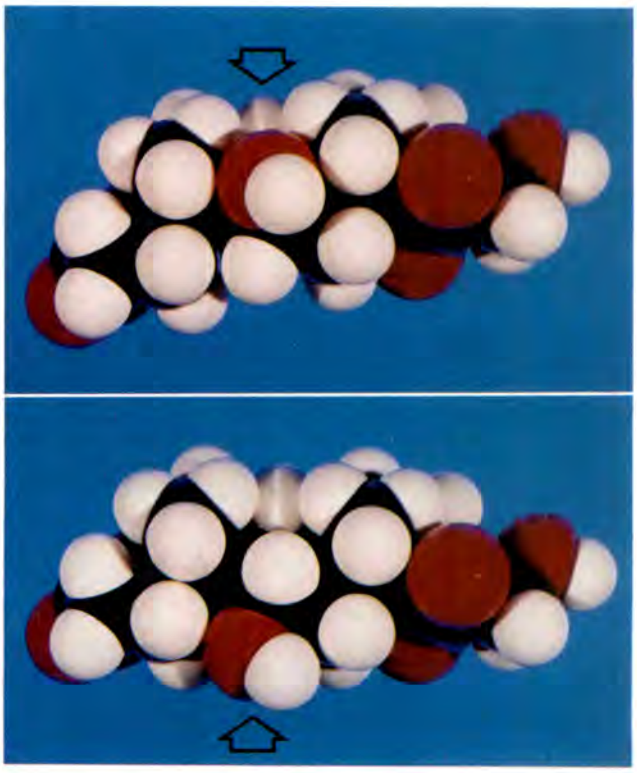


FIG. 3. Hydrocortisone and its biologically inactive stereoisomer, 11-alpha-epihydrocortisol differ only by the position of the 11-hydroxyl (arrow) in the plane of the molecule. The 11-hydroxyl lies above the plane in hydrocortisone (beta position) and below the plane in 11-alpha epihydrocortisol (alpha position). 11-alpha epihydrocortisol retains only angiostatic activity, and lacks all of the other functions of hydrocortisone.

greater diameter) at the most active dose, divided by the most active dose expressed in micromoles (for example, the molecular weight of hydrocortisone is 362.5. The most active dose was 60 μg. 60/362.5 = 0.166 μmol. Its antiangiogenic index was 60/0.166 = 361). The antiangiogenic indices of each compound were then compared.

Antiangiogenic Activity of Natural Steroids and Related Compounds

Of the naturally occurring corticosteroids, tetrahydrocortisol was the most potent inhibitor of angiogenesis. Its relative potency is shown in Table 1.

Tetrahydrocortisol lacks the 4,5 double bond in its A ring (Fig. 4), and, for this reason, lacks all of the known functions of cortisone. In fact, it is one of the major metabolites of cortisone[29] previously believed to be without biological activity. Steroids are mainly inactivated in the liver by the enzymatic reduction of the 4,5 double bond in the A ring forming the dihydro derivative (Fig. 4). The dihydro derivative is converted to a

TABLE 1. *Relative Antiangiogenic Potency*

Compound	Percent Potency
Tetrahydrocortisol	100
17a-hydroxyprogesterone	56
Hydrocortisone	51
11a-epihydrocortisol	14
Cortexolone	12
Corticosterone	12
Desoxycorticosterone	8
Testosterone	3
Estrone	2
Progesterone	0
Pregnenolone	0
Cholesterol	0

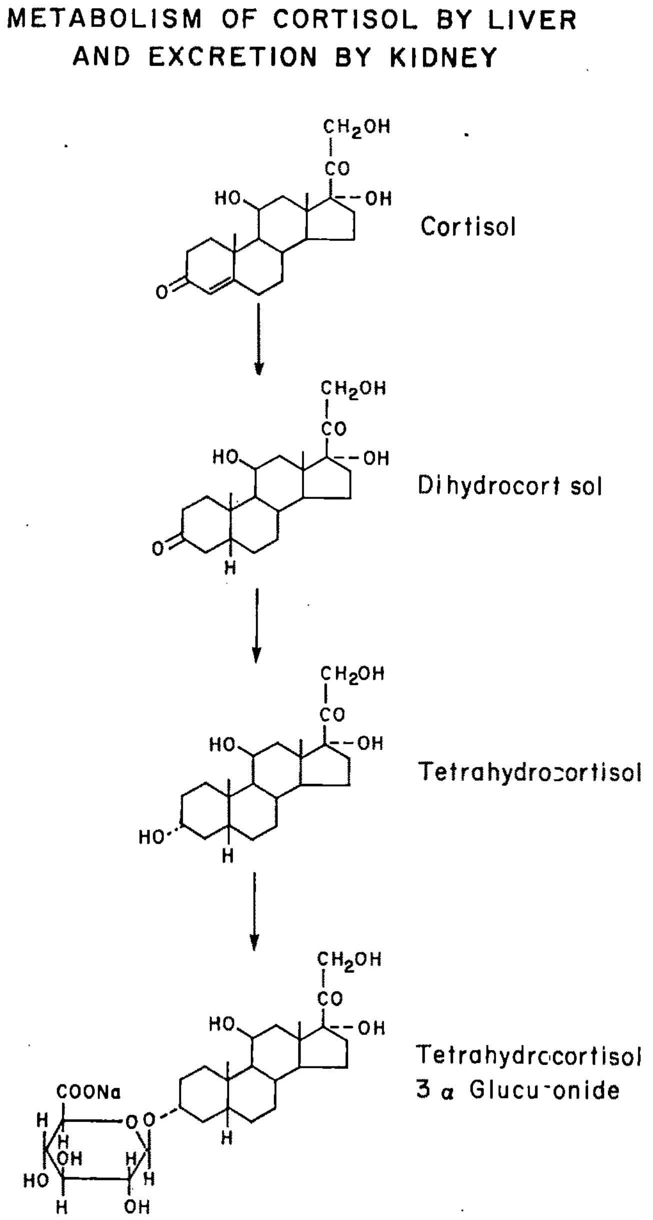

FIG. 4. The metabolic pathway by which cortisone is inactivated in the liver and excreted in the kidney. Tetrahydrocortisol, previously believed to be an inactive metabolite, is now known to be highly angiostatic (in the presence of a heparin fragment). Its urinary derivative, tetrahydrocortisol-3-glucuronide, is also a very active angiogenesis inhibitor.

tetrahydro derivative by the enzymatic reduction of the 3-oxo group to a 3-hydroxyl group. This compound is lipid soluble. It is then conjugated with glucuronic acid to become a water-soluble product that can be excreted by the kidney.[29]

Thus, tetrahydrocortisol represents a steroid with pure antiangiogenic activity independent of either glucocorticoid or mineralocorticoid activity. It defines a new class of steroids that we have named "angiostatic steroids." Cortexolone and 17a-hydroxyprogesterone are other examples of angiostatic steroids that lack gluco- and mineralocorticoid activities. When the structures of the compounds in Table 1 are taken together with structures of a variety of synthetic steroids (not shown) that we have tested, four rules predict antiangiogenic activity: (1) the 11- and 21-hydroxyl groups can be removed without significant loss of angiostatic activity; (2) the 17-hydroxyl group is essential, because its removal reduces antiangiogenic activity by approximately 76% of the activity of hydrocortisone.[16] Thus, maintenance of antiangiogenic activity is governed mainly by structural components on the D ring of the pregnane nucleus; (3) reduction of the A ring increases antiangiogenic activity by almost twice that of hydrocortisone; and (4) pregnenolone, a derivative of cholesterol and a general precursor for the biosynthesis of adrenal steroids, is inactive, as are structures such as progesterone, which lack all three hydroxyl groups (11-, 17-, and 21-).

Recently, it has been found that glucuronic acid can be synthetically conjugated to the 3-hydroxyl position of tetrahydrocortisol and that it retains very high antiangiogenic activity in the presence of heparin.[30] The conjugated compound is water soluble. This is the first demonstration of a biological activity for this urinary metabolite of hydrocortisone.

Inhibition of Tumor-Angiogenesis by an Angiostatic Steroid

Angiostatic steroids can inhibit tumor-induced angiogenesis when used at pharmacologic doses in the presence of exogenous heparin. This is most clearly demonstrated by inserting V2 carcinoma into a corneal pocket of a rabbit eye, a method that has been previously described.[14] A 1-mm^3 tumor implant is placed 2 mm from the limbal edge of the cornea. New capillaries grow toward the tumor in a dense pannus and increase their length at an average of 0.2 mm per day. A 1-mm pellet of ethylene vinylacetate copolymer[13] is impregnated with heparin and $\Delta^{9(11)}$ 11-deoxycortisol and inserted into the cornea between the tumor and the vascular bed. Control eyes contain either an empty polymer or a polymer with heparin or steroid alone (Figs. 5A–C). Capillary growth is almost completely inhibited only in the corneas implanted with both heparin and the angiostatic steroid.

A Proposed Physiologic Role for Angiostatic Steroids

Tetrahydrocortisol, when administered at pharmacologic doses with exogenous heparin, can induce capillary regression in the growing vessels of the chick embryo, and at the doses used, can inhibit but not regress capillary growth induced by intracorneal tumor. It is unclear whether circulating tetrahydrocortisol has a physiologic role. One can speculate that it may act synergistically

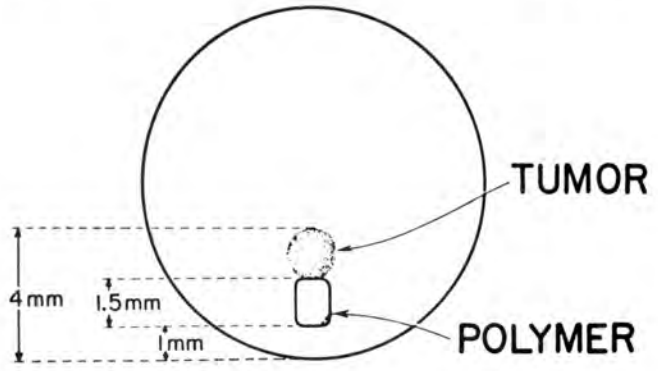

FIG. 5A. Diagram of position of intracorneal tumor implant and polymer pellet containing steroid–heparin mixtures.

with the heparin-like molecules that are known to be on the surface of the endothelial cell[31] and embedded within its basement membrane, as well as within nearby mast cells, to prevent capillary growth under normal conditions. We have obtained some experimental evidence to support this hypothesis. Desulfation is one of

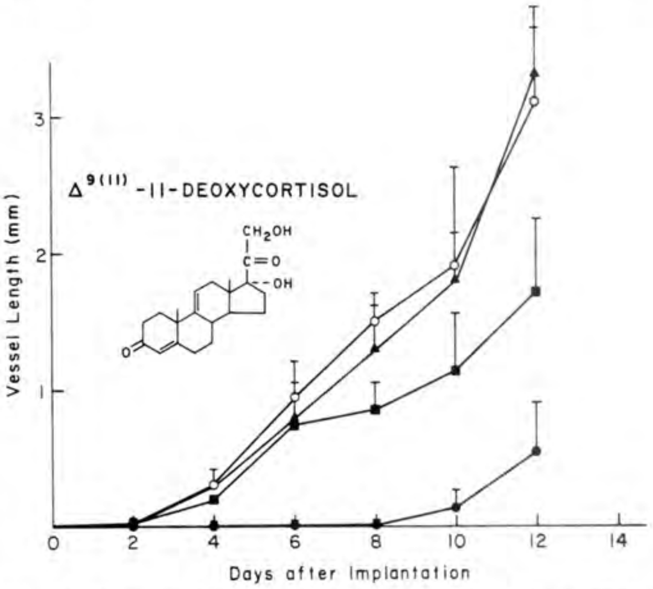

FIG. 5C. Mean growth rates (and SEM) of capillaries in Figure 5B. ● = $\Delta^{9(11)}$-11-deoxycortisol and heparin. ■ = $\Delta^{9(11)}$-11-deoxycortisol alone. ▲ = heparin alone. ○ = blank (empty polymer implant).

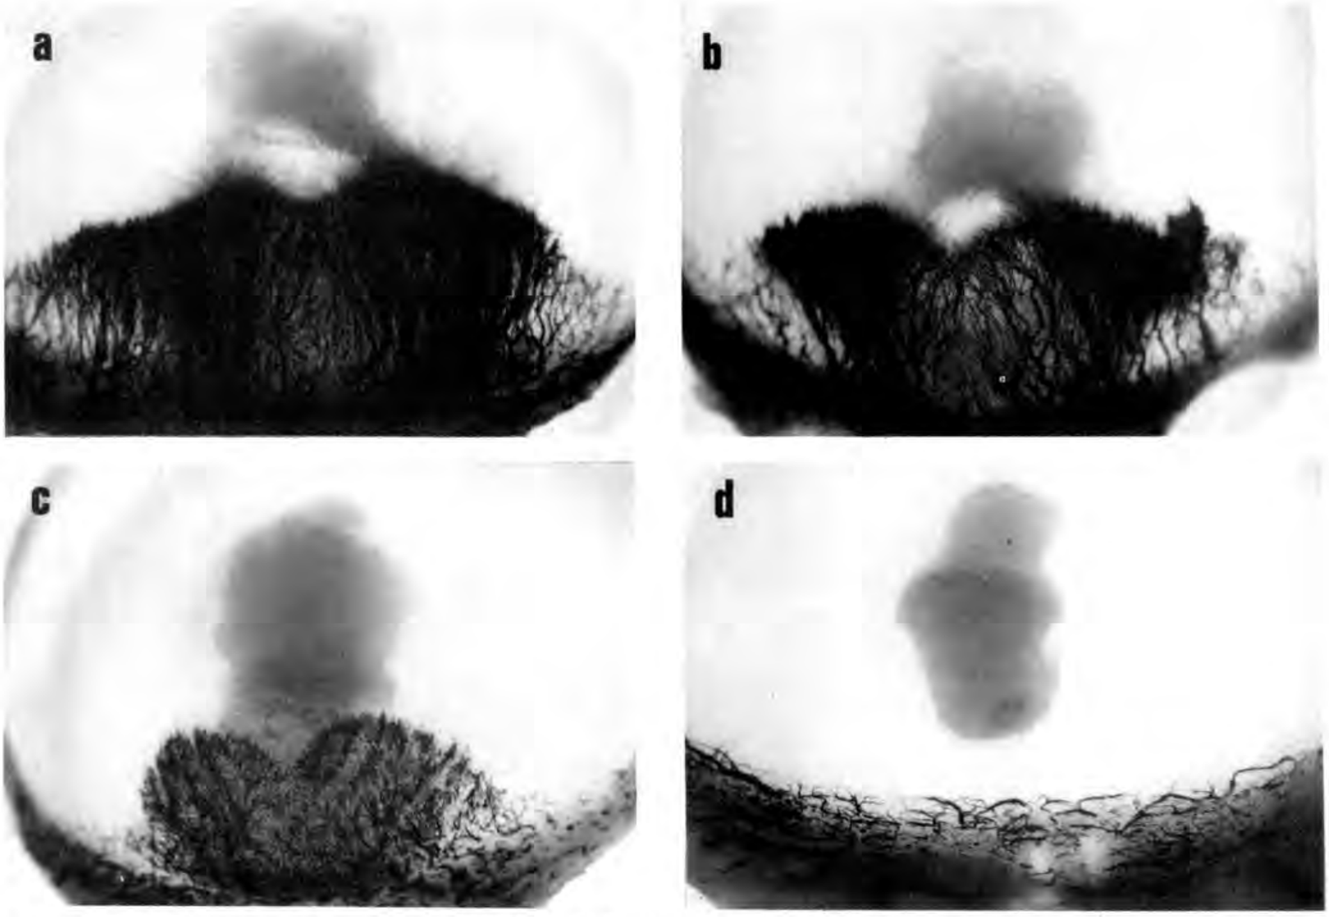

FIG. 5B. Rabbit corneas 11 days after intracorneal implant of V2 carcinoma (top of each photograph). Rabbits were killed and India ink was injected into both carotid arteries. A 1-mm^3 sustained-release pellet of ethylene vinyl acetate copolymer was implanted between the tumor and the vascular bed. It can be seen only in (*d*), and is obscured by a dense pannus of new capillaries in the other photographs. The polymer pellets contain heparin (Sigma), 1.8 μg/mL, and $\Delta^{9(11)}$-11-deoxycortisol, 135 μg/mL. (*a*) Blank (*i.e.*, empty polymer pellet). (*b*) Heparin alone. (*c*) Steroid alone. (*d*) Steroid-plus heparin. There is no vessel growth in (*d*) as long as the polymer pellet is present. When it is removed (up to 30 days after implant), new capillaries begin rapid growth.

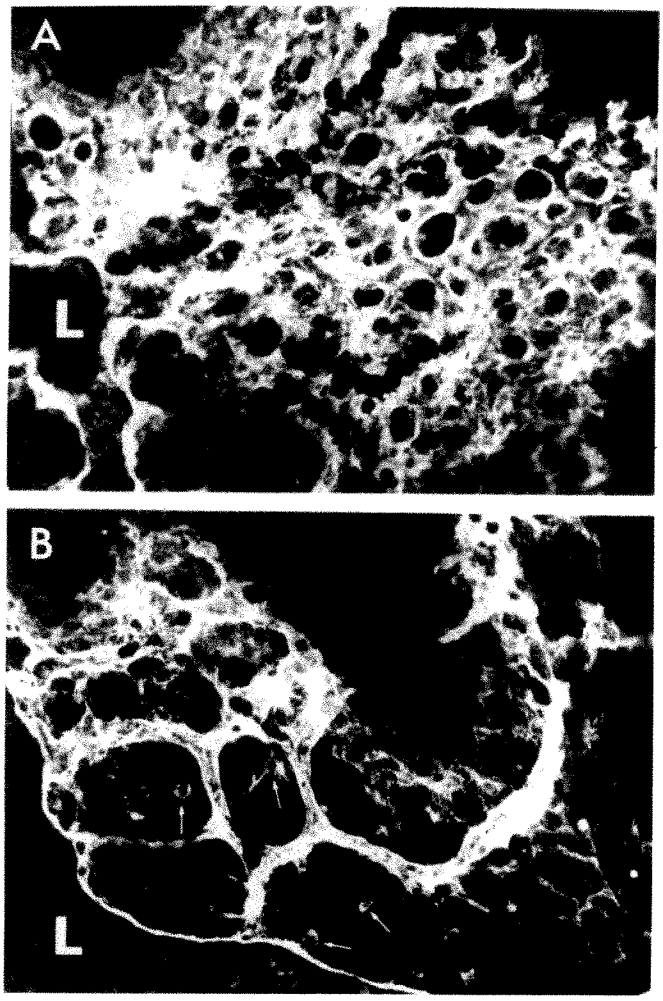

FIGS. 6A and B. Fluorescence localization of fibronectin within *en face* paraffin sections of normal (*A*) and angiostatic steroid-treated (*B*) CAMs. *A*. In the normal subectodermal vascular bed, fibronectin appears in a continuous linear pattern delineating basement membrane that surrounds large vessels as well as capillary structures. Note the small intercapillary distances within the normal capillary plexus. The amorphous pattern of staining along the top of this view is due to fibronectin present within the overlying ectoderm basement membrane. *B*. In regions of partial capillary regression, the finest capillaries and associated linear patterns of fibronectin are lost first. Progression of capillary involution is associated with additional loss of fibronectin, capillary retraction, and endothelial cell rounding. Small arrows indicate rounded endothelial cells in contact with wisps of fibronectin-containing material; L = lumen of large vessel (×400). Affinity-purified rabbit antibodies to fibronectin were obtained courtesy of Joseph Madri (Yale) and used as previously described.[17]

the pathways by which heparin and heparin-like molecules are normally degraded.[32] Recent experiments done with Neil Chen[33] in our laboratory demonstrate that the administration of hydrocortisone with a sulfatase inhibitor[34] but *without* exogenous heparin is just as effective in causing capillary regression in the chick embryo as is the steroid with heparin. The steroid alone has no effect. We found that sulfatase activity is abundant in the chorioallantoic membrane. The added sulfatase inhibitor appears to retard degradation of heparin and allows endogenous heparin to accumulate locally. Thus, it is possible that endogenous heparin together with circulating angiostatic steroids may act at low concentrations over long periods to defend against abnormal capillary growth at the wrong place or time.

Mechanism of Action of Angiostatic Steroids

When the angiostatic steroids were first revealed, the only known model of regression of growing capillaries was our previous study of the morphologic events that followed the removal of an angiogenic stimulus from a neovascularized cornea.[35] In this experiment, removal of an angiogenic stimulus (ethylene vinyl acetate copolymer pellet containing tumor extract) led to platelet aggregation and the formation of microthrombi at the tips of the new capillaries within 24–48 hours. Endothelial cells desquamated and macrophages migrated into the lumen of the vessels to phagocytize platelets and dying endothelial cells. In contrast, when capillaries regressed under the influence of angiostatic steroids and heparin, histologic sections showed no platelet accumulation, macrophage infiltration, or microthrombi. This suggested that a novel mechanism of capillary involution was taking place.

A clue to such a mechanism came from an examination of what is known about other tissues that undergo physiologic involution, *e.g.*, the mammary gland[36] and the Mullerian duct.[37] Involution of epithelium in these tissues is associated with degradation of basement membrane. Furthermore, the modulation of basement membrane integrity in these epithelial tissues appears to be regulated through a balance of steroids and specific polypeptide growth factors.[38] By analogy, it seemed possible that angiostatic steroids could regulate the growth and viability of capillary endothelium through their effects on the capillary basement membrane. Degradation of basement membrane could lead to gradual rounding and eventual detachment of endothelial cells, as predicted by experimental models of epithelial cells.[39] Normal endothelial cells progressively lose their ability to grow as they take on increasingly rounded forms, even when supplied with optimal growth factors.[40] They die after only a few hours of detachment from a substratum.[41] The normal vascular basement membrane contains collagen type IV, laminin, fibronectin, and glycosaminoglycans. We used immunofluorescence microscopy to study the distribution of two basement membrane components, fibronectin and laminin (method described in Fig. 6 legend).

Dissolution of Vascular Basement Membrane Accompanies Involution of Growing Capillary Blood Vessels

Chorioallantoic membranes treated with steroid–heparin mixtures revealed avascular zones with complete loss of capillary structure in the center, and partial involution of capillary blood vessels at the periphery. At the periphery of the avascular zones, the distance between capillaries was more than 10-fold greater than normal intercapillary distance in untreated parts of the chorioallantoic membrane (Fig. 6). As the avascular zones developed over 48 hours, there was fragmentation of capillary basement membrane and progressive loss of fibronectin and laminin within the regions of capillary involution. Eventually these basement membrane components disappeared completely as the capillary itself underwent total involution. The rapid breakdown of capillary basement membrane in the steroid–heparin-treated embryos correlated with endothelial cell rounding and desquamation. Capillary retraction presented a pattern that was the reverse of capillary growth. In the treated embryos, the basement membranes of surrounding large vessels, nongrowing capillaries, and neighboring epithelium were not affected.

In contrast, in untreated embryos, or in those treated with heparin or steroid alone, fibronectin and laminin appeared in continuous linear patterns within the basement membrane surrounding growing capillaries. Fibronectin outlined both the large vessels and fine capillaries throughout the entire vascular network of the chorioallantoic membrane.

The pathway by which only basement membrane associated with growing capillaries breaks down, leaving basement membrane of neighboring epithelium and large vessels intact, is not obvious. Nevertheless, the specificity of angiostatic steroids for growing capillaries is unparalleled. A possible explanation for this specificity is that normal capillary growth may require high turnover rates of basement membrane. Adjacent tissue and larger vessels may have much slower basement membrane turnover. Basement membranes of large vessels are more heavily stained with fibronectin antibodies than are fine capillaries. Older capillaries that are not growing are surrounded by a slightly more dense basement membrane that contains increased amounts of laminin and type IV collagen.

This biological system has also made it possible to demonstrate that the relation between matrix dissolution and tissue involution clearly correlates with changes in cell shape. For example, endothelial cell rounding was generally associated with progressive degradation of the vascular basement membrane. This supports a concept that we previously proposed,[39,41] that cell shape and especially matrix-dependent alterations of cell shape, may serve as physiologic regulators of tissue development *in vivo.* In support of this hypothesis, we have recently been able to select successful pharmacologic inhibitors of angiogenesis based simply on their ability to modulate capillary endothelial cell form *in vitro.*

Further Evidence that Alterations in Extracellular Matrix Turnover are Involved in the Mechanism of Capillary Regression

Additional evidence of a causal role for extracellular matrix alterations in capillary regression was obtained by a study of drugs that interfere with deposition or processing of collagen, a major component of basement membrane. L-proline is an essential amino acid for the synthesis of collagen. Analogues of proline that can be incorporated in the place of proline have been shown to interfere with triple helix formation and to inhibit collagen deposition. Co-administration of these inhibitors of collagen production were found to markedly synergize the capacity of angiostatic steroids to cause capillary regression, even in the absence of heparin. The synergism was further potentiated when heparin was added.

L-azetidine carboxylic acid (LACA) is an analogue of proline that was the most active potentiator of angiostatic steroids. When administered with an angiostatic steroid and heparin, LACA gave more than a twofold increase in antiangiogenic activity in the chick embryo (95% avascular zones *vs.* 40% with steroid plus heparin without LACA). Furthermore, combinations of LACA with steroid were more antiangiogenic (73% avascular zones) than our original heparin–steroid combination (43% avascular zones). Thus, LACA was a stronger potentiator of angiostatic steroids than heparin. It is well known that analogues of proline can inhibit collagen deposition in a wide variety of growing tissues when given at high doses over prolonged periods. However, when administered at lower doses for shorter times in conjunction with angiostatic steroids, proline analogues appear to potentiate capillary regression in a specific fashion. This observation suggests the possibility of the future use of "combined modalities" in the treatment of angiogenesis-dependent diseases. These results also strongly support the concept that the alterations in extracellular matrix turnover that we previously observed play a central physiologic role in capillary regression.

Summary

A new class of angiostatic steriods has been identified. These steroids inhibit angiogenesis in the presence of a nonanticoagulant heparin fragment. Tetrahydrocortisol, a metabolite of cortisone previously believed to be biologically inactive, is now known to be one of the most potent of the naturally occurring steroids. Both its plasma and urinary forms are antiangiogenic. This finding was made because of our original misinterpretation that dexamethasone lacked antiangiogenic activity.

Induction of capillary basement membrane dissolution is the first biochemical action described for this new class of steroids. Angiostatic steroids appear to induce specific alterations in basement membrane turnover only within growing capillaries when administered with heparin or a heparin fragment. Chemical inhibitors of collagen deposition can have specific effects on capillary growth when co-administered with angiostatic steroids. These results suggest that distinct conformations of the steroid molecule convey specificity for growing capillary endothelial cells. Endogenous tissue heparin, when properly protected from degradation, similarly appears to be capable of synergizing with angiostatic steroids to specifically induce capillary regression. The identification of molecules with antiangiogenic activity suggests the potential existence of other naturally occurring inhibitors of capillary endothelial cell growth that may act physiologically to maintain the normal quiescent state of vascular endothelial cells.

DISCUSSION

DR. FRANCIS MOORE (Boston, Massachusetts): As President Drake said yesterday, surgical work and surgical missions in our society change over time. One has been of importance for many years and is of growing importance today. That is the contributions of surgery to basic biomedical science.

This scientific contribution is not something that increases our income or fills our hospital beds, but it adds to the stature of surgery. It adds to our academic clout. It adds to the ability of all of us to obtain funds for our laboratories, and it lets society know that we are a scientific profession.

Dr. Judah Folkman's contributions are outstanding in this regard. There are now several hundred laboratories over the world working on angiogenesis, a word that Dr. Folkman coined and popularized many years ago when he first postulated the existence of angiogenic hormones, if you want to call them that.

Four chemical angiogenic structures have been identified currently. Two of them have been gene cloned. Thus, from a surgeon in our midst, has come a whole new field of science. I believe it is very exciting that our profession can continue to render this contribution to society as a whole and to Dr. Folkman we are grateful for his leadership.

I have two questions: first, many years ago, almost 33 years ago, we presented before this society a paper in which Dick Steenberg and Norman Gold were the chief authors, showing that THE and THF (tetrahydrocortisol and tetrahydro compound F) were very prominent in the urinary excretion of all surgical patients immediately after operation.

We were trying to outline the quantitative clinical and chemical kinetics of the adrenal response to surgery. Norman Gold discovered that these tetrahydro compounds were being excreted in the urine in large amounts after every surgical operation. We believed they were just totally inactive excretory-pathway steroids as the entire world believed until Dr. Folkman's paper this morning.

Therefore, it is interesting that after trauma there is a lag phase in wound healing. I ask Dr. Folkman if this burst of THE and THF that follows trauma acts by inhibiting the growth of new blood vessels. It might be responsible for the so-called lag phase of wound healing. Possibly that lag phase is important. When the wound has a pool of serum in it can it develop local concentrations of antibodies that are significant? Then, after a few days when the THE and the THF subside, the vessels can grow in and complete the job under the angiogenic influences.

My second question is the question that is on everyone's mind, and that is, has Dr. Folkman had an opportunity to experiment with THE and THF in tumors in the laboratory?

DR. JOSEPH E. MURRAY (Wellesley Hills, Massachusetts): Often when a person develops a highly visible profile in one phase of his professional life, there is a tendency to minimize his other talents. Everybody acknowledges Dr. Folkman's outstanding leadership in biological surgical research, but only those of us working daily with him realize his solid clinical judgments and skills and the extraordinary effect his inquisitive mind brings to the daily rounds of all of us working in the clinical services of the Children's Hospital.

Whether or not his studies lead ultimately to the control of neoplasms or to the control of arteriovenous malformations, his influence on the thinking and teaching of the staff, residents, and medical students is enormous. He is a superb, caring, clinical surgeon doing excellent research, and I believe that it is only appropriate for me to share these thoughts with all of the members of this Association.

DR. JUDAH FOLKMAN (Closing discussion): I want to thank Dr. Murray for his kind remarks. They were unsolicited. I especially want to thank Dr. Moore. I tell my house staff, "When you give your first paper at a national meeting, if you really want to understand what you have just said, ask Dr. Moore to open the discussion."

Dr. Moore's questions were important, and we really do not know yet what is going on physiologically with these metabolites. Here we have a picture of the endocrine system using breakdown products of cortisone to regulate the growth of the vascular system.

In answer to Dr. Moore's second question, we know much more about the pharmacologic effects of angiostatic steroids. It is possible in certain tumor-bearing mice, if you have the right heparin products, to regress some tumors, but large steroid doses are required.

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

INTRODUCING

THE NEW LOOK

IN ACID SUPPRESSION

100 ml
NDC 0173-0407-00
Zantac® Injection Premixed
(ranitidine hydrochloride)
50 mg
50 mg/100 ml in 0.45% sodium chloride
Sterile, single-dose flexible plastic container
Nonpyrogenic. Contains no preservative
See package insert.
98-1932-2/R-2 592802
Manufactured for Glaxo Inc.,
Research Triangle Park, NC 27709
by Abbott Laboratories, North Chicago, IL

Zantac®

Injection

Premixed

ranitidine HCl/Glaxo

New premixed 100-ml bag containing 50 mg ranitidine HCl

Convenient

☐ *Ready to use–no mixing needed*

☐ *Premixed 100-ml bag, containing 50 mg ranitidine (as the hydrochloride)*

☐ *No need to refrigerate*

☐ *Stores for up to 18 months*

Cost effective

☐ *Saves pharmacy and nursing time*

Raises gastric pH acid in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses

☐ *No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin*

**Some patients may require q6h dosing.*
See next page for brief summary of Product Information.

Glaxo/ROCHE

ZANTAC® Injection
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC® Headache, sometimes severe, seems to be related to ZANTAC administration. Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain have been reported. There have been rare reports of malaise, dizziness, somnolence, insomnia, vertigo, tachycardia, bradycardia, premature ventricular beats, and arthralgias. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.

Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.

Although controlled studies have shown no antiandrogenic activity, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Incidents of rash, including rare cases suggestive of mild erythema multiforme and, rarely, alopecia, have been reported, as well as rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
(NDC 0173-0362-38) 2-ml single-dose vials (Tray of 10)
(NDC 0173-0363-39) 10-ml multidose vials (Singles)
(NDC 0173-0362-01) 2-ml single-dose, prefilled, disposable cartridge-needle units (Tray of 10)
(NDC 0173-0362-00) 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

Durham, North Carolina

Occlusive Cerebrovascular Disease: Diagnosis and Surgical Management. Thoralf M. Sundt, Jr. 506 pp. Philadelphia: W. B. Saunders Co. 1987. $85.00.

THIS EXCELLENT MONOGRAPH is an in-depth study based on the experience at Mayo Clinic, supplemented by extensive references from the literature. There are 37 contributors and 38 chapters. Dr Sundt, Chairman of Neurosurgery at Mayo, is author or co-author of 26 chapters. The text is divided into six sections, illustrating the comprehensive coverage: basic considerations, carotid artery surgery, reconstructive surgery for the aortic arch branches and the vertebral arteries, extracranial to intracranial bypass arterial pedicles, extracranial to intracranial bypass vein grafts, and intracranial small vessel surgery. There are also chapters on extracranial carotid aneurysms and carotid body tumors.

The author's classification of patients differs from that used by most surgeons, who divide patients into categories of stroke, transient ischemia, and asymptomatic stenosis. Sundt places patients into five groups depending on combined medical, neurological, and angiographically defined risk factors. While his is an excellent system, it does cause difficulty in comparing results with other series.

The author's technique of carotid endarterectomy includes general anesthesia, routine EEG monitoring with cerebral blood flow determination, selective shunting, and arteriotomy closure with vein patch graft reinforced with a Teflon wrap. The monitoring studies have produced unique data, a major contribution by Dr. Sundt and colleagues.

The sections on EC-IC bypass are based on a large experience. Caution is advised regarding indications for performing this operation.

The book is profusely illustrated with arteriograms, CT scans, and operative photographs. The anatomic and operative procedure drawings are superb.

There is one chapter on controversies in carotid surgery. Interestingly, there is only a brief discussion of surgery for asymptomatic lesions, a highly controversial matter, except for comments relative to asymptomatic stenosis contralateral to a previously symptomatic lesion treated by carotid endarterectomy.

This splended book is well written, informative, authoritative, and scholarly. It will be a useful reference for general vascular surgeons and especially neurosurgeons managing cerebrovascular disease.

JESSE E. THOMPSON, M.D.
Dallas, Texas

Atlas of General Surgery, 2nd Edition. Hugh Dudley, David C. Carter, R. C. G. Russell. 980 pp. Boston: Butterworths. 1986. $65.00.

THIS ATLAS has been skillfully culled from the massive multivolume work on operative surgery by Rob and Smith, which is now in its third edition. The result is 97 presentations with few words but many drawings of actual operations by medical artists of repute. Herein lies the book's strength and also its weakness.

The contributing surgeons are leading exponents in their own fields, preponderately British, but many from North America and a few from Australasia. Their advice, tersely presented, could hardly be bettered, but among them they have relied on the work of no less than 38 artists. While some produce clear helpful line drawings, such as those of Robert Lane who teams up with John Goligher, others have expressed what they saw with subtle shading, possibly originally in color, which does not lend itself so well for conveying the niceties of surgical technique.

The choice of incisions and their proper closure is a valuable addition as is the inclusion of special techniques such as the stapling gun for anastomoses in inaccessible sites. Cardiopulmonary surgery is particularly well covered with the various approaches to the thoracic cavity and operations on lungs, heart, and esophagus and bypass technology. Blood vessel techniques, which lend themselves particularly to illustration, are contributed by such well-known protagonists as Eastcott and Adams, but the endocrine surgeon is not so well served, parathyroid surgery is contributed by a urologist, and there is no mention of transplantation or storage of the glands.

The quality of reproduction of both the illustrations and the text is of the highest order and the proofreading meticulous. It is noticeable that many of the references are not recent, but this is something inherent in a book with so many contributors.

In brief this is an excellent guide to current surgical techniques and full of sound common sense in its advice to those in training. It would be a useful addition to the reference library of any theatre suite.

SELWYN TAYLOR
Sussex, England

Silvergirl's Surgery: The Veins. Harold Laufman. 273 pp. Austin: Silvergirl, Inc. 1986. $39.95.

HAROLD LAUFMAN, M.D., Ph.D., himself a scholar and authority on venous disease, has collected in one volume the articles he believes are the basic developments in our knowledge of the venous system of the extremities. In the opening section on surgical anatomy, he goes back to the drawings of Fabricius and William Harvey. Advancing to diagnostic tests for venous disease of the lower extremities, his selection includes the lectures of Brodie, McPheeters, Berberisch, and Hirsch, and dos Santos' first paper on phlebography in humans. In the section on treatment of varicose veins, he traces sclerotherapy from the original injection of iodine to the use of sodium morrhuate in 1930, citing the work of Tavel, Schiassi, Sicard, Linser, and Higgins. Under surgical treatment, he begins with the work of Benjamin Brodie on treatment of varicose veins of the leg and includes contributions by Trendelenburg, Perthes, Moore, Thomas, C.H. Mayo, Babcock, Colt, and Ochsner and Mahorner. Compression therapy for venous ulcer was developed by Unna, Gay, and in our generation, Linton.

He has collected also the outstanding original articles on the disease of thromboembolism, starting with Hunter, Davis, Paget, Lee, Mueller, Trendelenburg, Ochsner and DeBakey, Homans, and ending with Lazar Greenfield's report on transvenous removal of pulmonary emboli by vacuum-cup catheter technique. The section on ischemic thrombotic disease includes the work of Trousseau, Homans, Gregoire, Audier and Haimovici, Laewen, Leriche, and Ochsner and DeBakey.

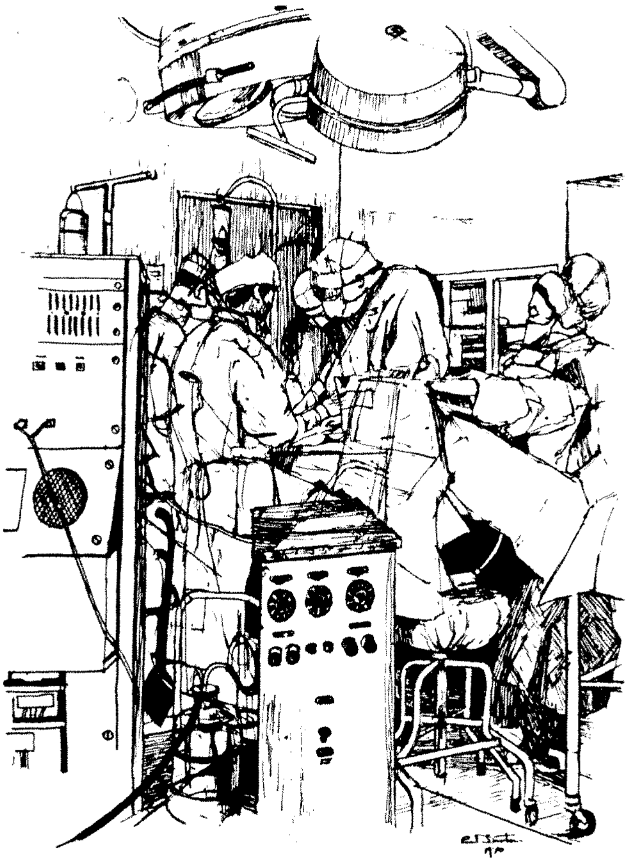
In the final section on the pharmacologic therapy of venous disease, his selection includes the work of Crafoord on postoperative treatment with heparin for the prevention of thrombosis, articles by Allen, Barker and Waugh, and Yin and Wessler on a naturally occurring plasma inhibitor of activated Factor X, plus contributions by Laufman himself, Jorpes, and, finally, by Robertson, Nilsson, and Nylander on the thrombolytic effect of streptokinase as evaluated by phlebography of deep venous thrombi of the leg.

Seldom has there appeared such a comprehensive collection of original work together with vintage woodcuts, historic phlebograms, excellent line drawings, and diagrams where needed. This volume is an archivist's treasure trove and deserves to be in medical libraries and on the shelf of physicians who study the history of vascular achievements as source material for new insight into contemporary research.

Had this volume been available when this reviewer was researching original, basic articles on venous disease, he could have spared himself much time and frustration. They are all here, complete with annotations. Another personal note: it was inspiring to find some of my teachers and colleagues included in this edition. Historic documents need not be dusty.

JOHN J. CRANLEY, JR., M.D.
Cincinnati, Ohio

SOUTHEAST ASIAN JOURNAL OF SURGERY



SOUTHEAST ASIAN JOURNAL OF SURGERY

This biennial journal is the major surgical publication in South East Asia. As the official journal of the Association of Surgeons of South East Asia, it reflects current surgical problems and their management in member countries.

The SOUTHEAST ASIAN JOURNAL OF SURGERY has widened its objectives in recent years to cater to the needs of surgical trainees as well as the accomplished surgeon. Allied specialty areas outside of general surgery form an integral part of the Journal.

With a wide readership, the Southeast Asian Journal of Surgery encourages a dialogue between surgeons in South East Asia and worldwide, this enables valuable exchange of ideas and experiences.

The editorial board is comprised of leading surgeons in South East Asia and ensures a high quality of published material.

THE SOUTHEAST ASIAN JOURNAL OF SURGERY FEATURES:

- Original Papers — focus on surgical practice in South East Asia region
- Reviews — in-depth reviews which help practising surgeons keep abreast of latest advances
- Short Notes and Case Reports — concisely presented practical information for daily use
- Correspondence — a forum for opinions and matters of general interest
- Association News and Information — news of the Association of Surgeons of South East Asia, major regional and international meetings and surgical workshops

TOPICS COVERED INCLUDE:

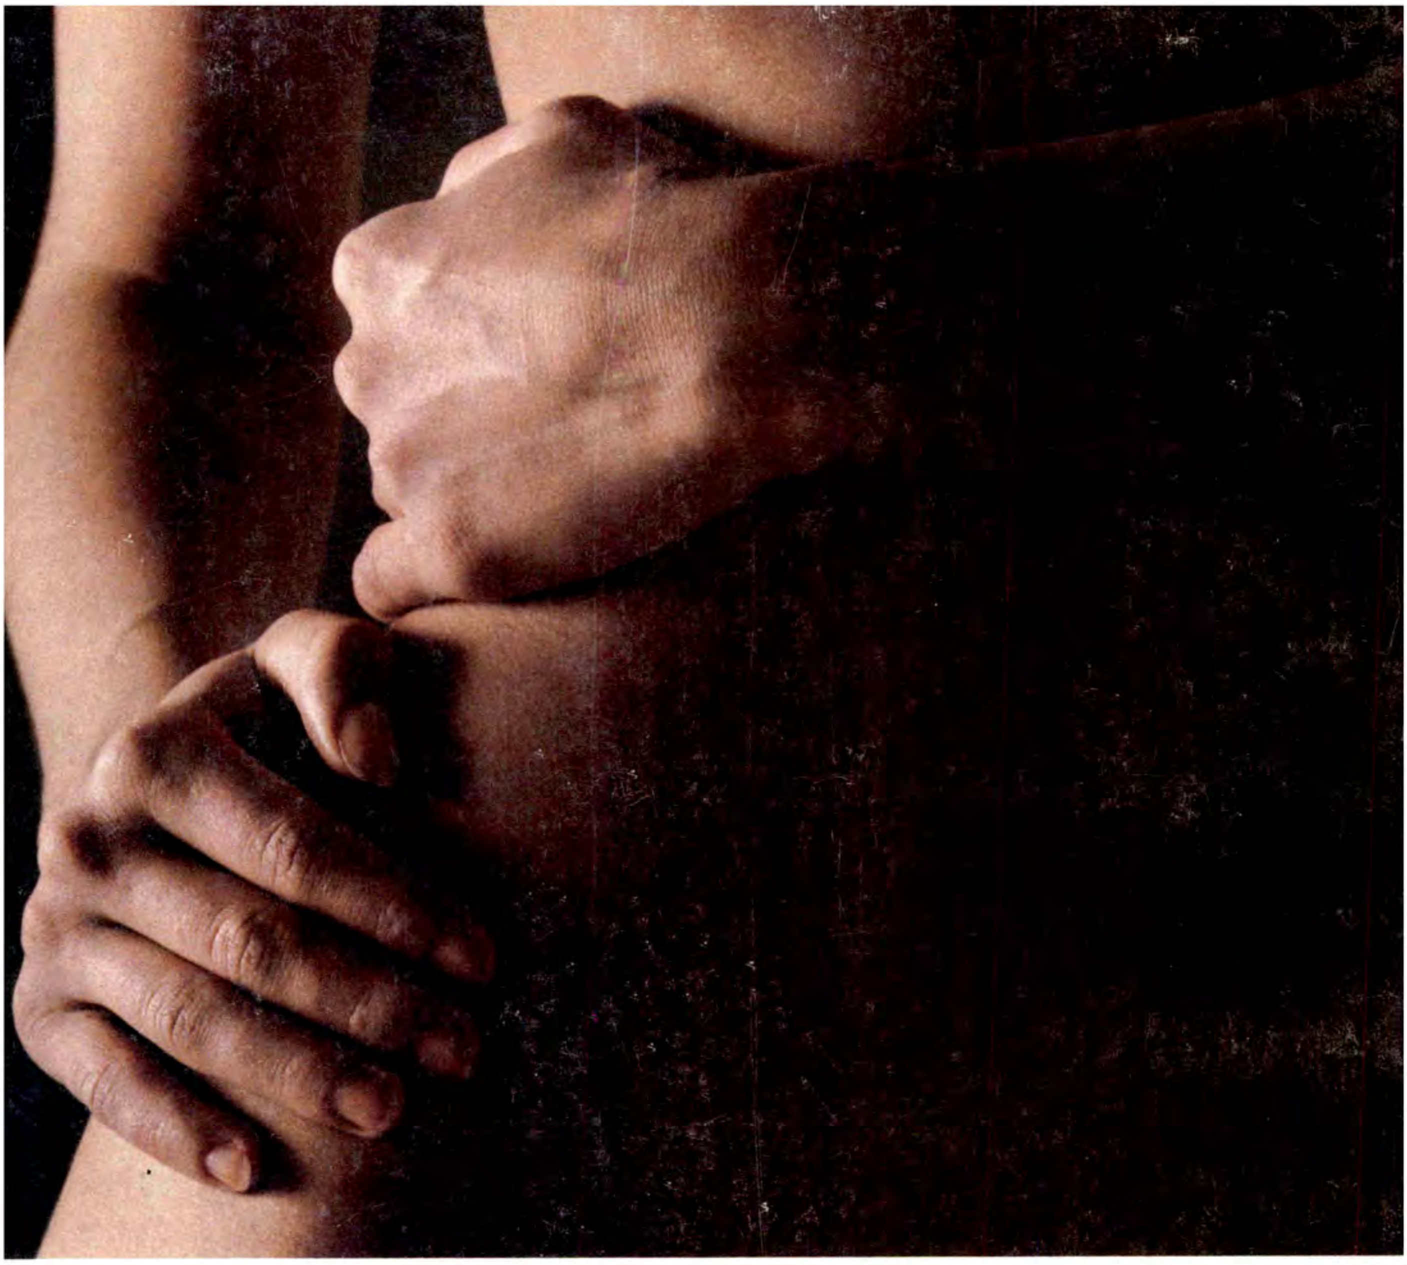
- Cardiothoracic surgery
- Colorectal diseases and proctology
- Endocrine surgery
- Gastrointestinal surgery
- Neurosurgery
- Oncology
- Otolaryngology and head and neck surgery
- Paediatric surgery
- Plastic and reconstructive surgery
- Transplantation
- Trauma
- Urology
- Vascular surgery

SUBMISSION OF MANUSCRIPTS

Original articles and editorial matters should be referred to the Editor, Southeast Asian Journal of Surgery, c/o Department of Surgery, University of Hong Kong. Queen Mary Hospital, Hong Kong.

SUBSCRIPTION FEE

Annual subscription rates for the Journal are US$20 (surface mail) or US$25 (airmail) per year. Orders and enquiries should be addressed to the Subscription Secretary, Southeast Asian Journal of Surgery, c/o Department of Surgery, University of Hong Kong, Queen Mary Hospital, Hong Kong.



SOON, GALLSTONES WILL BE GETTING THE SAME TREATMENT AS KIDNEY STONES.

Soon, the 20 million people suffering from gallstones may be getting new relief using a new treatment. One that's already helped over 300,000 kidney stone patients. Extracorporeal Shock Wave Lithotripsy.

Dornier introduced the first kidney stone lithotripter to America in 1984. And now, just three years later, our first lithotripter for gallstones is undergoing clinical evaluation.

This progress is evidence of our commitment to further utilizing ESWL® technology, today and tomorrow.

Since inventing the technique of shock wave lithotripsy, some 20 years ago, we have deliberately pursued our vision of its benefits. Its potential to spare the human body — and human beings — the pain and risks of surgery.

These latest advances in treating gallstones are only part of this vision. A vision that extends far beyond — into noninvasively treating tumors, and other internal disorders.

Seen in this way, the successful treatment of kidney stones and gallstones will not be the final achievement in shock wave lithotripsy.

Merely the beginning.

For more information, contact Dornier Medical Systems, 824 Livingston Court, Marietta, GA 30067. Or 1-800-DORNIER.

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

- **ATLAS OF PELVIC SURGERY, 2nd ed.**
  By CLIFFORD R. WHEELESS, JR., M.D., *The Johns Hopkins University School of Medicine, Baltimore, Maryland.. Illustrated by* John Parker. Exclusively devoted to pelvic surgery, this large atlas presents over 100 important pelvic operations including many colon and small bowel procedures, sterilization, and correction of congenital anomalies. New operations are included, among them port A cath, low colonic anastomosis, enterocoile repair and hysterascopy laser surgery. All procedures are documented by large line illustrations. *About 500 pp. (10 × 12), illus., 1988, Ready September 1987, $92.50.*

- **SURGICAL DISEASES OF THE PANCREAS**
  Edited and with contributions by JOHN M. HOWARD, M.D., *Medical College of Ohio at Toledo, Toledo, Ohio;* GEORGE L. JORDAN, JR., M.D., *Baylor College of Medicine, Houston, Texas;* and HOWARD A. REBER, M.D., *VA Medical Center, Sepulveda, California.* Information on the recent and rapid progress in understanding pancreatic diseases, and the encouraging developments in therapy have been gathered from diverse authoritative sources, and are presented within the framework of a "progress report". *958 pp. (7¼ × 10¼), 317 illus. (including 1 in color), 1987, $145.00.*

- **INFLAMMATORY BOWEL DISEASE, 3rd ed.**
  Edited and with contributions by JOSEPH B. KIRSNER, M.D., Ph.D., *University of Chicago Hospital and Clinics, Chicago, Illinois; and* ROY G. SHORTER, M.D., *Mayo Medical School, Rochester, Minnesota.* Discussions of etiology and pathogenesis include extensively revised chapters on epidemiology, experimental models of IBD, intestinal microflora, and new chapters on topics including intestinal defenses and immunologic features. *About 760 pp. (7¼ × 10¼), 330 illus. (3 in full color), January 1988, In Prep.* **About $95.00.**

- **SURGICAL TREATMENT OF CONGENITAL HEART DISEASE, 3rd ed.**
  By GRADY L. HALLMAN, M.D., *and* DENTON A. COOLEY, M.D., *both of University of Texas Medical School at Houston, Houston, Texas, and* HOWARD P. GUTGESELL, M.D., *University of Virginia, Charlottesville, Virginia.* Special attention has been placed on noninvasive methods of diagnosis. New operations including the Fontan operation for tricuspid atresia, and the Senning and Jatene operation for transposition of the great arteries are described and illustrated. *234 pp. (8½ × 11), 95 illus., 1987, $45.00.*

- **TREATMENT OF SHOCK: Principles and Practice, 2nd ed.**
  Edited and with contributions by JOHN BARRETT, M.D., *and* LLOYD M. NYHUS, M.D., *both of University of Illinois College of Medicine, Chicago, Illinois.* In this readable volume, a practical, step-by-step guide to shock management is skillfully reinforced with selected explanations of the pathophysiology of shock therapy. Although much of the content is new, the book maintains the practical nature of the first edition and continues to be oriented toward the clinical approach to the patient. *242 pp. (7 × 10), 34 illus., 1986, $27.50.*

- **DIAGNOSTIC PATIENT STUDIES IN SURGERY**
  Edited by BERNARD SIGEL, M.D., *The Medical College of Pennsylvania, Philadelphia, Pennsylvania.* The most frequently required and requested diagnostic studies from each category are gathered under one cover. Every procedure is explained, summarized as to its strengths, weaknesses and principal indications for use. The author presents topics relative to the general as well as specialty applications of patient studies, and has carefully selected both new and well-established procedures. *449 pp. (7¼ × 10¼), 359 illus., 1986, $60.00.*

- **THE SHOULDER: Surgical and Nonsurgical Management, 2nd ed.**
  Edited and with contributions by MELVIN POST, M.D, *Michael Reese Hospital and Medical Center, Chicago, Illinois.* Numerous new and important advances in understanding the physiologic and biomechanical mechanisms of normal and abnormal conditions of the shoulder have been skillfully integrated into the existing basic principles and treatment philosophies. Chapters on congenital conditions affecting the shoulder and the shoulder in sports medicine are new. *About 600 pp. (7¼ × 10¼), illus., January 1988, In Prep.* **About $110.00.**

- **SURGERY OF THE FOOT**
  By KENT K. WU, M.D., *Henry Ford Hospital, Detroit, Michigan.* Delivers consistent, detailed information for a multitude of congenital and acquired foot defects. Every one is specified as to degree of incidence, clinical signs and symptoms, roentgenographic manifestations, pathologic anatomy, surgical and nonsurgical methods of treatment. Organized with a regional approach, individual chapters on the great toe, the middle toes, the fifth toe, and the tarsal and metatarsal regions contain complete coverage. *537 pp. (7¼ × 10¼), 573 illus., 1986, $65.00.*

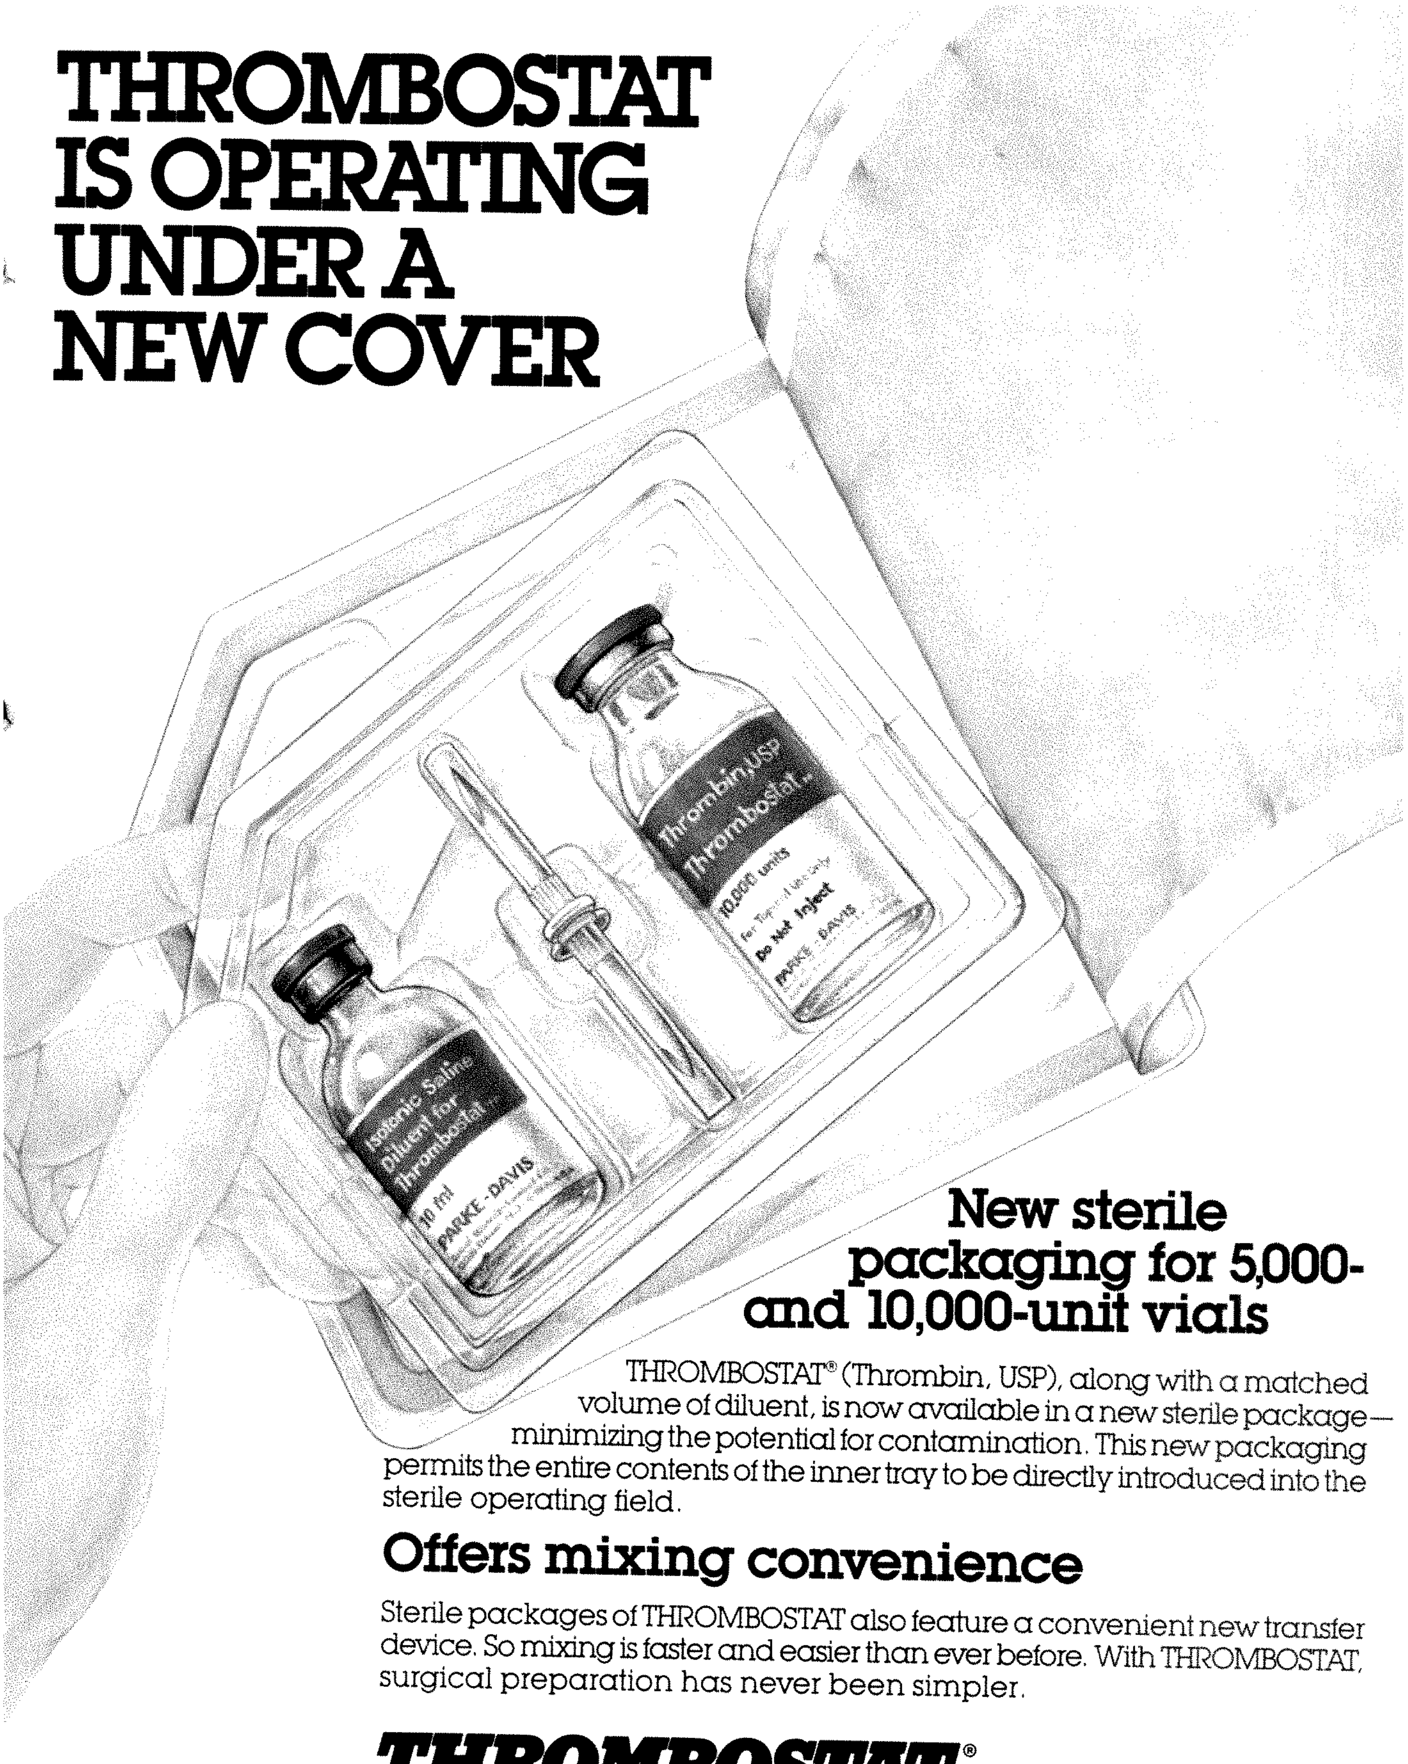
THROMBOSTAT IS OPERATING UNDER A NEW COVER



New sterile packaging for 5,000- and 10,000-unit vials

THROMBOSTAT® (Thrombin, USP), along with a matched volume of diluent, is now available in a new sterile package—minimizing the potential for contamination. This new packaging permits the entire contents of the inner tray to be directly introduced into the sterile operating field.

Offers mixing convenience

Sterile packages of THROMBOSTAT also feature a convenient new transfer device. So mixing is faster and easier than ever before. With THROMBOSTAT, surgical preparation has never been simpler.

THROMBOSTAT®
THROMBIN, USP

Please see next page for brief summary of prescribing information.

PD-34-JA-3853-P-1(1-87)

THROMBOSTAT® THROMBIN, USP
(Bovine Origin)

Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE
Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery, solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS
Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING
Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS
General:
Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated sponge procedure.

Pregnancy—
Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use:
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Allergic reactions may be encountered in persons known to be sensitive to bovine materials.

DOSAGE AND ADMINISTRATION
General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc., solutions containing approximately 100 units per mL are frequently used. For this, 10 mL of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per mL may be required. For this the 5000 unit vial dissolved in 5 mL or 2.5 mL, respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate voulme of diluent. In many situations, it may be advantageous to use Thrombostat in dry form on oozing surfaces.

Caution: Solutions should be used immediately upon reconstitution. If necessary, refrigerate the solution and use within 3 hours of reconstitution.

The following techniques are suggested for the topical application of Thrombostat.

1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge USP as follows:

1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Sterile Packages
Thrombostat Sterile Packages are available in two strengths, 5000 units and 10,000 units. A Sterile Package contains one sterile vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile transfer device. The Sterile Package may be used as follows:

1. Remove the Tyvek® blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared using the transfer device.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

Thrombostat Kit
Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The kit may be used as follows:

1. Remove the Tyvek® blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

Caution—Federal law prohibits dispensing without prescription.

following surgery for primary breast cancer…

What next?

Until now,

there has been no definitive treatment for stage II postmenopausal patients…

Chemotherapy

Contribution of cytotoxics uncertain; potentially serious/intolerable side effects

No therapy

Important new data[1] rule out no therapy

Today there is.

10 MG TABLETS

Nolvadex®

TAMOXIFEN CITRATE

Adjuvant Monotherapy

Now, the treatment of choice

A recent National Institutes of Health consensus report states that following surgery, "Tamoxifen [NOLVADEX] should now be regarded as standard therapy for postmenopausal patients with positive axillary lymph nodes and positive hormone receptor status."[1]

NOLVADEX increases disease-free time[2-5] by delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T_{1-3}, N_1, M_0). Moreover, NOLVADEX improves overall survival, with a 34% reduction in risk of mortality, as observed in the NOLVADEX Adjuvant Trial Organization (NATO) study.[4] This treatment is extremely well tolerated by patients[2-5]; in fact, one double-blind, placebo-controlled study demonstrated a NOLVADEX side effects profile similar to placebo.[2] And, since NOLVADEX has a mild side effects profile and is easy to administer, patients are afforded a better quality of life. NOLVADEX—today's promising breast cancer therapy for the postmenopausal woman—in the adjuvant setting and in metastatic disease.

Please see next page for brief summary of prescribing information.

ICI PHARMA
Division of ICI Americas Inc
WILMINGTON, DELAWARE 19897 USA

10 MG TABLETS

Nolvadex®

TAMOXIFEN CITRATE

BRIEF SUMMARY

INDICATIONS AND USAGE: NOLVADEX is effective in the treatment of metastatic breast cancer in postmenopausal women. Available evidence indicates that patients whose tumors are estrogen receptor positive are more likely to benefit from NOLVADEX therapy.

NOLVADEX is effective in delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T1-3, N1, M0). The estrogen and progesterone receptor values may help to predict whether NOLVADEX therapy is likely to be beneficial. In some NOLVADEX adjuvant studies, most of the benefit to date has been in the subgroup with 4 or more positive axillary nodes.

CONTRAINDICATIONS: None known.

WARNINGS: Pregnancy Category D: NOLVADEX may cause fetal harm when administered to a pregnant woman. Individuals should not become pregnant while taking NOLVADEX. Effects on reproductive functions are expected from the antiestrogenic properties of the drug. In reproductive studies in rats at dose levels equal to or below the human dose, nonteratogenic developmental skeletal changes were seen and were found to be reversible. In addition, in fertility studies in rats and in teratology studies in rabbits using doses at or below those used in humans, a lower incidence of embryo implantation and a higher incidence of fetal death or retarded in utero growth were observed, with slower learning behavior in some rat pups. The impairment of learning behavior did not achieve statistical significance in one study, and, in another study where significance was reported, this was by comparing dosed animals with controls of another study. Several pregnant marmosets were dosed during organogenesis or in the last half of pregnancy. No deformations were seen and although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. There are no adequate and well-controlled studies in pregnant women. There have been reports of spontaneous abortions, birth defects, fetal deaths, and vaginal bleeding. If this drug is used during pregnancy or the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Ocular changes have been reported in a few patients who, as part of a clinical trial, were treated for periods greater than one year with NOLVADEX at doses at least four times the highest recommended daily dose of 40 mg. The ocular changes consist of retinopathy and, in some patients, there are also corneal changes and a decrease in visual acuity.

In addition, a few cases of ocular changes including visual disturbance, corneal changes, and/or retinopathy have been reported in patients treated with NOLVADEX at recommended doses. It is uncertain if these effects are due to NOLVADEX.

As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastases within a few weeks of starting treatment with NOLVADEX. If hypercalcemia does occur, appropriate measures should be taken and, if severe, NOLVADEX should be discontinued.

PRECAUTIONS: General: NOLVADEX should be used cautiously in patients with existing leukopenia or thrombocytopenia. Observations of leukopenia and thrombocytopenia occasionally have been made, but it is uncertain if these effects are due to NOLVADEX therapy. Transient decreases in platelet counts, usually to 50,000-100,000/cu mm, infrequently lower, have been occasionally reported in patients taking NOLVADEX for breast cancer. No hemorrhagic tendency has been recorded and the platelet counts returned to normal levels even though treatment with NOLVADEX continued.

Laboratory Tests: Periodic complete blood counts, including platelet counts, may be appropriate.

Carcinogenesis: While no conventional bioassay has been conducted, endocrine changes in immature and mature mice were investigated in a 13-month study. Granulosa cell ovarian tumors and interstitial cell testicular tumors were found in mice receiving NOLVADEX, but not in the controls.

Mutagenesis: No genotoxic potential has been found in a battery of in vivo and in vitro tests with pro- and eukaryotic test systems with drug metabolizing systems present.

Impairment of Fertility: Fertility in female rats was decreased following administration of 0.04 mg/kg for 2 weeks prior to mating through day 7 of pregnancy. There was a decreased number of implantations, and all fetuses were found dead.

Following administration to rats of 0.16 mg/kg from days 7-17 of pregnancy, there were increased numbers of fetal deaths. Administration of 0.125 mg/kg to rabbits during days 6-18 of pregnancy resulted in abortion or premature delivery. Fetal deaths occurred at higher doses. There were no teratogenic changes in either rat or rabbit segment II studies. Several pregnant marmosets were dosed with 10 mg/kg/day either during organogenesis or in the last half of pregnancy. No deformations were seen, and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. Rats given 0.16 mg/kg from day 17 of pregnancy to 1 day before weaning demonstrated increased numbers of dead pups at parturition. It was reported that some rat pups showed slower learning behavior, but this did not achieve statistical significance in one study, and in another study where significance was reported, this was by comparing dosed animals with controls of another study.

The recommended daily human dose of 20-40 mg corresponds to 0.4-0.8 mg/kg for an average 50 kg woman.

Pregnancy Category D: See WARNINGS.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from NOLVADEX, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

ADVERSE REACTIONS: The most frequent adverse reactions to NOLVADEX are hot flashes, nausea and vomiting. These may occur in up to one-fourth of patients, but are rarely severe enough to require discontinuation of treatment.

Less frequently reported adverse reactions are vaginal bleeding, vaginal discharge, menstrual irregularities and skin rash. Usually these have not been of sufficient severity to require dosage reduction or discontinuation of treatment.

Increased bone and tumor pain and, also, local disease flare have occurred, which are sometimes associated with a good tumor response. Patients with increased bone pain may require additional analgesics. Patients with soft tissue disease may have sudden increases in the size of preexisting lesions, sometimes associated with marked erythema within and surrounding the lesions and/or the development of new lesions. When they occur, the bone pain or disease flare are seen shortly after starting NOLVADEX and generally subside rapidly.

Other adverse reactions which are seen infrequently are hypercalcemia, peripheral edema, distaste for food, pruritus vulvae, depression, dizziness, light-headedness and headache. There have been infrequent reports of thromboembolic events occurring during NOLVADEX therapy. Since for cancer patients in general an increased incidence of thromboembolic events is known to occur, a causal relationship to NOLVADEX remains conjectural. An increased incidence has been reported when cytotoxins are combined with NOLVADEX.

If adverse reactions are severe, it is sometimes possible to control them by a simple reduction of dosage without loss of control of the disease.

OVERDOSAGE: Acute overdosage in humans has not been reported. Signs observed at the highest doses following studies to determine LD_{50} in animals were respiratory difficulties and convulsions. No specific treatment for overdosage is known; treatment must be symptomatic.

DOSAGE AND ADMINISTRATION: One or two 10 mg tablets twice a day (morning and evening). In the three single agent adjuvant NOLVADEX studies noted above (See Clinical Pharmacology), NOLVADEX was administered for two years. The optimal duration of adjuvant therapy is not known.

HOW SUPPLIED: Tablets containing tamoxifen as the citrate in an amount equivalent to 10 mg of tamoxifen (round, biconvex, uncoated, white tablet identified with NOLVADEX 600 debossed on one side and a cameo debossed on the other side) are supplied in bottles of 60 tablets and 250 tablets. Protect from heat and light.

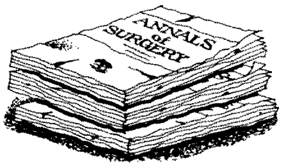
For your professional library **Bound volumes** of

Annals of Surgery



Long after your personal copies of ANNALS OF SURGERY have been read, shared with your office staff, used up and worn out, you can have instant access to the unique and valuable information in back issues of this distinguished journal by ordering bound volumes.

Your bound volumes give you a permanent and comprehensive reference for changes and advances in your specialty—a source that will grow and increase in usefulness over the years. Each volume features:

- *all text pages of every issue, including the complete author and title indexes*
- *no advertising—only professional, clinically pertinent material (a space-saver on your bookshelves)*
- *handsome, durable bindings in maroon buckram, with the journal name, year, and volume number imprinted in gold on the spine*

No need to return your personal copies to us, or to go to the trouble and expense of having them bound locally. We over-run copies of each issue in order to have sufficient quantities on hand. But we must tell our printer how many we need, so please let us know right away.

You must be a current subscriber to take advantage of this bound volume offer.

Use the convenient coupon to order your 1987 volumes today. They will be on their way to you shortly after the publication of the final volume issue.

Yes! Please send me the 1987 bound volumes of ANNALS OF SURGERY (65-98635/65-98643) for $49.00 U.S. ($59.00 elsewhere).

IAGNOSIS: CECAL CARCINOMA

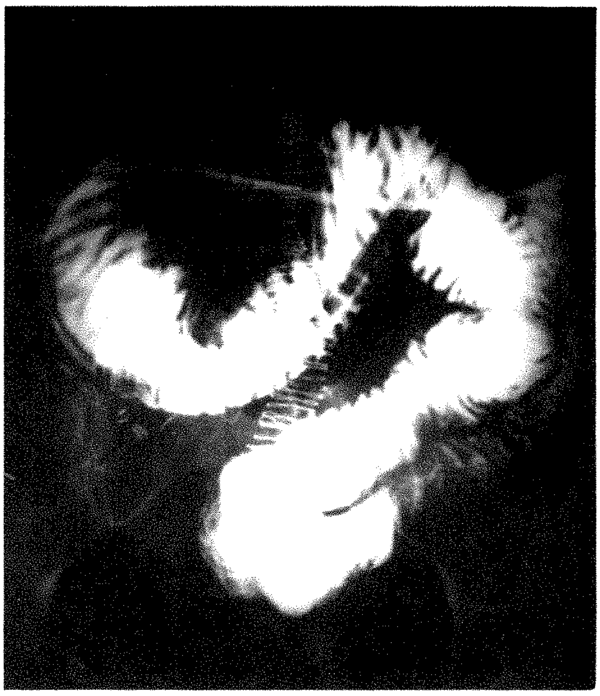
YMPTOMS: ANEMIA (Hg 6 gm/dl)

PERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

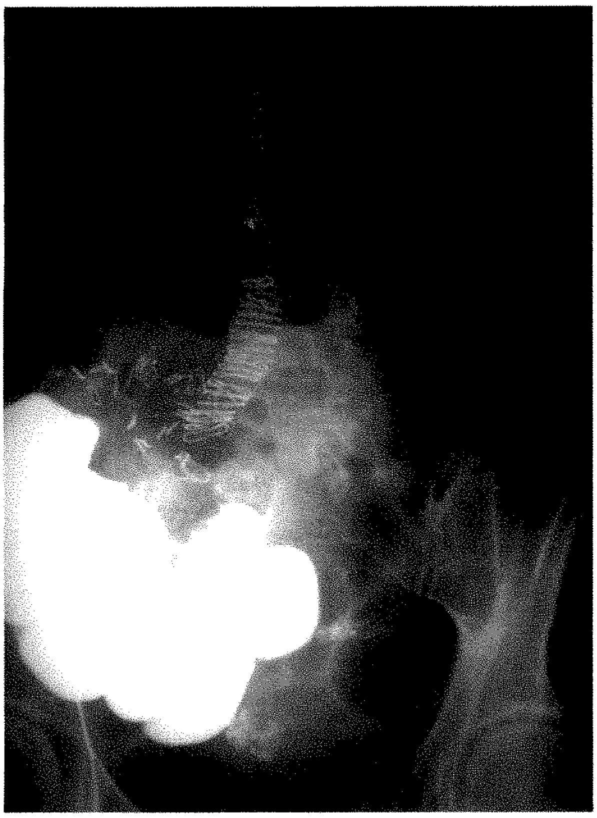
The patient had a right hemicolectomy with stapled (U.S. urgical Corp) anastomosis and fascia closure and a MOSS® astrostomy tube. The stomach and proximal duodenum were spirated, with immediate simultaneous feeding into the distal uodenum.

Barium feeding 5 hours postop documented adequate otility. The deliberate excess was totally removed. No ontrast (i.e.: excess feeding) escaped efficient aspiration ithin the proximal duodenum, to reflux into the stomach. igure A) Serial motility study showed barium had traversed e anastomosis and colon, and already was exiting in a pontaneous bowel movement by 21 hours postop. (Figure C)

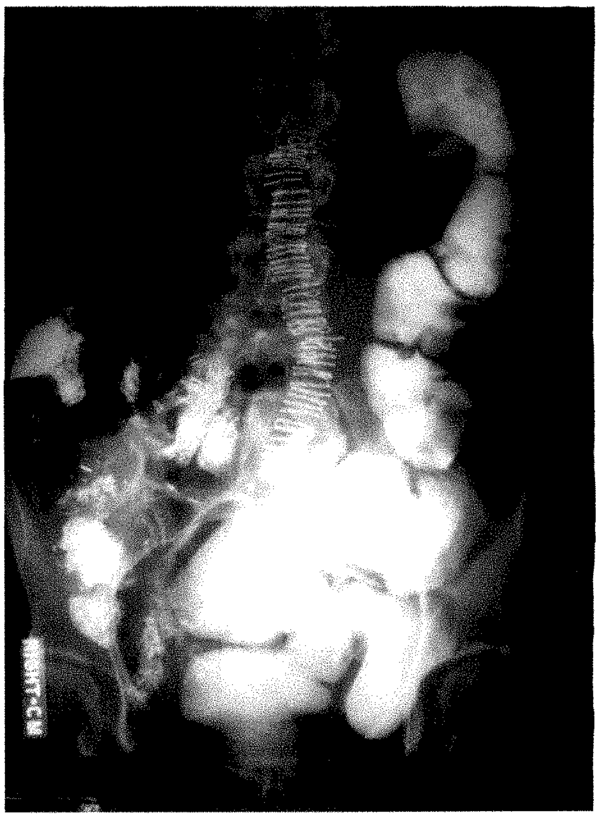
She received 300 ml/hr of Vivonex TEN (Norwich Eaton harm), absorbed 5,000 kcal the initial 20 hours, and then lerated a general diet. She was the 4th patient discharged neventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

"So tell me. Is there a graft that'll do both?"

"Absolutely. The Meadox® Woven Double Velour."

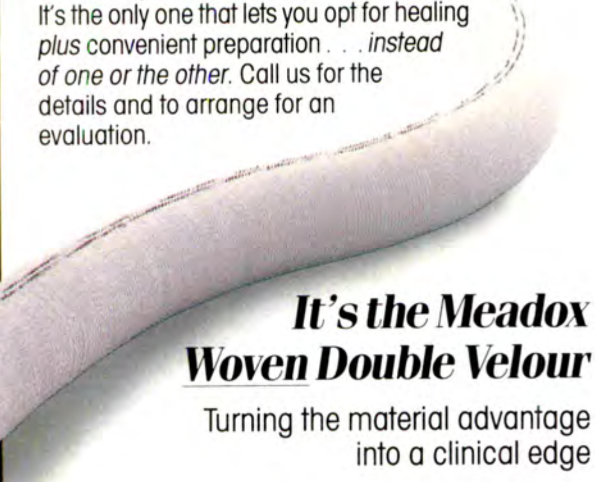
Reduces surgical time and preparation . . .

In the world of grafts, there are several advantages only a true hybrid, like the Meadox Woven Double Velour can offer. Easy and controllable *in situ* preparation—we call it *Quick-Prep*—is one. Then there's its low porosity combined with high strength. . . plus a weave so unique you won't think you're handling and suturing a woven graft at all. But that's only half the story.

And improves your patient's prognosis

This versatile graft is, in fact, a unique high strength woven offering true, low profile velour healing properties — such as thorough tissue ingrowth, a well anchored neointima, and excellent long-term patency.[1] All of this is available in a selection of 30 sizes . . . more than enough to make it your first all-around choice.

So try the Meadox Woven Double Velour. It's the only one that lets you opt for healing *plus* convenient preparation . . . *instead of one or the other.* Call us for the details and to arrange for an evaluation.



It's the Meadox Woven Double Velour

Turning the material advantage into a clinical edge

From the Departments of Surgery, Medicine, and Anesthesiology, UCLA School of Medicine, Los Angeles, California

A clinical program in liver transplantation was begun at UCLA in 1984 after a period of laboratory investigation. The first 100 orthotopic liver transplants (OLT) were performed in 83 patients (43 adults and 40 children) between February 1, 1984 and November 1, 1986. Donors and recipients were matched only for size and ABO blood group compatibility, with OLT performed across blood groups in 28 patients. Standard operative techniques were used, including venous–venous bypass in adults. Arterial reconstruction was performed using an aortic Carrel patch or "branch patch" in 65% of cases and by end-to-end or aortic conduit techniques in the remainder. The hepatic artery thrombosis rate was 5%. Biliary reconstruction was choledochocholedochostomy in 67 OLT and Roux-en-Y choledochojejunostomy in 33 (complication rate of 24% and 24%, respectively). Average lengths and ranges of donor liver ischemia, operating time, and blood replacement were 4 hours (range: 1–10 hours), 7.6 hours (range: 4–15 hours), and 17 units packed cells (range: 2–220 units). Immunosuppressive regimen was cyclosporine–steroid combination, with monoclonal anti-T-cell antibody (OKT3) used for refractory rejection. All patients had one or more complications: pulmonary (78%), infectious (51%), renal dialysis (25%), neurologic (22%). All patients had at least one episode of acute rejection, and 3.6% had chronic rejection. Retransplantation was needed in nine patients once and in four patients twice. The overall retransplant survival rate was 54%, and two of four patients who received a second retransplant are alive. Sixty-three of the 83 patients (76%) are alive (adults 72%, children 80%). The 1- and 2-year actuarial survival rate is 73% (adults 68%, children 78%). Thirty-eight of 43 patients (88%) who had transplantation in the past year are alive. Of 14 perioperative variables assessed as predictors of early mortality, only postoperative dialysis ($p < 0.0005$) and presence of severe rejection ($p < 0.01$) had statistical significance. Seventy per cent of adults returned to work, and 84% of children had normal or accelerated growth. A new program in liver transplantation provides a dramatic option in patient care and an academic stimulus to the entire medical center.

Presented at the 107th Annual Meeting of the American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

THE FIRST HUMAN ORTHOTOPIC LIVER TRANSPLANT (OLT) was performed in 1963.[1] Although this achievement marked a dramatic surgical milestone, two decades would pass before clinical liver transplantation was recognized by a national medical consensus as a therapeutic option for patients with end-stage liver disease. During those 20 years, intensive laboratory and clinical investigation was conducted primarily by Starzl and colleagues[2,3] and later by Calne et al.[4] on immunology, technique, and applications of the procedure.

At the time of the National Institutes of Health Consensus Conference on Liver Transplantation in 1983,[5] there was only one major center in the United States (Denver/Pittsburgh) with a sizeable experience in OLT. Several other centers had reactivated or initiated new programs. By 1987, over 50 centers in the U.S. have programs in OLT, emphasizing the rapid acceptance of this therapy. At the University of California at Los Angeles (UCLA), a liver transplant program was organized in 1983, and the first clinical transplant was performed on February 1, 1984. Between that date and November 1, 1986, 100 transplants were performed in 83 patients. Forty-seven transplants that have been performed in 40 children (less than 18 years of age) and 53 transplants in 43 adults form the basis of this report.

Materials and Methods

The organization, development, and structure of the UCLA Program have been described.[6-8] The Liver Transplant Team includes the following individuals involved with the day-to-day care of both adults and children: surgeons (4), anesthesiologists (2), surgical residents (2), and a surgical fellow, anesthesia fellow, hepatologist, nephrologist, infectious disease specialist, psychiatrist, social worker, clinical nurse coordinator, donor nurse coordinator, administrative coordinator, and perfusionist. Personnel involved in the care of pediatric patients specifically include hepatologists (3) and specialists in critical care, nephrology, infectious diseases, and psychiatry. Prospective transplant recipients are evaluated in the hospital on the pediatric or adult liver transplant services and presented to the multidisciplinary Patient Selection Committee, which considers both adult and pediatric candidates. All patients are managed before and after operation by the surgical team in close collaboration with either the adult or pediatric specialists.

Patients Evaluated and Transplanted

Two hundred thirty-six patients were evaluated for transplantation. The diagnoses of these patients evaluated and transplanted and the individual survivals are shown in Tables 1 and 2. Mean age for children was 5 years with a range of five months to 16 years. Biliary atresia and its variants were the diseases seen and transplanted most frequently among children (Table 1). End-stage cirrhosis from various causes and metabolic disorders, particularly alpha-1-antitrypsin deficiency, were also common. Inflammatory diseases were seen less often, and only a few pediatric patients were evaluated for hepatic tumors. Mean age for adults was 41 years with a range of 18–60 years. Among adults, chronic active hepatitis, primary biliary cirrhosis, sclerosing cholangitis, and cryptogenic cirrhosis were the most common diseases seen and transplanted (Table 2).

Follow-up for all patients transplanted has been 100%. Range of follow-up is 1–33 months with a mean of 11.8 months. Each patient is numbered by transplant.

Donors and recipients were matched for size (weight and height) and ABO blood groups. No prospective tissue matching was performed. Transplants were performed across blood groups in 28 patients. In 24 of these patients, a Type O liver was placed in an A or B recipient. In four patients, a Type A or B liver was placed in an O recipient because of an urgent need for transplantation (two retransplants and two first transplants).

Twenty patients (12 pediatric and 8 adult) who had been accepted for transplantation died before a suitable donor could be found. Average age of the pediatric patients was 9.5 months (range 6–16 months). Diagnoses were biliary atresia in nine patients (previous portoenterostomy procedure in 7) and fulminant liver failure, Wilson's disease, and end-stage cholestatic cirrhosis in one patient each. All had severely depressed hepatic synthetic function. Adults who died while waiting for transplantation included three patients with chronic active hepatitis, two with cryptogenic cirrhosis, and one each with primary biliary cirrhosis, protoporphyria, and fulminant hepatic necrosis. Overall, for every three pediatric patients transplanted, one died waiting; for every five adults, one died waiting.

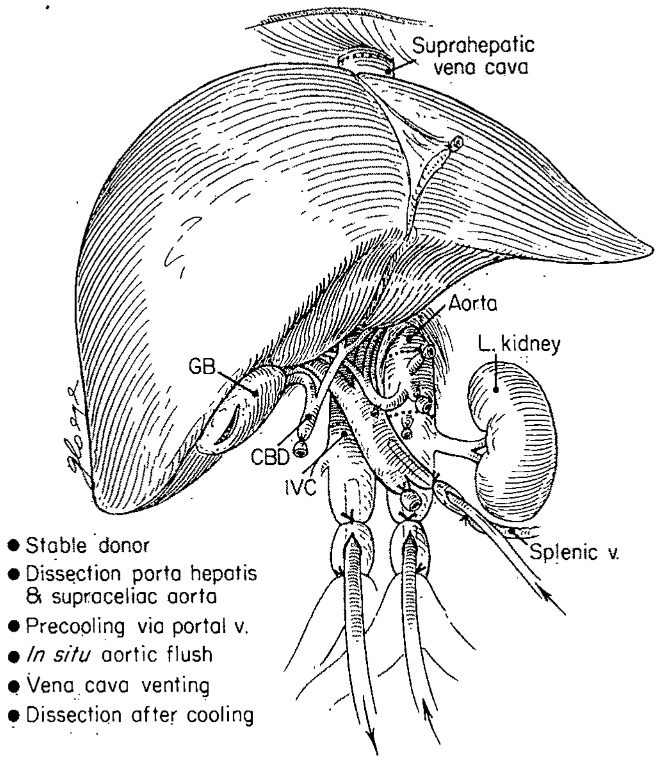

FIG. 1. Preparation for harvesting of the donor liver.

Operative Approach and Complications

Donor and recipient operations were performed using techniques described by Starzl et al.[9] Ninety-eight of 100 liver harvests were performed by members of our team who traveled to the donor hospital. In two cases, another team, Pittsburgh and Dallas, performed the donor hepatectomy and sent the organ to UCLA. The donor procedure allows for harvesting of heart, liver, and kidneys[10,11] (Fig. 1).

For the recipient, large-bore intravenous catheters and Silastic (Hickman® or Broviac®) catheters were placed before operation. Pulmonary artery monitoring, always used in adults, was rarely used in children except in teenagers. The abdomen was entered *via* a bilateral subcostal incision with midline extensions to the xiphoid in adults. A thoracotomy extension was used only once (OLT #64), and one patient (OLT #23) required transdiaphragmatic intrapericardial control of the inferior vena cava because of extensive previous surgery. No irreversible surgical maneuvers were performed during recipient hepatectomy before return of the donor liver to UCLA, although a satisfactory liver was harvested in every instance. In one case, recipient hepatectomy was not begun when the donor liver was found to be cirrhotic. Transplantation was also aborted in one patient with a hepatoblastoma and in one patient with hepatocellular carcinoma who were found to have tumor ex-

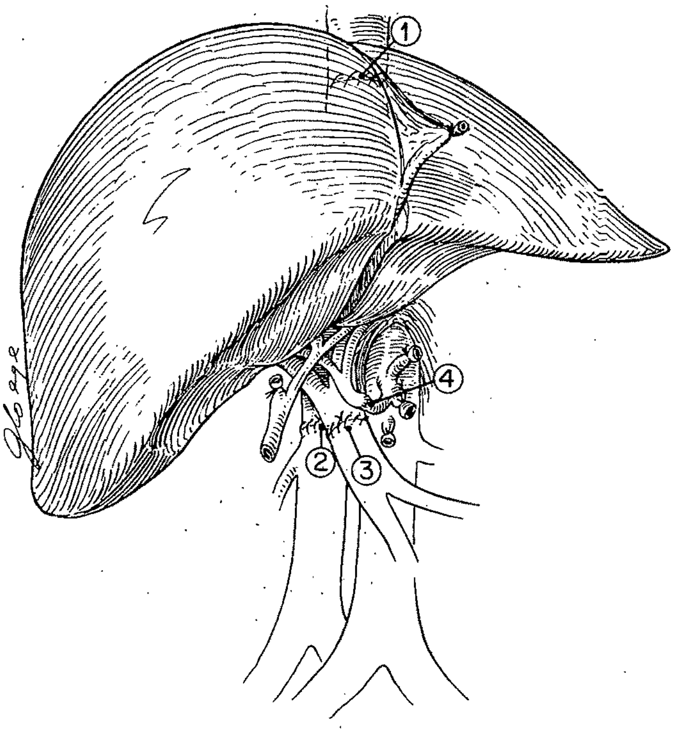

FIG. 3. Order of vascular anastomoses (see text).

tension beyond the liver thus precluding a curative resection.

Before removal of the native liver, trial clamping of the vena cava was performed. This was tolerated well in 44 of 100 transplants. Venous–venous bypass using femoral and portal venous return and axillary venous inflow, a routine in adults, was used in only three children, two (ages 14 and 15 years) who exhibited hypotension on trial clamping and one (OLT #23) with massive bleeding from multiple adhesions and portal hypertension who was placed on bypass for circulatory support (Fig. 2).

Vascular Anastomoses

Anastomoses were performed in the following order: suprahepatic inferior vena cava (IVC), infrahepatic IVC, portal vein, and hepatic artery (Fig. 3). While the infrahepatic IVC was being completed, the liver was flushed with cold normal saline solution *via* an indwelling portal vein cannula that had been placed for precooling during the donor hepatectomy. In the latter part of the series, 25 g of mannitol were added to the flushing solution. After the portal vein anastomosis was completed, the vena caval clamps were removed and the liver was reperfused with portal blood while the arterial anastomosis was performed.

Venous. The supra- and infrahepatic inferior vena caval and portal venous anastomoses were performed using a running polypropylene suture (3-0 or 4-0 for vena cava and 6-0 or 7-0 for portal vein). The posterior wall was sewn from within, with care taken to achieve an everting intima-to-intima approximation. An interrupted anterior row was used in small children to allow for growth of the vessel. "Growth factors" were used occasionally in adults.[12]

Arterial. Arterial reconstruction (Table 3) was variable and depended on donor and recipient anatomy.[13] Although most donor livers had normal (Type 1) arterial anatomy, variants were seen in 19 cases: 10 Type 2 (replaced left hepatic artery arising from left gastric artery), two Type 4 (right hepatic replaced from superior mesenteric and left hepatic replaced from left gastric arteries), and seven Type 3 (right hepatic replaced from superior mesenteric artery [SMA]). Recipient arterial anatomy was Type 2 in two cases, Type 3 in one case, and Type 1 in all others.

Running or interrupted sutures of 6-0 or 7-0 polypropylene were used for arterial anastomoses. A "branch patch" technique described by our group was often used to facilitate anastomosis of small vessels.[14]

An aortic Carrel patch of the entire donor celiac artery used in 21 transplants was sewn to a branch patch of the proper hepatic-gastroduodenal bifurcation (9 transplants), to a branch patch of the common hepatic bifurcation (7), to a branch patch of the celiac-splenic bifurcation (3), to the aorta (2), and to the common hepatic, and SMA (1 each). Although use of the celiac-hepatic trunk with a Carrel patch generally produced a redundant lie that would seem to be prone to kinking, no instances of arterial thrombosis occurred with this reconstruction.

A simple end-to-end technique was used in 21 transplants: hepatic-to-hepatic (13), hepatic-to-celiac (1), and celiac-to-hepatic (5), hepatic-to-recipient aorta with iliac graft (1), and donor SMA trunk-to-recipient celiac axis (1). There was one episode of thrombosis treated with retransplantation and arterial reconstruction using an aortic conduit (OLT #26).

A primary branch patch technique was used in 42 transplants. In 28 transplants, the hepatic artery or celiac-splenic bifurcation was sewn to a branch patch of the hepaticogastroduodenal bifurcation. In one transplant, the hepatic artery was sewn to a branch patch of the common hepatic bifurcation. In the donor with a double replaced arterial supply, the proximal SMA was joined to the celiac and the distal SMA to a branch patch of the hepaticogastroduodenal bifurcation. There were three thromboses, one of the celiac axis branch patch-to-recipient aorta and two of the hepatic-to-hepatic gastroduodenal branch patch type. One (OLT #27) thrombosis of the left hepatic artery occurred and produced left lobar necrosis and a biliary fistula. The lobar necrosis manifested as Citrobacter sepsis and was treated with operative lobar debridement; the later biliary fistula was treated with Roux-en-Y jejunal onlay on the fistulous orifice. The other thromboses (OLT #36 and OLT #79) involved the entire artery and were treated successfully with two subsequent retransplants in one patient and with a single retransplant in the other.

An aortic conduit from donor-to-recipient aorta was used in eight transplants, principally in our early experience. The initial episode of thrombosis in OLT #36 was managed with retransplantation and arterial reconstruction using an aortic conduit and an iliac artery interposition graft. This in turn thrombosed, and arterial anastomosis in the successful third transplant was performed using an aortic Carrel patch to a branch patch of the celiac-splenic bifurcation.

All thromboses occurred in the pediatric patients, and it is our impression that the majority occurred because of the small caliber of the donor arteries. Arterial inflow was tested carefully, and if it did not appear to be adequate, an alternative inflow was chosen. This experience with arterial reconstruction has indicated that each anastomosis must be individualized to accommodate the variable anatomy of donor and recipient.

Total	100	81	10	7	2	5

* 1 left lobar infarction.

Biliary Reconstruction

The biliary anastomosis was a choledochocholedochostomy with a t-tube stent in 67 transplants and Roux-en-Y choledochojejunostomy with a straight tube or internal stent in 33 transplants (Fig. 4). Technetium-HIDA hepatobiliary scintigraphy was found useful for postoperative evaluation of the biliary anastomoses as well as of graft function.[15]

The overall biliary complication rate was 24%. There were 16 complications of choledochocholedochostomy (24%): bile peritonitis in nine after t-tube removal (reoperation required in 2), t-tube malposition or migration in four (reoperation in 2), biliary fistula in two, and bile duct tumor recurrence in one (anastomotic and distant recurrence). There were eight complications of choledochojejunostomy (24%). Five complications were related to duct-jejunal anastomosis: fistulas in three (one due to hepatic artery thrombosis), obstruction in one, and a tube problem in one. Three complications were related to the jejunojejunal anastomosis: perforation in two and bleeding in one. There were no deaths attributable to biliary complications, although one patient died of recurrent cholangiocarcinoma.

Other Operative Considerations

Average length of liver ischemia was 4 hours (range: 1–10 hours); of operation, 7.6 hours (range: 4–15 hours); and of anesthesia, 8.4 hours (range: 5.5–16 hours). Average requirements for blood and products were: packed red cells, 17.0 units (range: 2–220 units); fresh frozen plasma, 18.2 units (range: 2–190 units); platelets, 14.7 units (range: 0–100 units). Re-exploration for bleeding was necessary in 17 of 100 transplants; only two of these were done in the past year.

Splenectomy was performed in five patients, one at the time of the transplant to permit abdominal closure (OLT #33) and four later. One late splenectomy was done for thrombocytopenia from hypersplenism (OLT

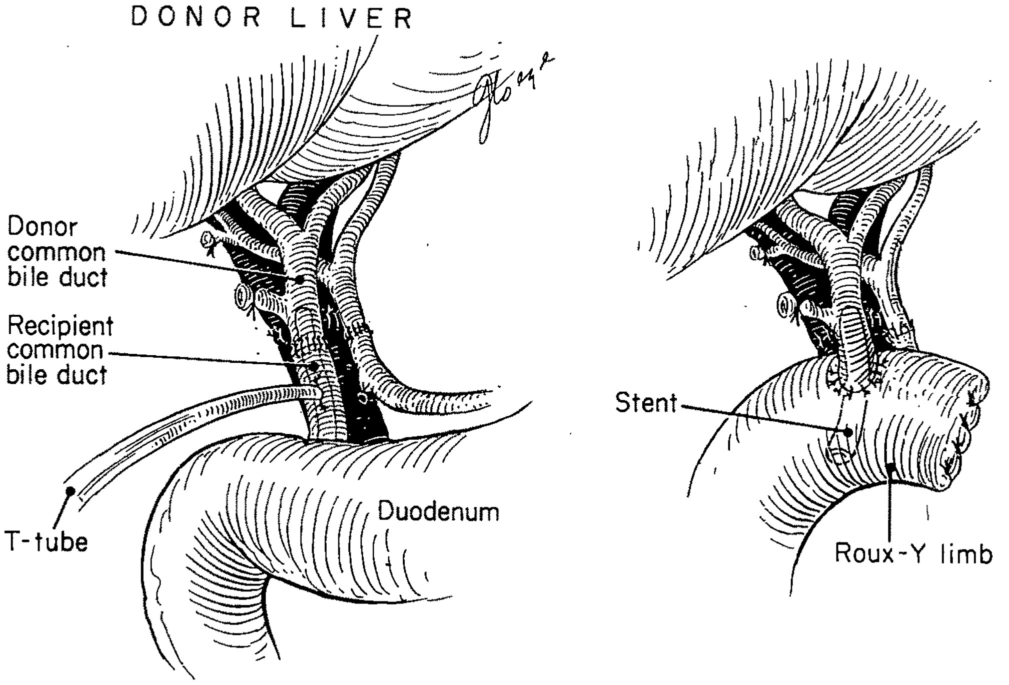

FIG. 4. Biliary reconstruction by choledochocholedochostomy with T-tube stent (left) or Roux-en-Y choledochojejunostomy with indwelling straight stent.

#30), one as part of a gastric devascularization for bleeding (OLT #15), and the other to facilitate ventilator weaning made difficult by diaphragmatic pressure from the large spleen (OLT #26). One adult had splenectomy for a lacerated spleen (OLT #52). The first patient had an episode of *Hemophilus influenzae* sepsis 5 months after transplantation that was treated successfully, the second patient has done well for 15 post-transplant months, and the other three patients (OLT #26, OLT #15, OLT #52) died of sepsis and liver failure in the postoperative period.

Immunosuppression and Rejection

Cyclosporine and prednisone were used as the principal regimen. Before operation, the patients received cyclosporine, 17.5 mg/kg orally (5 mg/kg intravenously if oral intake was not possible), and methylprednisolone, 20 mg/kg intravenously. After transplantation, they received cyclosporine, 5 mg/kg/day intravenously, in divided doses until oral intake was adequate, then 17 mg/kg/day orally in divided doses. There was usually a 5–7 day crossover period during which both intravenous and oral cyclosporine were given to ensure adequate blood levels. Cyclosporine levels (plasma radioimmunoassay) were followed daily and dosages adjusted to maintain a trough level of 200–300 ng/mL and for renal dysfunction. Intravenous methylprednisolone dose after operation was 10 mg/kg/day initially, tapered to 0.3 mg/kg/day by the end of the first week. Prednisone was given by mouth when oral intake resumed.

When acute rejection was suspected based on clinical findings or on abnormalities in tests of liver function or liver biopsy, an algorithmic approach was used. Intravenous methylprednisolone, 20 mg/kg, was given for 2 days. If a response was seen, the patient was returned to maintenance cyclosporine and methylprednisolone. If there was no response, a 5-day methylprednisolone recycle was begun, 30 mg/kg on the first day, then 10 mg/kg tapered to 0.3 mg/kg. If this did not reverse rejection, the patient was enrolled in a protocol to evaluate OKT3 monoclonal T-cell antibody.[16] Retransplantation was considered for failure to respond to OKT3. Responders received azathioprine, 1–2 mg/kg/day.

Virtually all patients had at least one mild rejection episode treated with a steroid pulse. Twenty-one patients refractory to these measures were treated on the OKT3 monoclonal antibody protocol, 17 with acute rejection during their initial hospitalization and four with chronic rejection who were readmitted to the hospital. Thirteen patients had a complete response with normalization of liver function, eight had a partial response, and two patients died of ongoing sepsis. Two patients eventually required retransplantation, one for hepatic artery thrombosis and one for chronic rejection. The remaining 17 grafts (76%) are currently functioning satisfactorily. Measurements of total bilirubin, SGOT, and SGPT were found to be reduced significantly after

OKT3 therapy. Survival of patients receiving OKT3 was 86%.

Percutaneous liver biopsies were performed on 114 occasions in 57 patients. Half of the biopsies showed rejection and half showed other phenomena such as ischemic injury, viral hepatitis, or cholangitis. Liver biopsy was a safe procedure: one bleeding episode requiring transfusion was the only complication. The results of biopsy data have been reported previously.[17]

Results

Postoperative Course

Average length of hospitalization for the 63 patients who survived after transplantation was 50 days (range: 18–155 days). Certain complications were seen on a recurring basis.

Seizures. Eighteen of 83 patients (22%) had grand mal seizures. In only one of these patients was a focal neurologic deficit found. This was a 2-year-old child in stage IV hepatic coma in whom postoperative sepsis developed before brain herniation and death. In the other patients, seizures were multifactorial. However, in six of 10 adults and in five of eight children, magnesium levels were below 1.6 mg/mL. Mean trough cyclosporine level of patients who had seizures was 405 ng/mL. No other significant abnormalities in electrolyte, glucose, or osmolar balance were found. Thirteen of the 18 patients survived to leave the hospital, and none had neurologic sequelae.

Pulmonary complications. Twenty-one patients (25%) required mechanical ventilation for more than 5 days after operation. Causes included limited nutritional reserve, diaphragmatic compression by abdominal viscera (both before and after transplant), and diaphragmatic paralysis. Paralysis of the right diaphragm occurred in 12 patients. This was a chest x-ray finding that was confirmed with real-time ultrasonography and is probably the result of a clamp injury to the phrenic nerve when obtaining control of the suprahepatic vena cava cuff. Transient right-sided pleural effusions occurred in 45 patients and right upper lobe atelectasis occurred in 36 patients.

Renal failure. Virtually all patients exhibited oliguria in the first 24–48 hours after transplant, and 50 (60%) had elevations of serum creatinine levels to twice the preoperative value. Of four children (OLT #19, 23, 26, 75) requiring hemodialysis because of severe oliguria with resultant fluid overload, hyperkalemia, and acidosis, all ultimately died of sepsis and organ failure (one of these children, OLT #75, had fibrinolysis as the cause of her organ failure). Seventeen adults required hemodialysis in the perioperative period, and six died.

TABLE 4. *Infectious Complications in 42 of 83 Patients (51%)*

	No. of Episodes
Early	
Bacterial	34
Viral	22
Fungal (Candida)	15
Late	
Viral	7
Bacterial	10

Early = less than 2 months.
Late = greater than 2 months.

Infection. Patients were scrutinized closely for infectious complications. All received oral antibiotic bowel preparation (neomycin and erythromycin base), nystatin and chlortrimazole antifungal prophylaxis, and perioperative parenteral antibiotic therapy with ampicillin and cefotaxime for 72 hours. Antiviral prophylaxis (Acyclovir®) was not used. Postoperative infections occurred in 42 patients, or 51% (Table 4). Half of the patients who died had at least one infection identified. A detailed analysis of our infectious complications was the subject of another report.[18]

Hypertension. Systolic and diastolic hypertension was a frequent finding in the children. This is perhaps an effect of cyclosporine and steroids. Thirty-three children (87%) required intravenous antihypertensive therapy, and discharge medications included antihypertensives in 16 of 31 patients who left the hospital. Only eight of 33 adults were discharged requiring antihypertensives.

Survival

Of the 83 patients, 63 are alive (76%; adults 72%, children 80%). The 1- and 2-year actuarial survival rate is 73% and 73% respectively (68% and 68% in adults, 78% and 78% in children) (Fig. 5). Of 43 patients transplanted in the past year, 38 are alive (adults 88%, children 89%). Causes of the 20 deaths are shown in Table 5.

There were no operative deaths. Three late deaths were due to recurrent tumors. Three patients died in the early postoperative period; one of a ruptured splenic artery aneurysm, one of pulmonary hemorrhage and resultant respiratory failure due to an episode of primary fibrinolysis that occurred shortly after liver reperfusion, and one of ongoing bleeding after transplantation for alcoholic cirrhosis. The remaining 15 deaths occurred within 4 months of transplantation and were due to varying combinations of sepsis, organ failure, rejection, and bleeding.

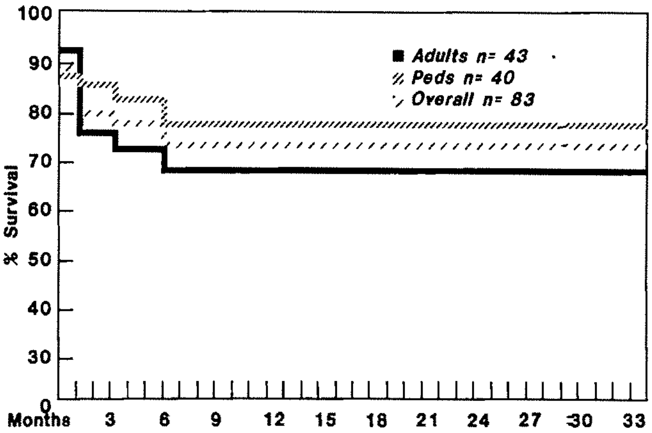

FIG. 5. Acturial survival curve of all patients undergoing liver transplantation. Computed by Kaplan-Meier method.

Of four patients who received an ABO incompatible liver, three are alive and one died. This patient (OLT #26), with blood type O, was retransplanted with a type A liver and died of sepsis and liver failure. One patient (OLT #41) with blood type A was retransplanted with a type B liver due to emergent circumstances. She had a second retransplantation with a type A liver 7 months later because of chronic rejection and is now well. The other two patients (OLT #56 and #82), both blood type O, received type B livers and have normal liver function at 8 months and 2 months, respectively. Of 21 patients with a compatible, yet not identical, ABO match, eight patients died. The overall graft survival is significantly lower at both 1 and 2 years in ABO nonidentical matches *versus* ABO identical matches (Fig. 6).

Routine cytotoxic antibody testing against donor lymphocytes was performed but did not play a role in donor selection. Graft survival *versus* reactivity to B-cell warm, B-cell cold, and T-cell warm antibodies was evaluated. No statistical difference in survival was seen, although there was a suggestion of lower 1-year graft survival in those patients with greater than 10% T-cell warm antibodies compared with patients with less than 10%; graft survival was 50% *versus* 65.4%, respectively.

Retransplantation

A total of 17 retransplants were performed in 83 patients (20%). Four patients had retransplantation twice. Overall retransplant survival was seven of 13 patients (54%). Survival of retransplantation for hepatic artery thrombosis, rejection, and primary nongraft function were 100%, 57%, and 33%, respectively (Table 6).

TABLE 5. *Mortality in 20 of 83 Patients*

OLT #	Disease	Cause of Death	Time Post-transplant	Comment
1	Hepatic schwannoma	Recurrent tumor	4 months	
4	Hepatocellular carcinoma	Anoxic brain death	32 days	Retransplant
5	Budd-Chiari	Disseminated herpes	28 days	1st Retransplant primary nonfunction 2nd Retransplant for suspected rejection
8	Idiopathic cirrhosis	Chronic rejection/sepsis	3 months	
11	Tyrosinemia with hepatoma	Recurrent tumor	10 months	Tumor involved hepatic veins
13	Primary biliary cirrhosis	Liver failure/sepsis	12 days	
15	Primary biliary cirrhosis	Sepsis	49 days	
16	Biliary atresia	Disseminated adenovirus	17 days	Retransplanted for suspected rejection
19	Biliary atresia	Fungal sepsis/liver failure	7 weeks	
23	Biliary atresia	Fungal sepsis	25 days	Extensive previous biliary surgery (12 operations)
24	Chronic active hepatitis	Chronic rejection	2 months	Refused retransplant
26	Biliary atresia	Sepsis/liver failure	4.5 months	Retransplant/hepatic artery thrombosis
28	Chronic active hepatitis with hepatocellular carcinoma	Recurrent tumor	9.5 months	
29	Chronic active hepatitis	Fungal sepsis	27 days	Retransplant
31	Acute hepatitis A	Brain dead	10 days	Did not regain consciousness
46	Sclerosing cholangitis	Sepsis, liver failure	2.5 months	Retransplant twice for nonfunction
51	Alpha-1-antitrypsin	Ruptured splenic artery aneurysm	5 days	Normal liver function
52	Alcoholic cirrhosis	Coagulopathy/ARDS	3 days	
61	Sclerosing cholangitis	Pseudomonas pneumonia	37 days	Normal liver function
75	Tyrosinemia	Intrapulmonary hemorrhage	2 days	Primary fibrinolysis

Risk Factors

A number of pre-, intra-, and postoperative factors were assessed to determine if variables predictive of early (2 months) postoperative survival could be identified. In addition, a group of pre- and intraoperative factors were analyzed to seek a correlation with blood loss. Factors assessed included age, diagnosis of liver disease, previous operations, liver chemistries, encephalopathy, donor liver ischemia, rejection, and need for dialysis. The unpaired Student's t-test was used to compare means and chi-square analysis to compare proportions. Overall 2-month survival was 67 of 83 patients (81%). None of these factors showed statistical correlation with survival except the need for dialysis and severe rejection (requiring retransplantation). Only 11 of 21 patients (43%) of those requiring dialysis survived *versus* 56 of 62 patients (90%) who did not ($p < 0.0005$). In patients who have severe rejection, five of 11 (45%) survived *versus* 42 of 52 (81%) with mild rejection and 20 of 20 (100%) with moderate rejection ($p < 0.01$).

Age over 50 years and presence of a portacaval shunt significantly affected intraoperative blood loss ($p < 0.02$ and $p < 0.005$, respectively). Blood loss could not be correlated with diagnosis, previous abdominal surgery (including nonportacaval portasystemic shunts), or liver chemistries. Actuarial survival curves of 100 allografts are shown in Figure 7. The three curves illustrate three groups of patients according to intraoperative blood loss; group I, 1–10 units PRBC; group II, 11–30 units; group III, greater than 30 units. One-year graft survival was superior in group I *versus* group II ($p = 0.04$). Although a trend toward improved long-term survival with lower blood loss is evident, this did not reach statistical significance.

Growth and Development

The effects of liver transplantation on growth of 29 pediatric patients was assessed. Mean follow-up was 13.9 months (range: 4–33 months). Average age at the time of transplant was 5.8 years (range: 7 months to 16 years). Percentiles for weight, height, and weight-for-height were calculated before and after transplantation. Results are shown in Table 7.

Most patients exhibited normal or accelerated growth after transplant. The three patients who showed growth failure had been receiving higher than usual steroid dosages for repeated bouts of rejection. The growth velocity index (GVI), or increment of height per year, was also assessed. These results are compared with velocity standards for height based on chronologic age. Twenty-seven (93%) of patients demonstrated a GVI greater than 100 (normal value is greater than 80). GVI before transplant was 79.6 ± 20.78 *versus* 147.4 ± 16.36 after transplant ($p < 0.01$).

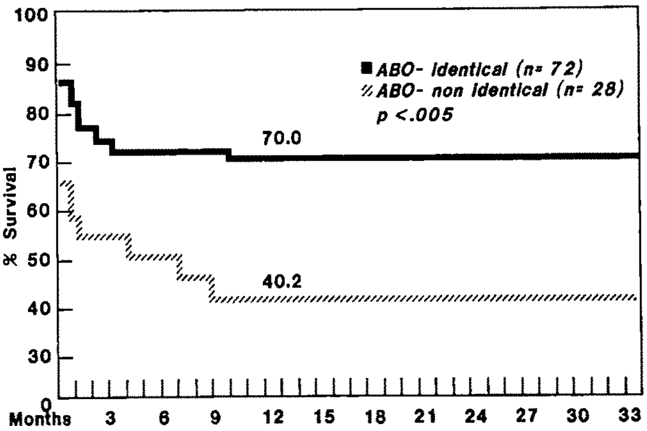

FIG. 6. Actuarial graft survival of ABO identical and ABO nonidentical donor/recipient matches. All grafts included.

The effects of liver transplantation on cognitive and intellectual development are anecdotal at present. Currently we are evaluating our patients with psychomotor tests.

Through December 1, 1986, 29 adults who had transplantation have been discharged from the hospital for a minimum of 4 months follow-up. Twenty of 29 patients (70%) have returned to normal activity or returned to work. Nine patients have improved activity compared with pretransplant status. No discharged patients have demonstrated a regression in functional capability.

Fiscal considerations

The financial burden of the procedure falls to commercial insurance carriers, state-funded medical pro-

grams, or self-payment. At the UCLA Medical Center, guarantee of payment is required before a patient is placed on the active list. Adherence to this hospital policy is mandatory to maintain solvency. Hospital charge for pediatric patients has ranged from $46,000 to $637,000, with a median of $109,000; hospital charge for adult patients has ranged from $66,000 to $609,000, with a median of $138,000. Mean charges for children and adults have been $164,000 and $175,000, respectively.

Discussion

After the National Institutes of Health Consensus Conference on liver transplantation concluded that the procedure should be considered a therapeutic modality in selected patients with end-stage liver disease, a number of centers either expressed intent or initiated programs in OLT. UCLA began its preparation for such a program 6 months before the Consensus Conference. This program was built on a foundation of basic laboratory preparation and cautious early clinical efforts. Expansion was gradual but steady, with 20 OLTs performed in 1984, 38 in 1985, and 53 in 1986. The 100th transplant occurred in the 33rd month of the program.

The protocols for both pediatric and adult patient evaluation and selection have been detailed.[6,7] As our program has evolved, an increasing number of patients are being referred for consideration. The primary reason for this phenomenon is that OLT is now recognized more frequently by both the gastroenterologist and primary care physician as the definitive treatment for patients with chronic liver disease. Rarely is a patient categorically rejected from consideration until a full evaluation is performed. In many cases, patients who might be judged as noncandidates at first presentation have been accepted and transplanted. With improving results, absolute contraindications are decreasing. Although age greater than 55 years was considered a relative contraindication, we and other groups have transplanted patients in the seventh and eighth decades who have returned to productive lifestyles. A recent report[19] suggests no difference in survival of patients over 50 years of age. Although the numbers are small, our results indicate a poorer survival in patients over 50 years of age because of greater blood loss in this group. Our current policy is not to refuse candidacy on the basis of age alone if a thorough cardiopulmonary and renal assessment does not disclose a specific physiologic contraindication.

TABLE 7. *Growth Data in 29 Pediatric Patients*

	Percentile Curves After OLT					
	Weight		Height		Weight for Height	
	N	(%)	N	(%)	N	(%)
Accelerated	25	86	17	59	23	80
No change	4	14	11	38	3	10
Loss	0		1	3	2	10

"Unresectable hepatic malignancy" is one of the most problematic indications for transplantation. Reports from other centers[20] and ours[21] have indicated a 50–70% recurrence rate within 2 years. Moreover, even the most thorough preoperative assessment may not discern the presence of extrahepatic spread, which would preclude a curative operation with total liver replacement. Despite these pitfalls, we have offered transplantation to carefully selected patients with malignancy. Of seven patients transplanted for this indication, five are alive and free of disease from 5 months to 3 years after transplant. In all patients, the quality of life after transplant has offset the uncertainty of tumor recurrence. Adjuvant chemotherapy has been given before and after operation in some patients. Protocols based on increasing experience will be needed to define specific indications for liver transplantation in patients with malignancy.

Liver transplantation in the adult population for chronic active hepatitis, primary biliary cirrhosis, and sclerosing cholangitis is becoming well accepted with patients with end-stage disease. However, as has been pointed out by Neuberger et al.,[22] the timing of OLT is perhaps one of the most crucial issues in the evolution of this treatment.

In our series, we have seen no significant differences in survival after OLT among adults with chronic active hepatitis, sclerosing cholangitis, or primary biliary cirrhosis. This is in contrast to the experience of Starzl et al.,[23] in which patients with cirrhosis secondary to chronic active hepatitis fared worse. The longer follow-up in the Pittsburgh series, with recurrence of chronic active hepatitis in some patients, may contribute to this difference. In a recent report, Demetris et al.[24] found a 100% recurrence of antigen positivity after 2 months in patients transplanted for hepatitis B. In our series, recurrent B antigen positivity developed in 50% of patients despite the administration of hyperimmune anti–B-gamma globulin during the anhepatic phase. However, no patients thus far have had histologic evidence of recurrence of chronic active hepatitis up to a 2-year follow-up.

The results of liver transplantation in children have been generally superior to those for adults.[23] Not only is the pediatric patient more resilient to the rigors of transplantation, but there appears to be a lack of influence of the primary disease on the eventual outcome after OLT. This is evident both in children with biliary atresia and with inborn errors of metabolism. Actuarial survival in each group at 2 years is close to 80%. Because of the favorable statistics, it is rare to reject a child for transplantation despite substantial preoperative risk factors. In many cases, the transplant procedure will be technically much more demanding after multiple attempts at portoenterostomy revision, yet this has not proved to be a significant deterrent to success.

It is accepted that for OLT to be successful, the operation must be technically perfect. This assumes a well-preserved and immediately functional graft, an expeditious and blood-sparing recipient hepatectomy, and a precise anastomotic reconstruction of vascular and biliary components. Our techniques in these phases of the operation have been based on those described by Starzl et al.,[9] modified and adapted to our own team.[11] Flexibility in response to changing demands of the operative circumstances is essential to the conduct of the procedure. This is illustrated by our approach to arterial reconstruction, in which five different methods have been used. Using this adaptable strategy, we have achieved a 95% patency rate, which is comparable to the Pittsburgh series (93%).[25] There have been no arterial thromboses in our adult series. Our methods of biliary reconstruction have been choledochocholedochostomy or Roux-en-Y choledochojejunostomy. The complication rate has been 24%, but no complications have resulted in death of any patient. This figure, although higher, is similar to the 13.2% complication rate reported by Lerut and colleagues[26] in 393 grafts.

The use of cyclosporine has been the single most important factor in the improved survival for OLT. In the early series (1963–1979) reported by Starzl et al.,[3] less than one third of patients lived 1 year. Now, it is routine for 1-year survival to be twice that figure. An important adjuvant to the cyclosporine/steroid immunosuppression regimen has been the introduction of OKT3 monoclonal antibody to treat acute allograft rejection.[27] Our experience has mirrored the multi-institutional trial[28] in that all of our patients have had either a partial or complete reversal of rejection. The results of OKT3 have been so favorable and its lack of nephrotoxicity is so appealing that a trial for prophylactic use has been initiated.

An actuarial survival rate of 73% at 1 and 2 years after OLT in our series has been comparable with outcomes reported by others.[23,29,30] Also, the pediatric population has fared better than the adults, with a 2-year actuarial survival rate of 78% *versus* 68% for adults. It appears that the 9-month survival is most important, since late attrition after this time is significantly decreased. Factors that influence late mortality include recurrence of primary disease, chronic rejection, and late infectious complications. In our patients, recurrent tumor and infection were the predominant causes of late death.

The causes and predictors of early mortality after OLT have been studied extensively by Shaw et al.[31] In a similar analysis of our patients, only need for dialysis or severe rejection predicted early mortality. However, intraoperative blood loss that exceeded 10 units resulted in a statistically lower 1-year survival than a blood loss of less than 10 units. No difference was found in blood loss from 10–30 units or greater than 30 units. This is in contrast to the report of Shaw et al.[31] that demonstrated superior survival in the group requiring 0–35 units *versus* 36–100 units *versus* greater than 100 units, respectively. Our data support the observation that of all factors studied, low intraoperative blood loss correlates most strongly with early survival.

Although recent experimental data by Knechtle and co-workers[32] demonstrate the occurrence of hyperacute hepatic allograft rejection in sensitized recipients, we have not observed graft survival to be decreased significantly in patients with preformed cytotoxic antibodies. However, in our analysis of graft survival, nonidentical ABO-matched organs faired worse than identically matched ones. A much larger analysis of this has been presented by Gordon et al.[33] with similar results.

Despite the major role that cyclosporine has played in the improvement of patient survival after OLT, there is the continued threat, particularly in the first 3 months, of irreparable allograft dysfunction. Retransplantation is the only hope for these patients. We have maintained an aggressive posture in this regard, with 17 of our first 100 cases being retransplants (20%). Best results are obtained if the indication for retransplantation is arterial thrombosis or early acute refractory rejection. Primary graft nonfunction generally has a poorer prognosis both in our series and that of others.[34]

Extrahepatic postoperative complications after OLT are expected and must be anticipated. An operative endeavor of such magnitude performed on a compromised host who is then immunosuppressed cannot be expected to be free of problems. Infection, renal failure, pulmonary, gastrointestinal, and neurologic complications occurred singly or in combination in approximately 60% of patients in this series. Notably absent, except in terminal patients, were cardiac complications such as arrhythmias, congestive heart failure, or myocardial infarction. Neurologic complications were unexpectedly frequent with grand mal seizures occurring in 22% of patients. In most patients, seizures were associated with low magnesium and elevated cyclosporine levels. The relationship between hypomagnesemia and cyclosporine-induced neurotoxicity has been previously reported by Thompson and co-workers.[35] None of our patients exhibiting seizures had permanent neurologic deficits.

Return of functional status in adults and growth and development in children are important parameters in the ultimate assessment of the benefits of OLT. Seventy per cent of our discharged adults have returned to gainful employment and virtually complete rehabilitation to their premorbid condition. The remainder have shown significant improvement, without a single patient demonstrating regression. More objective criteria are available for evaluation of the success of OLT in pediatric patients. When growth and development were monitored, 59–86% of our children demonstrated acceleration of weight, height, or weight-for-height ratio.[36] Gartner et al.[37] analyzed a similar series of 22 patients and found accelerated growth in 11, normal growth in 10, and growth failure in only one.

Liver transplantation is a procedure in evolution. Through the principal pioneering efforts of Starzl et al.,[1] this therapy may now be offered to patients in a logistical scope that was barely thinkable less than one decade ago. The cost of this procedure is high. However, the operation has now provided successful treatment and cure of diseases heretofore considered dismal or hopeless. As a consequence of transplant-related research, our basic understanding of hepatobiliary physiology, pathology, and surgery have expanded dramatically. Fertile areas for future study include preservation and protection of the ischemic liver, the molecular basis of acute and chronic rejection, multiple organ transplantation, and new immunosuppressive agents.

Acknowledgments

DISCUSSION

DR. JOHN S. NAJARIAN (Minneapolis, Minnesota): I would like to congratulate Ron Busuttil on an excellent paper, which is both beautifully illustrated and presented. In addition, this paper chronicles the establishment of a new liver transplant unit, and I believe that similar results are now being achieved at other units.

I had the privilege of reading this manuscript before, and I have a few comments and a few questions.

Dr. Busuttil has noted a high incidence of rejection. He is quoted as stating that 100% of the patients had at least one rejection episode and several had more.

(Slide) At this point in our own program, we have carefully followed a program that was started in Minnesota using triple therapy, as we reported 3 years ago in our kidney transplantation program. You can see that with triple therapy, which is azathioprine, prednisone, and cyclosporine, we had results with our HLA-matched relatives of 100% over 1 year, 95% with mismatched-related donors, and approximately 85% using cadaver kidneys.

(Slide) If we then turned our attention to cardiac transplantation, again using triple therapy, we have achieved about 95% graft survival in 73 cardiac transplants over the past 2 years.

(Slide) Finally, with liver transplantation we now are looking at approximately 76% patient survival, which is similar to what Dr. Busuttil showed. However, our retransplant rate is only 3%, not 20%, as presented, so that basically our survival statistics here not only represent patients but they represent graft survival as well. Therefore, we believe that triple therapy can save some of the high retransplantation rates, and as was pointed out by Dr. Busuttil, those patients fare less well, about 54%, when they require retransplantation.

If we look at our statistics in liver transplantation, we see that in the very young, under the age of 10, we do well (85%), and between 10 and 18 years of age, we also have excellent survival statistics. However, our adults over the age of 19 have a graft survival of around 70%, results that are not too dissimilar from those shown by Dr. Busuttil.

The second point concerns arterial problems. We found that the only arterial problems we observed are primarily seen in our pediatric population, in which we noted five thromboses. All occurred when we used an aortic-to-aortic anastomosis for a total rate of about 8%; therefore, we believe that this type of arterial revascularization should be avoided if possible. Currently, we no longer do aortic-to-aortic anastomoses.

I would like to ask a few questions. There was one case that came up in the manuscript in which a splenectomy was done and gastric devascularization was performed for esophageal bleeding. Was this done because of an occlusion of the portal vein, and if so, how was the diagnosis made?

Secondly, Dr. Busuttil reported an infection rate of 51%. This is about right, but the concern that I had is if this rate is any higher in the group of steroid-resistant rejections that required OKT3 or was it similar in both groups? In other words, was it possible that OKT3 added to the higher infection rate compared with those patients who just received steroids alone?

The third question concerns blood loss. Dr. Busuttil reported that there was no good correlation of blood loss and mortality noted. Under 10 units there was a good correlation with survival; from 19 to 30 units, Dr. Busuttil did not have a good correlation; above 30 units there was no correlation. My question is since we found a very close correlation with blood loss and survival statistics, are your results affected primarily by pediatric cases? Certainly, a 10-unit blood loss in a small infant is quite different than a 10-unit blood loss in an adult.

My final two questions are: virtually all of the patients had oliguria, and from that group, 60% had a doubling of their serum creatinine level. Dialysis was required in 25% and of 21 patients, 10 died who required dialysis. Six of 17 adults died requiring dialysis. We do not use a veno-veno shunt. We have not found it necessary in any of our patients, and we wondered if with the lower renal dysfunction rate, which is supposed to be one of the advantages of the veno-veno shunt, why do you think you had this high rate of oliguria and eventually renal failure? Is there some problem here that we do not recognize, because certainly, without the use of the veno-veno shunt, we have had only 6% of our patients require dialysis.

We believe that it is important to keep the operation short. Our mean operative time is 6 hours or less, and we believe that elimination of the use of the veno-veno shunt is helpful in that regard. I would be interested in Ron's comments.

Finally, Dr. Busuttil reported that 22% of his patients had grand mal seizures. This occurred in 18 patients. Five of these patients died. We saw this complication in only 5% of our patients.

We started using Decadron before operation, during operation, and for the next 72 hours. Since that time we have not had a single episode of seizures. Have you tried using Decadron, or what have you done to try to decrease the number of seizures in your patients?

DR. G. KLINTMALM (Dallas, Texas): I truly enjoyed this paper very much. The results that have been achieved at UCLA are absolutely staggering.

At Baylor in Dallas we have our own program since 2 years back, and we have performed about 95 transplants with a survival rate of 85%. I have one comment and one question.

We have routinely measured the hepatic and arterial blood flows in all our patients, and as a consequence of the findings, during the transplant surgery we have revascularized three arteries and one portal vein. I believe that this technique may help to prevent some of the unexpected problems such as vascular thrombosis we may find after operation.

Despite this, we have found three arterial thromboses, and they have been caused twice by acute angulation of the artery and once by a recipient artery intimal dissection.

The three patients were rushed to surgery where revascularization including thrombectomy and arterial reconstruction was carried out. The outcome of these patients was satisfactory. I propose that the concept that we have had up to this time that we should go to retransplantation in hepatoarterial thrombosis is not valid any more.

My question is the same as Dr. Najarian's. You have an extremely high rejection rate. We have a 72% rejection rate that has been histologically verified. I would like to know on what ground you made your diagnosis. Was this done by only clinical symptoms or were the rejections verified by other means?

DR. S. IWATSUKI (Pittsburgh, Pennsylvania): I would also like to congratulate Dr. Busuttil and the UCLA liver transplant team on their excellent results and thank them for the opportunity of reviewing their manuscript.

It seemed like only a few months ago rather than years that Dr. Jim Maloney, the former Chairman at UCLA, sent Dr. Busuttil and his colleagues to Pittsburgh on sabbatical before their first clinical trials of liver transplantation in 1984.

I would like to present our own experience in Pittsburgh to show that the series at UCLA is one of the best.

We have performed more than 1000 liver transplantations with cyclosporine and steroid therapy since 1980, but for this discussion I reviewed our first 100 patients during the 33 months from March 1980 to December 1982, 4 years before the UCLA series.

During this period the proper use of cyclosporine still had to be learned. Cyclosporine blood level monitoring was not available. The venovenous bypasses had not been invented and the monoclonal ALG was not available.

With this primitive situation 60 of our first 100 patients lived for at least 1 year and 50, exactly one half of the patients, are still alive and well as of April 1987, between 4.5 and 7 years after liver transplantation.

The causes of the 50 deaths have usually been too complex for simple classification. However, 14 patients died as a result of surgical technical errors or complications that could have been minimized if modern surgical techniques had been applied. Ten patients died of infectious complications and nine died of graft rejection or complications after retransplantation.

Other main causes of death included recurrent hepatic malignancy, recurrent hepatitis B, recurrent Budd-Chiari syndrome, and lymphoproliferative disorder.

The complication rate of the UCLA series seems to be higher than ours. Our biliary complication rate after duct-to-duct anastomosis with a "T" tube was 5% and that of duct-to-Roux-en-Y jejunum was 6%.

I realize that it is difficult and sometimes even meaningless to compare the results obtained from different clinical populations and especially during different time periods. Nevertheless, the results achieved by the UCLA group are superb. I would like to ask Dr. Busuttil a couple of questions.

How many patients were not accepted as candidates for liver transplant at UCLA and what were the reasons? In other words, what are the acceptance and nonacceptance criteria during that reported period and currently?

I congratulate again the UCLA liver transplant team on their excellent results and thank the members of the society for this privileged opportunity for discussion.

DR. PAUL S. RUSSELL (Boston, Massachusetts): Dr. Busuttil kindly invited me to discuss his interesting paper that I have read. It is a good paper. It is full of interesting information, and there are many things that one could discuss in connection with it. It bears out his conclusions that with the right people and in the right place, you currently can do very well with liver transplantation. His survival rate is, of course, commendable, as it includes all comers, and there are indications in the paper that it is improving nicely.

I believe his conclusions also bear out the impressions of the NIH Consensus Conference on Liver Transplantation in 1983, which suggested that the time had come for cautious peripheralization of this damanding procedure throughout the United States.

It is interesting to recall that at that time a number of observers told us that we should be randomizing these patients and that was something we did not accept. We did not do so because they are selected for having the best markers we know for impending death.

Now, with the results that Dr. Busuttil and others are achieving, there will be a great tendency to push out the envelope of indications for this operation in all sorts of different directions. Remembering that we are all using the same restricted resource of donors, this is something that we should do with great care. I believe that a place for randomized studies could be found in this difficult area, particularly if we are going to push it back to earlier stages where impending death is not obviously present. Of course, if we take patients earlier, we will get better survival, and we will probably have a less expensive operation.

There is much to be learned about liver transplantation. The question had been raised already in this discussion about how one diagnoses rejection. We do not know exactly how to diagnose rejection yet.

There is an NIH study that has been instituted called the National Liver Transplant Data Base, which is a multiinstitutional effort, and from that perhaps some new information will come in part.

I have a few questions for the UCLA group which has achieved such fine results. It is interesting that they had bile peritonitis as commonly as they did. This is something we did not see. I am curious what their plans are in the future about this. Did the tubes come out too early or was there anything else you can obviously see that might be avoided in the future?

Secondly, the secondary effects of cyclosporine, I believe, are fairly prominent in your patients. The early renal function has been referred to. There were a number of patients who had seizures, and in fact, 22% had neurologic symptoms. In that group the blood levels were 405 ng/mL, which is a bit high.

Your standard maintance dose of cyclosporine seems to be around 17 mg/kg, which I would have said is a bit too high particularly with the triple drug therapy that John Najarian referred to. I am wondering about the cyclosporine dose as well.

The retransplant rate is an interesting question. This is a complicated issue. There are many things involved in the retransplant rate that John referred to as well. A rate of about 20%, which you have had, is fairly common. It is higher than what we have encountered, and I only raise it here for one final question.

With 54% survival, which is very good for retransplant rates, you do have the issue about who gets a liver. In other words, here is a patient who need a transplant and you have got a primary liver transplant success rate that is higher. What is your thinking about this? It depends, of course, entirely on the number of livers available.

Therefore, my question is: how are you doing for donors on the West Coast?

A final comment, if I can make it, is a criticism of transplantation usage, which is widely in vogue. This is the constant referral to "patients transplanted," as in "we transplanted 20 patients." We transplant organs, not patients, of course.

DR. C. BROELSCH (Chicago, Illinois): For everyone who has undertaken the task of establishing a liver transplant program, the work and results of Dr. Busuttil and colleagues seem to be admirable and the authors need to be congratulated.

Their report exemplifies and heralds a new step in the evolution of liver transplantation. That is the development of regional programs, their necessity and their goals. Within a short time the number of patients requiring liver transplants will exceed a few thousand per year in the United States. Careful estimates are between 15 and 20 candidates per one million inhabitants per year.

It is mentioned correctly that 50 centers have been prepared or are being prepared to start a liver transplant program. However, up to now, fewer than five centers have performed around 100 procedures or more than 50 procedures per year within the last 2 years. Certainly others will catch up, but the development of regional centers should not become a race for numbers. Regional responsibility, to cite Dr. Starzl, is meant to serve an area, its patient population, enhance experience with liver transplant, and educate the medical profession by offering this new treatment.

A huge number of patients are now seen by many liver transplant specialists and selections are made on criteria that are not yet defined among the hepatologists and surgeons. Consequently, it is extremely difficult to compare overall survival rates, although this is exactly what is being done currently among the new centers and the "standard center," Pittsburgh.

Regional centers, at least initially, as I believe, have to take patients with extreme high risks who cannot be transferred and should not be transferred to unload a problem on someone else's responsibility, not to mention survival statistics.

Apparently the UCLA group paid the initial tribute when 15 of their first 40 patients died compared with only five of the subsequent 54.

The quality of the program in the long run is what counts and obviously makes up for these losses.

The UCLA group presents excellent results and particularly in the pediatric group, which have been favorable in many centers. From my own previous experience at the University of Hannover, Germany, results have always been above the 70% range.

However, one has to be aware that up to 50% of the children, although accepted for transplantation, die while they are waiting for a transplant. This is particularly true for children younger than 2 years, and in the UCLA experience the average age of pediatric recipients who were accepted and died before transplantation was 9.5 months.

The very small children are the ones with the highest risk for hepatic artery thrombosis or receiving a bad functioning graft, because some potentially damaged donor organs are used to overcome scarcity of small pediatric organs.

In our first year we had rather surprising results, while we have seen 36 children with 65% younger than 2 years. Twenty-seven received a transplant, whereas six were not candidates and could be treated otherwise. Only three died while they were on the waiting list.

(Slide) We paid a price for that because our survival rates in the first year barely hit 55%, and that includes patients with one intraoperative death, early transplant failure, and a small percentage of retransplantation. It includes the attempts of performing reduced-size liver organs that are obtained from adults for those children. However, becoming more selective, although not exclusive, immediately as of May 1986, with the subsequent 17 cases, one can accomplish >80 percent. That includes a couple of segmental grafts from adult donors as well.

The UCLA presentation has strongly emphasized that operative procedures, patient monitoring, including immunosuppression therapy, have become fairly standardized, thus making liver transplantation a safer procedure for the patient.

Since I had the privilege of reviewing the manuscript, I would like to add three questions: would you elaborate more, Dr. Najarian asked this question before, on the high incidence of convulsions. We have seen this only in patients who were fluid overloaded and required dialysis after surgery. I wonder if this is a pure fluid overload effect rather than a pharmacologic effect on cyclosporine A or the chemical carrier substances that are histamine releasers.

The second question is, from what I read in your manuscript, that nine patients had peritonitis after removal of the "T" tube. We have had almost the same experience and since then in the subsequent 27 adults, we abandoned using a "T" tube and had only one patient with mechanical obstruction, although not related to the anastomosis. If you have bleeding cut edges of the duct, one can perform a safe end-to-end anastomosis with PDS or Dexon. I wonder what the logistics or the necessity for the "T" tube are, to really put them into place any longer.

The last question is about the hepatic artery thromboses you observed. Have they always been in association with a rejection? Have they been related to a bad functioning graft, or is this an effect caused by corticosteroid administration during rejection in the patient?

We have only seen thromboses in the pediatric group as you did and only in combination with high corticosteroid treatment.

DR. W. MILLIKAN (Atlanta, Georgia): The Emory group, like the other people who had the opportunity to review this manuscript, congratulate the UCLA group for this fine paper and record. For those of us who have just initiated liver transplantation, it is a standard of excellence that we will try to emulate.

I have specific questions regarding the high incidence of acute tubular necrosis or need for dialysis since this perioperative variable was the only predicter of short-term survival. Much has been said about that already by Dr. Najarian and others.

Ron, do you really believe this was related to cyclosporine or was it a function of pre-existing disease, *i.e.*, functional distribution of volume hepatorenal syndrome?

Secondly, did you use acute dialysis? I cannot tell from the manuscript, or was it ultrafiltration because of the massive overload that frequently accompanies these patients in the immediate postoperative period?

Third, have you ever used peritoneal dialysis in this setting? We recently had a patient in whom 7 days after her transplant, had occlusion of both the hepatic artery and portal vein accompanying acute rejection. We were able to maintain this patient for 36 hours with peritoneal dialysis until we could harvest and retransplant the patient.

DR. RONALD W. BUSUTTIL (Closing discussion): I would like to thank all of the discussants for their comments and questions.

Dr. Najarian, we have been using triple therapy more frequently as I outlined in the slide showing our OKT$_3$ results. Approximately 40% of patients currently receive low-dose cyclosporine, Imuran®, and steroids. All patients who are treated with OKT$_3$ or ATG for rejection are maintained on chronic triple therapy. We have an impression that the use of three drugs has lowered our incidence of rejection, but we have not yet critically analyzed this.

Regarding the incidence of infection after OKT$_3$ we have not found an increase in bacterial or fungal infections in those patients who received the monoclonal antibody *versus* those who did not. However, it is my impression that there is a higher incidence of CMV infection in those patients treated with OKT$_3$.

Renal failure after liver transplantation is indeed a crucial issue since it forbodes so poorly for the patient. There is no question that if dialysis is required in the early postoperative period that mortality will be higher. In our experience 43% of those requiring dialysis died *versus* 10% of those who did not.

Renal failure in these patients is multifactorial. It is difficult, except in the rare patient, to identify one etiologic factor. Cyclosporine clearly plays a part; however, this is only one facet of a scenario that includes multiple blood transfusions, sepsis, nephrotoxic antibiotics, and perhaps most importantly, the presence of preoperative renal failure. In our series over 60% of the patients who required dialysis after operation were in renal failure before operation.

Our view on venous-venous bypass is that it is an important adjunct to the intraoperative management of adult patients. We routinely clamp the suprahepatic vena cava, with volume loading as a trial; however, this maneuver was tolerated in only 44 of the 100 transplants. By tolerated, I mean maintaining a blood pressure within 15 mmHg of preclamp levels. Venous-venous bypass decreases blood loss by decompressing the portal and caval systems. It only takes us about 30 minutes more to place the patient on bypass, and we are comfortable with this technique.

Like renal failure, the cause of postoperative seizures is multifactorial. An analysis for risk factors for the development of postoperative seizures revealed that two variables were apparent in most patients: one, low magnesium levels, and two, high cyclosporine levels. This has been reported by other groups, particularly with heart transplants. Patients in our series who had seizures had a mean cyclosporine level of 400 and a magnesium level less than 1.6. We routinely maintain cyclosporine levels at the 200–250 range and magnesium levels around 2.

We have not used Decadron since all patients are receiving steroids. Only a few of the seizure patients were fluid overloaded and I doubt that volume status contributed to their seizure disorder. None of the patients in whom grand mal seizures developed had long-term neurologic sequelae, and we only had one death of that group, which was not a neurologic death.

Dr. Klintmalm, we have had no venous thrombosis, either portal or vena caval. We are now in the early phases of using duplex scanning to determine arterial patency, and we believe that this will be a very useful modality. Currently, any patient with suspected arterial thrombosis undergoes angiography. We have not had arterial thrombosis in adults; all have occurred in children. In two patients we attempted thrombectomy of the hepatic artery and neither of these were successful. Both patients required retransplantation.

The diagnosis of rejection after liver transplantation is not easy. Generally speaking it is a diagnosis of exclusion. We must first rule out a technical problem such as thrombosis or bile duct obstruction, then rule out infection and drug toxicity. Exclusive of these, biopsy confirmation is essential but not totally diagnostic. We have some ongoing studies with monoclonal identification of T-cell subsets, but the results of these are too preliminary to discuss.

Dr. Iwatsuki, clearly we are indebted to Dr. Starzl and yourself for your counsel and guidance. How well I remember the multiple phone conversations on our first few transplants in which I sought your advice and encouragement and I am very grateful for that.

In regard to the numbers of patients who are transplanted *vis a vis,* those who are evaluated I can give you some rough figures. About one of three children will die before we transplant them and one of every five adults will also die before a donor is found. Roughly 15% of the patients who are evaluated are rejected for transplantation. The reasons for this are multifactorial. In many patients, we considered the stage of their disease too early. In some, we did not consider it an appropriate indication.

I believe it is important to point out that in our early experience we thought it best to avoid the excessively difficult patient until our track record could be established, and I know of four patients who we referred to Pittsburgh in our first year of operation.

Dr. Russell, regarding the bile peritonitis, it is a problem, and we have since changed our technique. Rather than performing the choledochocholedochostomy with an absorbable suture, we are now using monofilament 6-0 prolene. It is our impression that by using a nonabsorble material that the incidence of bile peritonitis is less. Again we have not critically analyzed this data. We tend to leave our T tubes in place for a minimum of 2 months.

Regarding our retransplantation rate, our overall experience was 20%. In our last 50 cases, the incidence was closer to 10%, and I believe it may be because of the multimodality immunosuppression that we are using. The more aggressive use of OKT_3, I believe, has definitely decreased our incidence of rejection.

Dr. Broelsch, I certainly agree with your concept of regionalization. Your question about convulsions, I believe I have already answered, and your question about bile peritonitis we have already discussed.

Dr. Millikan, again regarding dialysis, I believe that if we look at our series, the majority of our patients had renal failure before transplantation, and I believe that this is probably the primary cause of postoperative renal failure. We have not used peritoneal dialysis, and in only about one third of our patients who have required dialysis have we used ultrafiltration. This was used in those patients who did not have metabolic indications for dialysis but only fluid overload.

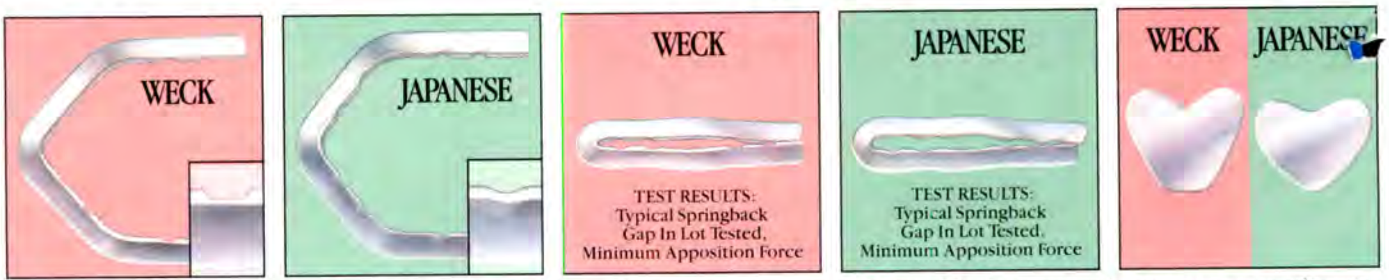
We make the
Hemoclip® clip like it
is because of the
way nature made
blood vessels.

Hemoclip® ligating clips are made for blood vessels.

That sounds obvious, but it's not to everyone.

It's not easy to make ligating clips that are finely balanced between strength and malleability–two desirable ligating clip properties.

But in a quarter-century of manufacture, Weck has learned to do the job on this key implant device as no one else has.



The Hemoclip® ligating clip is coined with distinct rectangular transverse grooves, designed for longitudinal gripping power. Clip wire is processed metallurgially for malleability in closure. The Japanese imitation clips have shallow-drawn wire, and smaller, rounded transverse grooves. Deeper Hemoclip® wire shape aids retention in Weck appliers. (Typical closure illustrated from independent study.)

But now there's a problem you should be aware of. Some U.S.-based companies have begun distributing–not manufacturing–Japanese imitations of the Hemoclip® ligating clip. These clips are not the product of Weck manufacturing expertise and the technical performance of these clips is simply not the same as that of Hemoclip® ligating clips, an exclusive Weck product.

They may look the same, but they're not.

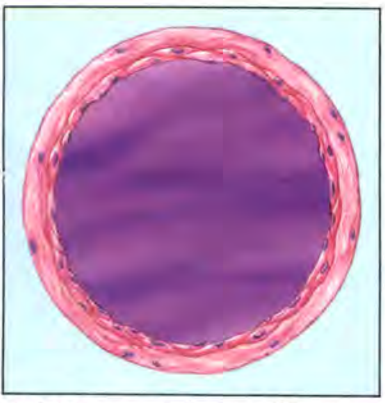
The recently-introduced Japanese clips look the same as Hemoclip® ligating clips to the naked eye. But a recently completed independent lab study of sample quantities of clips confirms Weck's own observation of substantial differences in closure properties between the Japanese clips and Weck clips.

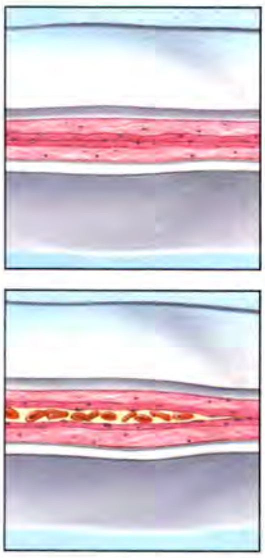
Vessel walls may be as thin as one-twelfth of vessel diameter.

Veins, in contrast to arteries, have very thin walls. When you consider that the vein tributaries ligated in surgery are sometimes one millimeter in diameter or smaller, with combined vessel walls as small as seven-thousandths of an inch (178 microns), according to animal studies on comparable vessels, you can appreciate the functional importance of differences in closure gap.

Arterial tributaries can be tiny, too, and although their walls are generally thicker than vein walls, arterial pressure is higher than venous pressure.

It seems prudent to employ ligating clips which offer the response and clip-closure performance Weck usage has established in your surgery.





ABOVE. A vein tributary of 1mm can have a combined wall thickness of just seven-thousandths of an inch (178 microns), according to animal studies. RIGHT. A ligating clip that demonstrates greater springback than the clip you have regularly used for such vessels may be more likely to leave a closure gap larger than the vessel-wall thickness of a tiny vessel.

Weck's titanium clip vs. their titanium clip. A 23-27% difference.

Examine the chart for a visual representation of the difference in closure springback an independent research firm discovered between a set of Weck titanium medium-size clips and a set of Japanese titanium medium-size clips obtained directly from U.S. distributors of those clips. Both sets of clips were closed in Weck appliers through use of force-control devices.

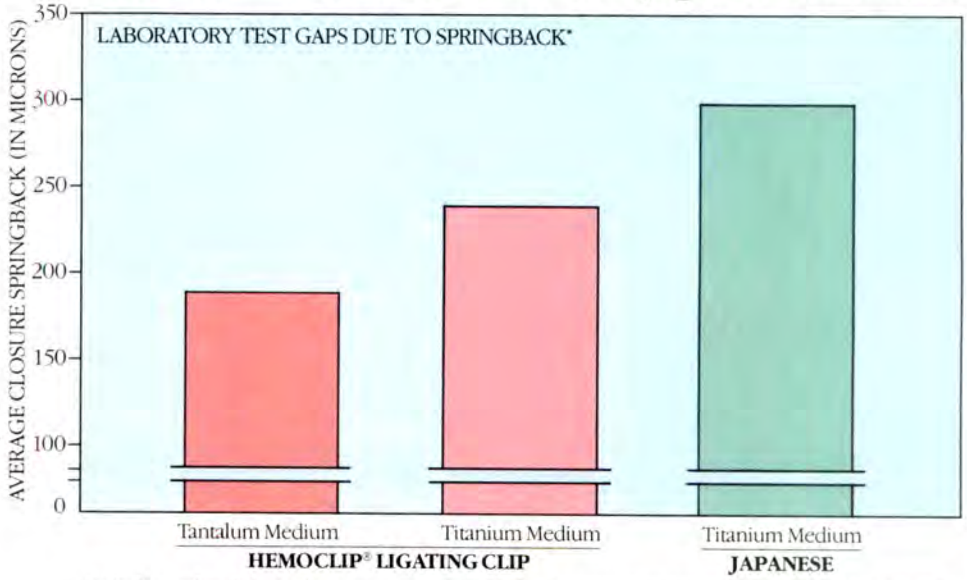
Closure of two sample sets of 25 Japanese titanium medium clips at forces adequate to achieve initial complete touching along clip legs resulted in closures of about 12 thousandths of an inch (305 microns) for the Japanese clips, 23-27% larger than the Weck titanium clip closure gap.

Weck's tantalum clips vs. their titanium clips. A 56% springback difference.

The comparison of Japanese titanium with Weck tantalum clips is even more important.

The Japanese companies make only titanium clips, and so they have sold hard on the benefits of titanium.

Tantalum is a softer material known for excellent clip closure. And the study revealed 56% and 61% larger mean closure gaps after springback for two sets of Japanese titanium clips, a ringing endorsement of the closure advantages of the Weck tantalum clips tested.



An independent lab study on two sample sets of 25 Japanese imitation clips vs. Weck clips found that the Japanese medium-size clips, closed to initial complete touching of clip legs, evidenced mean closure gaps, due to springback, 23-27% larger than Weck medium-size titanium clips, and 56-61% larger than Hemoclip® tantalum clips from Weck. Other sizes produced similar results. (Closure gap in microns-one micron = one thousandth of one millimeter).

Stronger closure forces would likely be employed during actual surgery cases.

The comparison was similar for Weck stainless vs. Japanese titanium, with the stainless scoring substantially smaller gaps after springback.

Odds are, if you are using Weck clips you are accustomed to tantalum or stainless steel clip closure, because the vast majority of Weck accounts use these two metals.

And a new Weck-funded NMR major-university study indicates that magnetic deflection of tantalum clips is negligible, just as it is for titanium clips. So if your local competitive salesman distributing Japanese clips tries to convince you that titanium clips are exclusively acceptable for NMR magnetic deflection in preference to tantalum, we suggest you cite the new Weck-sponsored university study.

Look for the Weck name on the cartridge.

To visually and quickly confirm that you really are using Weck clips, look at the end of the clip cartridge. If you are using Weck clips, you should see there the Weck name molded into the plastic. The Weck name is your assurance of genuine Hemoclip® clip processing experience and knowledge.

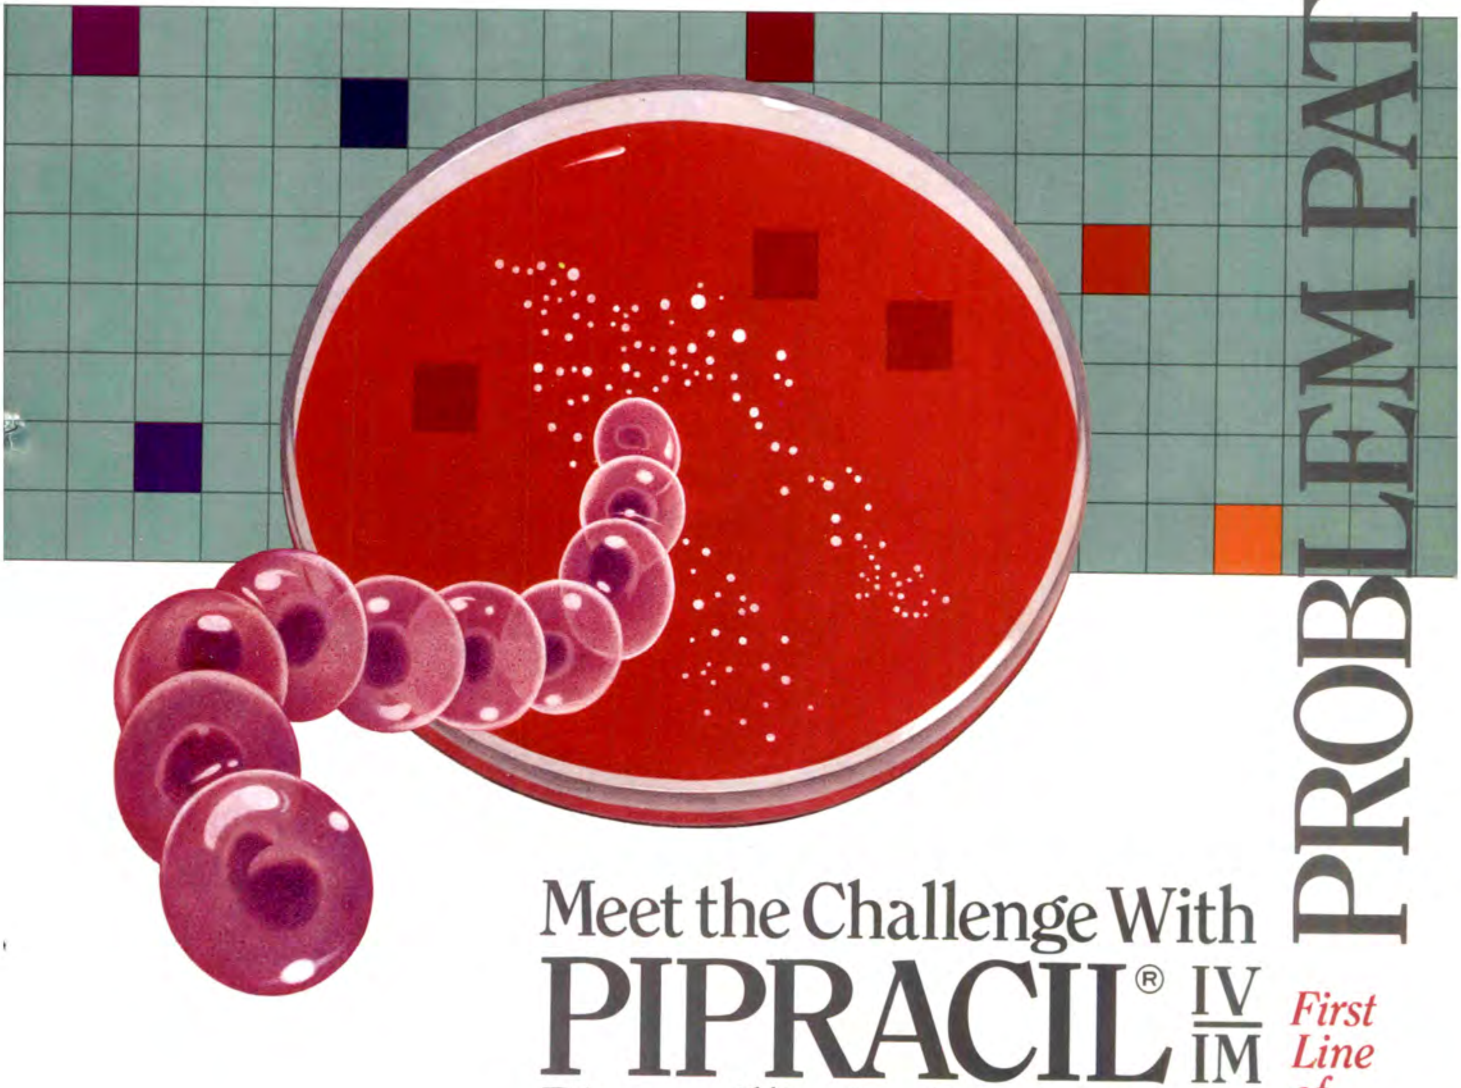
When Enterococcus is the Threatening Organism

PROBLEM PATHOGENS



Meet the Challenge With

PIPRACIL® $\frac{\text{IV}}{\text{IM}}$

Piperacillin Sodium/Lederle

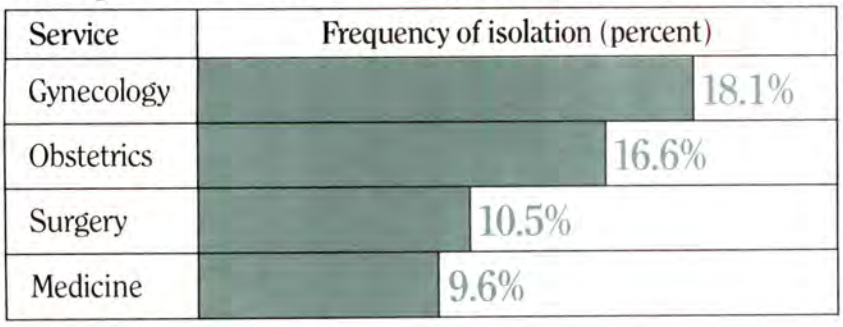
First Line of Defense

Please see brief summary of prescribing information on next page.

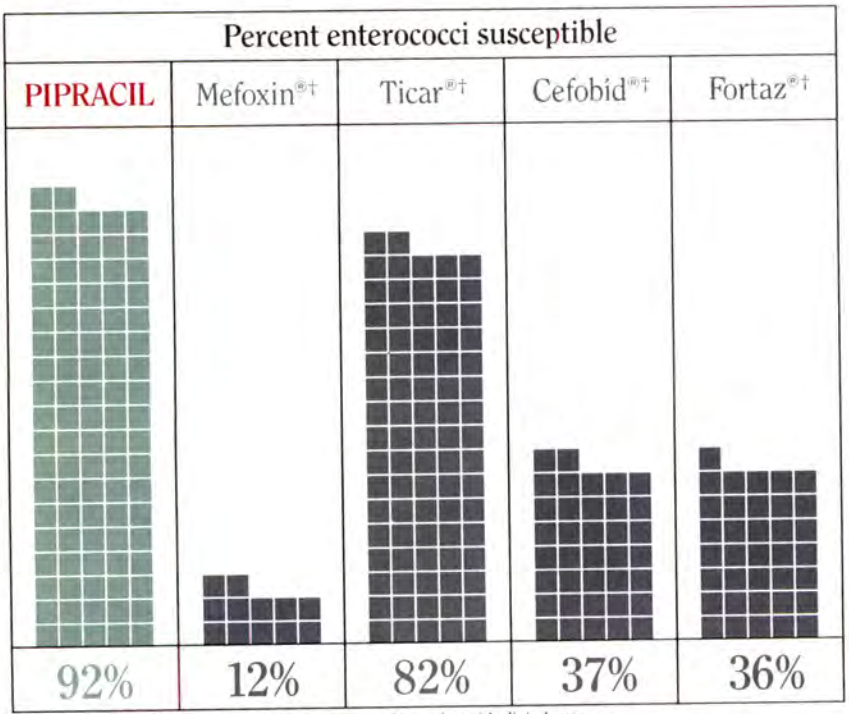
PIPRACIL: Excellent Activity* *v* Enterococcus

Enterococcus: "...as difficult to treat as *Pseudomonas aeruginosa*..."[1]

Among the three most common nosocomial pathogens[2]



PIPRACIL: More Active Than Other Beta-lactam Antibiotics[3]



*Although a useful guide, *in vitro* activity does not necessarily correlate with clinical response.

PIPRACIL®
STERILE PIPERACILLIN SODIUM FOR
INTRAVENOUS AND INTRAMUSCULAR USE

A Brief Summary
Consult package insert for full prescribing information.

INDICATIONS AND USAGE: Therapeutic. PIPRACIL is indicated for the treatment of the following serious infections caused by susceptible strains of the designated organisms: Intra-abdominal, urinary tract, gynecologic, lower respiratory tract, skin and skin structure, bone and joint, gonococcal infections, and septicemia.

Prophylaxis. PIPRACIL is also indicated for prophylactic use in surgery including intra-abdominal (gastrointestinal and biliary) procedures, vaginal hysterectomy, and cesarean section.

CONTRAINDICATIONS: A history of allergic reactions to any of the penicillins and/or cephalosporins.

WARNINGS: Serious and occasionally fatal hypersensitivity (anaphylactic) reactions have been reported in patients receiving therapy with penicillins. These reactions are more apt to occur in persons with a history of sensitivity to multiple allergens.

There have been reports of patients with a history of penicillin hypersensitivity who have experienced severe hypersensitivity reactions when treated with a cephalosporin. Before initiating therapy with PIPRACIL® sterile piperacillin sodium, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, and other allergens. If an allergic reaction occurs during therapy with PIPRACIL, the antibiotic should be discontinued. The usual agents (antihistamines, pressor amines, and corticosteroids) should be readily available. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS AND AIRWAY MANAGEMENT INCLUDING INTUBATION SHOULD ALSO BE ADMINISTERED AS NECESSARY.

PRECAUTIONS: General. While PIPRACIL possesses the characteristic low toxicity of the penicillin group of antibiotics, periodic assessment of organ system functions including renal, hepatic, and hematopoietic during prolonged therapy is advisable. Bleeding manifestations have occurred in some patients receiving β-lactam antibiotics including piperacillin. These reactions have sometimes been associated with abnormalities of coagulation tests such as clotting time, platelet aggregation, and prothrombin time and are more likely to occur in patients with renal failure. If bleeding manifestations occur, the antibiotic should be discontinued and appropriate therapy instituted.

The possibility of the emergence of resistant organisms which might cause superinfections should be kept in mind, particularly during prolonged treatment. If this occurs, appropriate measures should be taken.

As with other penicillins, patients may experience neuromuscular excitability or convulsions if higher than recommended doses are given intravenously.

PIPRACIL is a monosodium compound containing 1.85 milliequivalents of Na^+ per gram. This should be considered when treating patients requiring restricted salt intake. Periodic electrolyte determinations should be made in patients with low potassium reserves, and the possibility of hypokalemia should be kept in mind with patients who have potentially low potassium reserves and who are receiving cytotoxic therapy or diuretics.

Antimicrobials used in high doses for short periods to treat gonorrhea may mask or delay the symptoms of incubating syphilis. Therefore, prior to treatment, patients with gonorrhea should also be evaluated for syphilis. Specimens for darkfield examination should be obtained from patients with any suspected primary lesion and serologic tests should be performed. In all cases where concomitant syphilis is suspected, monthly serological tests should be made for a minimum of four months.

As with other semisynthetic penicillins, PIPRACIL therapy has been associated with an increased incidence of fever and rash in cystic fibrosis patients.

Drug Interactions. The mixing of PIPRACIL with an aminoglycoside *in vitro* can result in substantial inactivation of the aminoglycosides.

Pregnancy—Pregnancy Category B. Although reproduction studies in mice and rats performed at doses up to four times the human dose have shown no evidence of impaired fertility or harm to the fetus, safety of PIPRACIL use in pregnant women has not been determined by adequate and well-controlled studies. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. It has been found to cross the placenta in rats.

Nursing Mothers. Caution should be exercised when PIPRACIL is administered to nursing mothers. It is excreted in low concentrations in milk.

Pediatric Use. Dosages for children under the age of 12 have not been established. The safety of PIPRACIL in neonates is not known. In dog neonates dilated renal tubules and peritubular hyalinization occurred following administration of PIPRACIL.

ADVERSE EFFECTS: PIPRACIL is generally well tolerated. The most common adverse reactions have been local in nature, following intravenous or intramuscular injection. The following adverse reactions may occur:

Local Reactions. Thrombophlebitis (4%), pain, erythema, and/or induration at the injection site (2%) and, less frequently, ecchymosis, deep vein thrombosis, hematomas.

Gastrointestinal. Diarrhea and loose stools (2%); less frequently, vomiting, nausea, increases in liver enzymes (LDH, SGOT, SGPT), hyperbilirubinemia, cholestatic hepatitis, bloody diarrhea, and, rarely, pseudomembranous colitis.

Hypersensitivity Reactions. Anaphylactoid Reactions (see WARNINGS). Rash (1%); less frequently, pruritus, vesicular eruptions, positive Coombs tests.

Renal. Elevations of creatinine or BUN and, rarely, interstitial nephritis.

Central Nervous System. Headache, dizziness, fatigue.

Hemic and Lymphatic. Reversible leukopenia, neutropenia, thrombocytopenia, and/or eosinophilia have been reported. As with other β-lactam antibiotics, reversible leukopenia (neutropenia) is more apt to occur in patients receiving prolonged therapy at high dosages or in association with drugs known to cause this reaction.

Serum Electrolytes. Individuals with liver disease, or individuals receiving cytotoxic therapy or diuretics, were reported rarely to demonstrate a decrease in serum potassium concentrations with high doses of piperacillin.

Skeletal. Rarely, prolonged muscle relaxation.

Other. Superinfection, including candidiasis.
Hemorrhagic manifestations.

and PETER KALMAN, M.D., F.R.C.S.(C.)*

This paper presents the results of a prospective study of percutaneous transluminal angioplasty (PTA) for the treatment of patients with peripheral arterial occlusive disease and identifies the variables that are predictive of long-term success. The variables believed to be important prognostically were recorded for 984 consecutive PTAs performed between July 1978 and July 1986. Success or failure was defined using a combination of clinical and objective vascular laboratory criteria. The overall long-term success was estimated by the Kaplan-Meier method and differences between curves of success rate *versus* time for each variable were determined by the Wilcoxon and log-rank statistics. The combination of variables associated with success were determined by the Cox proportional hazards regression model. For all cases, the initial success rate was 88.6 ± 1.0% and at 5 years was 48.2 ± 2.3%. The following variables, when considered individually, were associated with success ($p < 0.05$): indication for PTA, site of PTA, severity of lesion, runoff, number of sites dilated, diabetes, and the occurrence of a complication. From the Cox model, by using a stepwise multiple regression procedure, the following combination of variables were found to be predictive of success ($p < 0.05$): (1) indication (claudication *vs.* salvage), (2) site (common iliac *vs.* other), (3) severity of lesion (stenosis *vs.* occlusion), and (4) runoff (good *vs.* poor). For all combinations of these four significant variables, curves of the success rate *versus* time were calculated. In conclusion, this study has identified the combination of four variables that together predict if PTA is likely to be successful in the management of a patient with peripheral arterial occlusive disease.

PERCUTANEOUS TRANSLUMINAL DILATATION (PTA) is now accepted as an important technique in the management of patients with peripheral arterial occlusive disease. For example, during a 6-month period in 1985, in the Province of Ontario, 2257 procedures were performed for the treatment of peripheral arterial occlusive disease. PTA was carried out in 28% and surgery in 72% (Scobie TK, personal communication, 1986).

From the Departments of Surgery, Preventive Medicine and Biostatistics,† and Radiology,‡ University of Toronto, Toronto, Ontario, Canada*

This paper presents the 5-year results of a prospective study of PTA and identifies the variables that predict the long-term success of the procedure.

Methods

During the 8 years between July 1978 and July 1986, 984 PTAs performed at the Toronto General Hospital for the management of peripheral arterial occlusive disease were studied prospectively. The variables believed to be important prognostically were recorded and the results determined by using a combination of clinical and vascular laboratory criteria.

Patients

Patients were included in the study if they were able to return for follow-up every 6 months. The decision to perform a PTA was made in consultation between the referring physician and the vascular radiologist. The variables analyzed in this report are listed in Table 1. Details of the subcategories of the variables are listed in Table 1 or described below. If the PTA failed, the clinical grade and subsequent treatment were documented.

Radiologic Technique

Experienced vascular radiologists performed or directly supervised all procedures. The details of our tech-

TABLE 1. *Variables and Subcategories*

1. Indication for the PTA (*i.e.*, the clinical grade)
   - Asymptomatic
   - Mild claudication (greater than 2 blocks)
   - Disabling claudication (less than 2 blocks)
   - Ischemic night pain or rest pain
   - Ulceration or gangrene
2. Site of PTA (see Table 2)
3. Severity of lesion
   - Stenosis
   - Occlusion
4. Runoff as determined from the angiogram
   - Good (for iliac PTA <50% femoral/popliteal stenosis and for femoral or popliteal PTA 2 or 3 tibial artery outflow)
   - Poor (for iliac PTA >50% femoral/popliteal stenosis and for femoral or popliteal PTA 0 or 1 tibial artery outflow)
5. Occurrence of a complication
6. Presence and severity of diabetes
7. History of previous PTA at the same site
8. Number of sites dilated
9. Specialty of the referring doctor
10. Age
11. Sex
12. Year PTA performed
13. Limb
14. Ankle/brachial systolic blood pressure ratio before PTA
15. Ankle/brachial systolic blood pressure ratio after PTA
16. Pressure gradient measured across the lesion before PTA
17. The Post-PTA pressure gradient

nique have been described previously[1] and are similar to Gruntzig's original description.[2] Aspirin, 325 mg b.i.d., and dipyridamole, 50 mg t.i.d., were administered for 1 month starting 3 days before the procedure. Heparin, 5000 units, was given at the time of the PTA.

Criteria for Success of PTA

The criteria for evaluating the outcome of a PTA have been described previously.[3] Specifically, the PTA was considered a success if the clinical grade improved by at least one level (*i.e.*, asymptomatic, mild claudication, disabling claudication, ischemic night pain or rest pain, or ulceration or gangrene) and one or more of the following vascular laboratory measurements improved: ankle/brachial systolic pressure ratio increased by at least 0.10, monophasic Doppler frequency analysis recordings became biphasic or triphasic, the Doppler pulsatility index increased by more than 20%, and/or the treadmill exercise distance at least doubled.

Data Analysis

The data were stored on a microcomputer (Hewlett Packard 9816, Hewlett Packard, Fort Collins, CO) using a database program written specifically for this study. In the following discussion, the statistical difference between groups was determined by a two tailed t-test for the continuous variables and Pearson chi square test for the discrete variables. The statistical methods for determining the long-term results are discussed in the following sections: the Kaplan-Meier method was used for univariate analysis and the Cox model was used for multivariate analysis.

Kaplan-Meier Method (product-limit method). For evaluating individual variables (univariate analysis), the Kaplan-Meier method was used to estimate the survival function, *i.e.*, the curve of the cumulative percentage success rate *versus* time of follow-up.[4] It was selected over the actuarial life table method since it gives results that are independent of the choice of the time intervals.[5] To test if there was a statistically significant difference between survival curves ($p < 0.05$), the generalized Wilcoxon (Breslow) test and the log-rank (Mantel-Cox) test were used.

Cox proportional hazards model.[6] The Cox regression model was used to: (1) determine which combination of the multiple variables are associated with success of the PTA and (2) estimate the chance of success for all combinations of the significant variables. A backward stepwise regression analysis procedure determined the significant variables ($p < 0.05$), their regression coefficients and estimated standard errors, and the likelihood ratio statistic that was used to assess the statistical significance of the variables (BMDP Statistical Package, Biomedical Computer Programs, P Series) (Statistical Software, Department of Biomathematics, UCLA, Los Angeles, CA). A microcomputer program was written to plot graphs of percentage successful *versus* time for each combination of the significant variables from the estimated regression coefficients and the estimated baseline survival function.

Results

The results will be presented in three sections: (1) description of the study population, (2) univariate analysis of the variables associated with success, and (3) multivariate analysis of the variables associated with success.

Description of Study Population

Over the 8 years between July 1978 and 1986, 984 PTAs in 902 patients were included in this study. The average age of the patients was 60.4 ± 10.2 years (mean ± 1 SD) but the patients having a femoral/popliteal PTA were an average of 4.3 years older than the aorto/iliac group ($p < 0.001$). The percentage of patients with diabetes was 19.7%, 5.1% had an abnormal blood sugar and were being treated by diet alone, 6.1% were receiving oral hypoglycemics, and 8.5% were receiving insulin. Diabetes was more frequent in the femoral/popliteal group ($p < 0.001$).

The percentage of cases referred by the vascular surgeons at our institution was 89.6%, 7.0% by cardiologists and 3.4% by general surgeons, general internists, family doctors, or others.

The indications for the procedure were mild claudication *i.e.*, more than 2-block walking distance) 5.0%, disabling claudication 79.4%, ischemic night pain or rest pain 5.1%, and ulceration or gangrene 8.0%. PTA was performed as an adjunct to a distal arterial reconstructive procedure to correct focal graft stenosis or for other indications in 2.5%. Claudication was a more common indication in the aorto/iliac group (88.4%) than in the femoral/popliteal group (79.0%) ($p < 0.001$).

The sites of PTA are detailed in Table 2. Note that 69.5% were aorto/iliac and 25.7% were femoral/popliteal. Overall, the severity of the arterial lesion was a stenosis in 80.9% and an occlusion in 19.1%; however, in the aorto/iliac segment, a stenosis was more common than in the femoral/popliteal area (87.9% *vs.* 62%, respectively, $p < 0.001$). The number of sites dilated were one in 82.8% and two or more in 17.2%. Dilatation of more than one lesion was more frequent in the aorta/iliac segment than in the femoral/popliteal segment ($p = 0.003$). The right limb was dilated in 51.5% and the left side in 48.5%. In 8.3% the PTA was repeated at the same site.

The runoff of the arterial segment just distal to the site of the PTA was normal in 50%, had less than a 50% arterial stenosis or one tibial artery occluded in 10.7%, had greater than 50% arterial stenosis or two tibial arteries occluded in 17.5%, and had a complete arterial occlusion or three tibial arteries occluded in 21.8%.

In the aorto/iliac region, the average pre-PTA pressure gradient fell from 41.8 ± 27.3 to 7.0 ± 10.9 mmHg after the PTA. In the femoral/popliteal segment, the change was from 78.1 ± 45.3 to 16.6 ± 22.4 mmHg ($p < 0.001$) but was exaggerated by catheter through the lesion.

The average pre-PTA ankle/brachial systolic blood pressure ratio was 0.58 ± 0.19 and increased to an average 0.71 ± 0.23 ($p = 0.001$).

The percentage of procedures considered technical failures because the catheter could not be passed through the stenosis was 3.8%.

Complications occurred in 9.5% of the patients as follows. Four patients (0.4%) died during their hospital stay, three died of myocardial infarction and one died of bleeding after rupture of the artery. Emergency surgery was necessary in 1.1% because of bleeding at the puncture site (1 case), severe extremity ischemia (8 cases), false aneurysm (1 case), or an arteriovenous fistula (1 case). Major complications occurred in an additional 3.4% and included shock from bleeding from the puncture site (4 cases), large hematomas delaying hospital discharge (22 cases), and ischemia not requiring emergency surgery (7 cases). Minor complications occurred in 4.6% and included small hematomas (29 cases), distal emboli without tissue damage (6 cases), arterial dissection or intimal tear that had no local consequences (3 cases), dye extravasation or intramural injection (3 cases), and other (5 cases). Complications were more common after femoral/popliteal than aorto/iliac PTA ($p = 0.02$), mainly due to the higher incidence of large hamatomas (5.1% *vs.* 2.6%, respectively).

TABLE 2. *Sites of PTA*

	N	Percent
Aortic stenosis	17	1.7
Common iliac stenosis	318	32.4
Common iliac occlusion	58	5.9
External iliac stenosis	210	21.4
External iliac occlusion	12	1.2
Common iliac stenosis and external iliac stenosis	57	5.9
Common iliac occlusion and external iliac stenosis	2	0.2
Common iliac stenosis and external iliac occlusion	3	0.3
Common iliac occlusion and external iliac occlusion	7	0.7
Common femoral stenosis	17	1.8
Common femoral occlusion	1	0.1

Profunda femoris occlusion	1	0.1
Femoral/popliteal stenosis above knee	131	13.4
Femoral/popliteal occlusion above knee	79	8.0
Popliteal stenosis below knee	25	2.6
Popliteal occlusion below knee	18	1.8
Tibial stenosis	1	0.1
Tibial occlusion	5	0.5
Bypass graft	9	0.9
Other	1	0.1
Total	984	100.0

After failure of PTA, 46.5% had no further treatment within 6 months, 19.8% had repeat dilatation, 25% had vascular surgery, 7.8% had amputation, and 0.9% had other treatment.

Univariate Analysis of Results

Overall results. The overall results are illustrated in Figure 1. At the time of analysis, 64.9% of the observations were censored: in 47.8% of the patients the PTA had not yet failed, 10.6% died of unrelated causes, 1% were lost to follow-up, and in 5.5% the success or failure could not be assessed because the contralateral limb was more symptomatic, another concurrent disease involved the limb, or there was development of a disease that prevented walking.

Significant variables. The Kaplan-Meier method was used to estimate the survivor function (*i.e.*, the cumulative percentage success *versus* time of follow-up) for each variable. The generalized Wilcoxon (Breslow) and the log-rank (Mantel-Cox) tests were used to determine if there was a statistically significant difference between

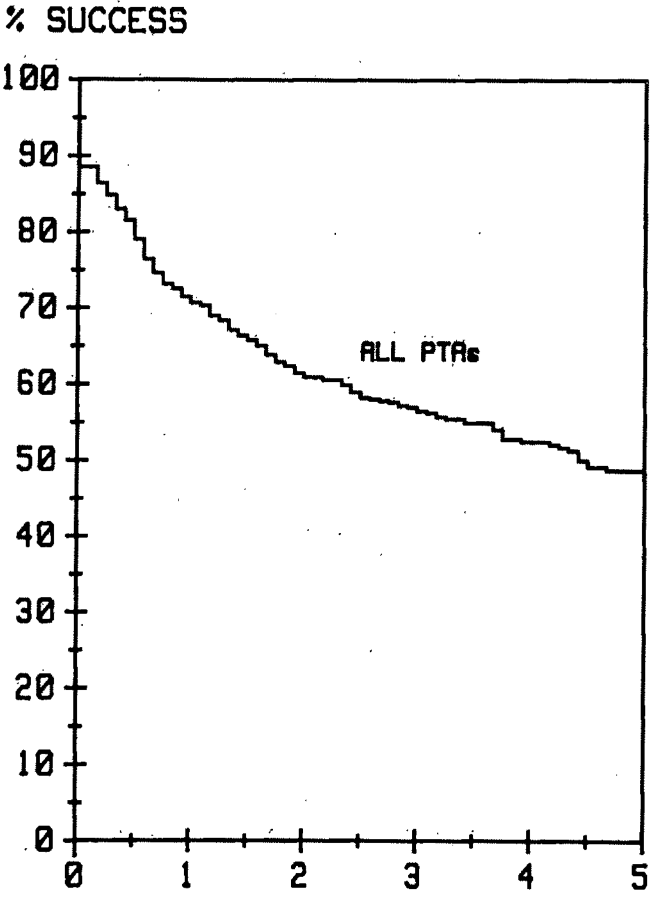

FIG. 1. Overall results for 984 PTAs.

survivor curves. The following sections describe the variables that were found to be significant by univariate analysis.

1. *Indication for PTA.* Patients having PTA because of mild or disabling intermittent claudication had a better success rate than those with limb salvage (*i.e.,* ischemic night pain, rest pain, ulceration or gangrene) as illustrated in Figure 2.

2. *Site of PTA.* As illustrated in Figure 3, the success rate of PTA of the common iliac artery was higher than other sites. Specifically, the common iliac results were superior to the external iliac (Wilcoxon = 4.1248, $p = 0.042$; log-rank = 4.682, $p = 0.030$) and to the femoral/popliteal (Wilcoxon = 14.146, $p < 0.001$; log-rank = 17.745, $p < 0.001$). Since there was no difference between the external iliac and femoral/popliteal sites (Wilcoxon = 2.940, $p = 0.09$; log-rank = 3.265, $p = 0.07$), for purposes of subsequent analyses, these sites were grouped together. By comparison to common iliac PTA, the results for this combined group of other sites were lower (Wilcoxon = 11.856, $p < 0.001$; log-rank = 14.482, $p < 0.001$).

The results of PTA of uncommon sites such as aorta, common femoral, profunda femoris, tibial, and bypass graft were not included in the overall analysis but are tabulated in Table 3.

3. *Severity of lesion.* Arterial stenoses were dilated more successfully than occlusions (Fig. 4).

4. *Runoff.* Patients with good runoff had a higher success rate than those with poor runoff (Fig. 5).

5. *Number of sites dilated.* The results were better when only one site was dilated compared with multilevel dilatations (Fig. 6).

6. *Diabetes.* Nondiabetics (defined as no diabetes or diet-controlled) had better results than diabetics controlled by oral hypoglycemics or insulin (Fig. 7).

7. *Occurrence of a complication.* If the patient did not have a complication at the time of the PTA, the long-term success rate was higher (Fig. 8).

Insignificant variables. The following section describes the variables that were not related to long-term success of PTA. The age and sex of the patient and the limb (right or left) were not significant. The results of the

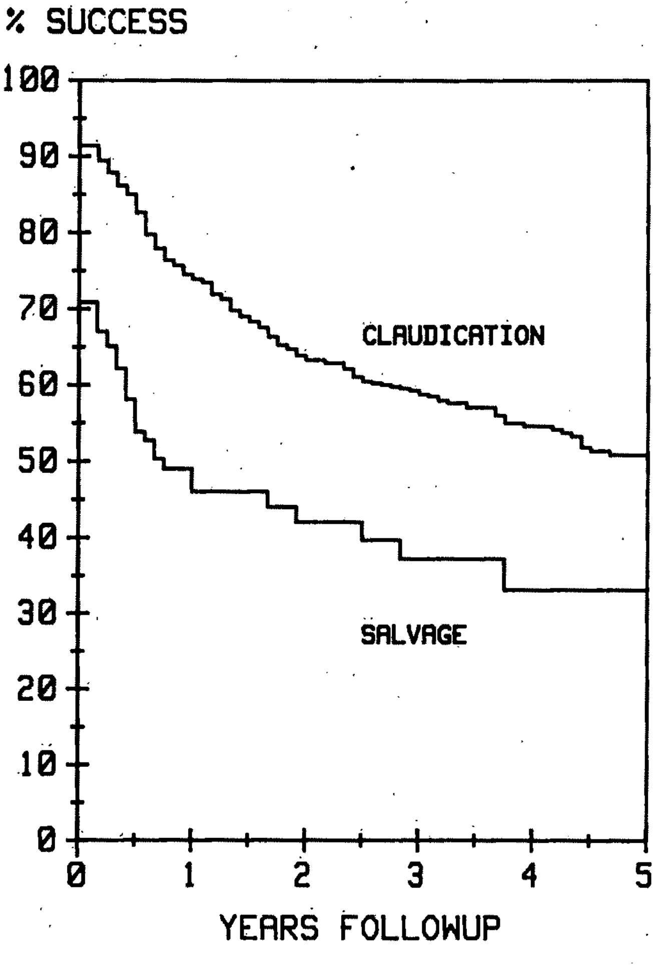

FIG. 2. Indication for PTA: claudication *versus* limb salvage. (Wilcoxon = 9.218, $p < 0.001$; log-rank = 9.590, $p < 0.001$).

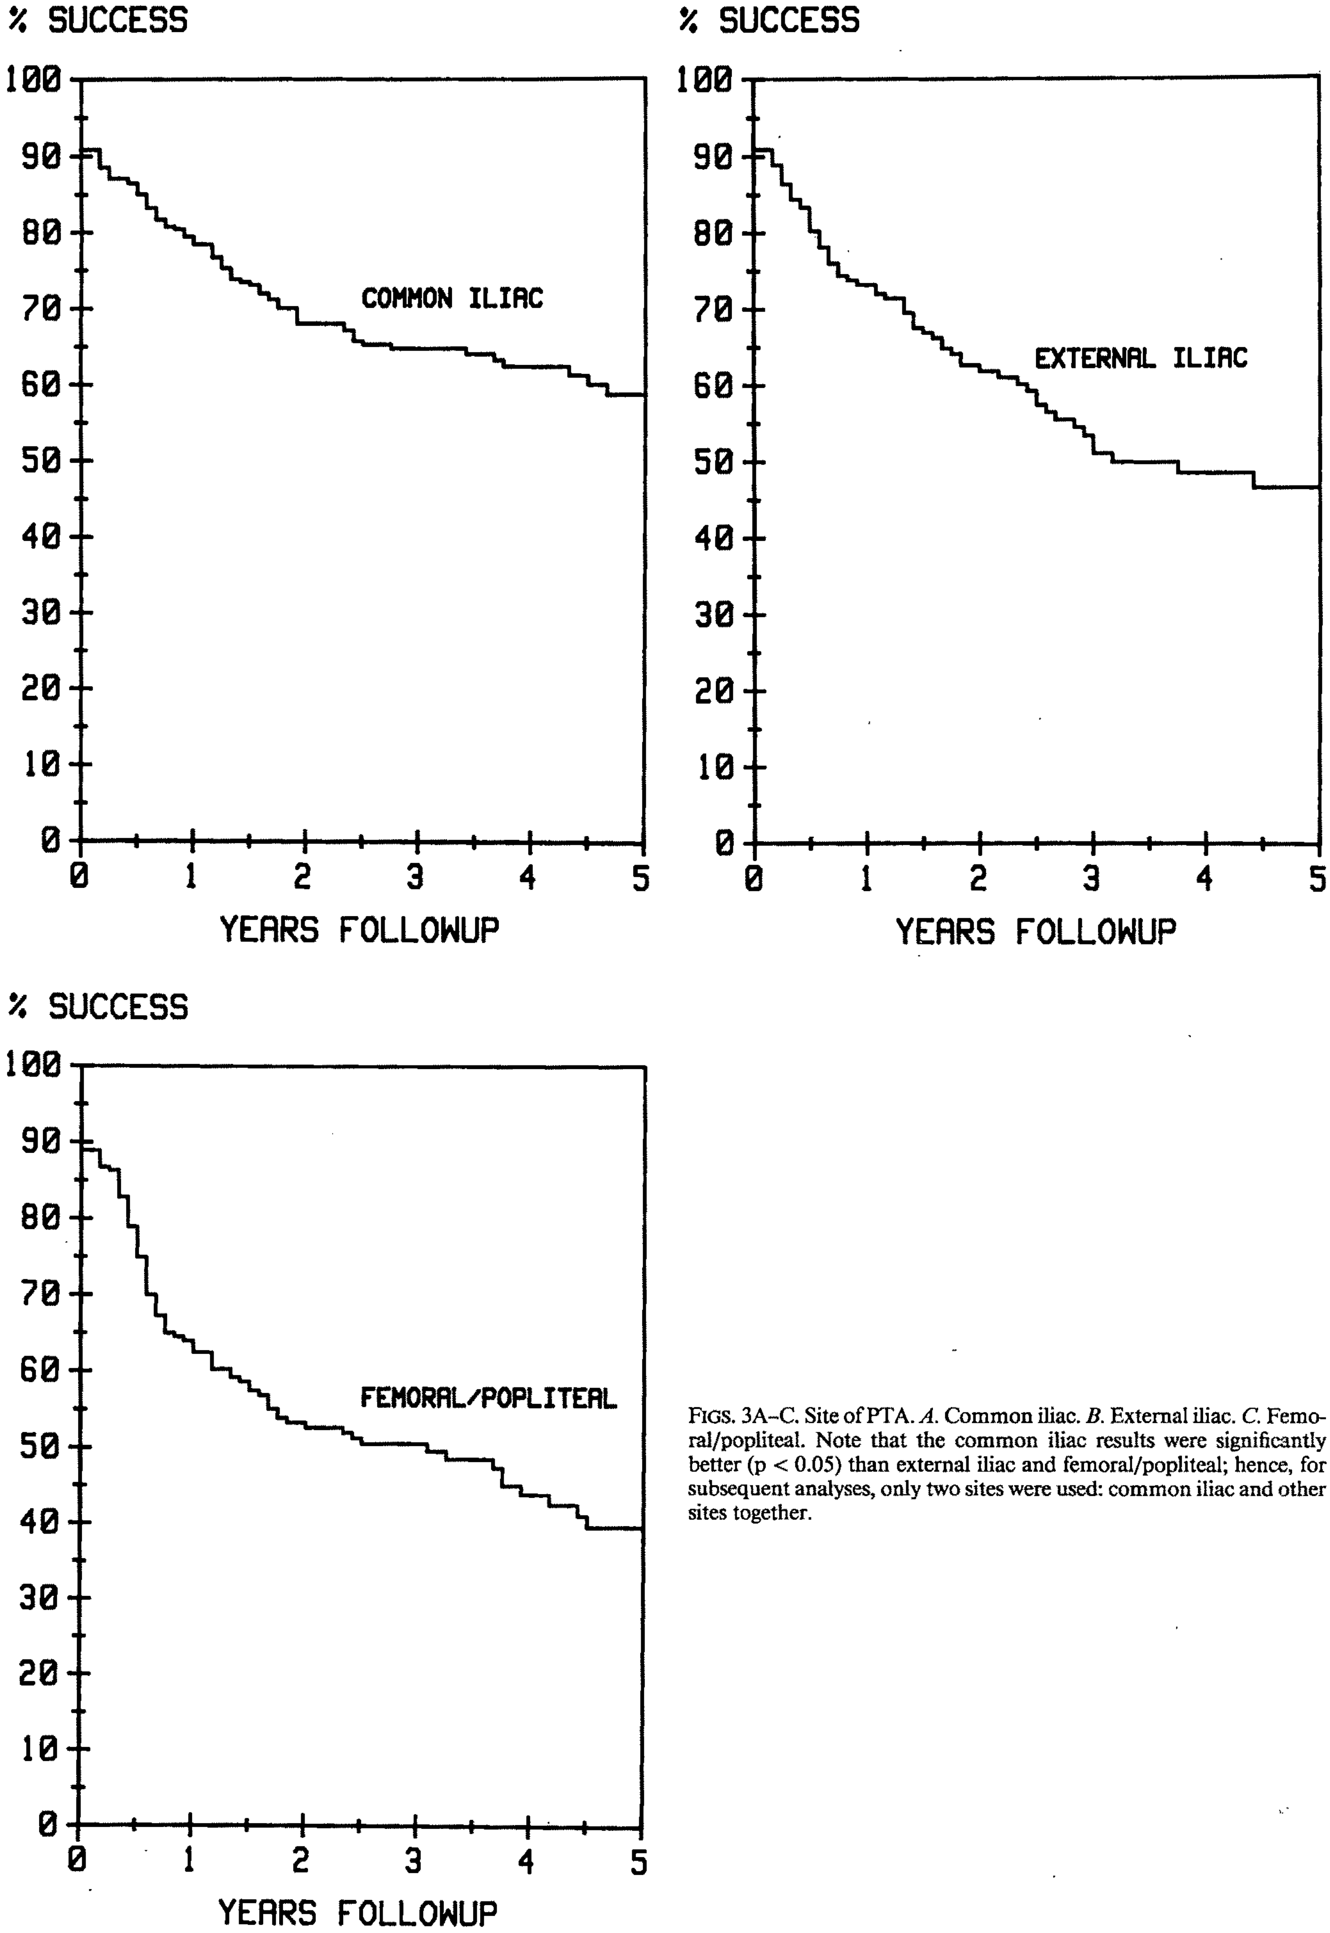

Figs. 3A–C. Site of PTA. *A.* Common iliac. *B.* External iliac. *C.* Femoral/popliteal. Note that the common iliac results were significantly better ($p < 0.05$) than external iliac and femoral/popliteal; hence, for subsequent analyses, only two sites were used: common iliac and other sites together.

TABLE 3. *Results of PTA at Miscellaneous Sites*

Site	Initial No. of Patients	Success Rate			
		1 Month	1 Year	2 Years	3 Years
Aorta	17	94.1 ± 5.7	80.1 ± 10.4	80.1 ± 10.4	70.1 ± 13.0
Common femoral	18	77.9 ± 9.8	58.5 ± 12.2	48.8 ± 13.5	36.6 ± 14.6
Profunda femoris	13	46.2 ± 13.8	23.1 ± 17.7	—	—
Tibial	6	16.7 ± 15.2	—	—	—
Bypass graft	9	77.8 ± 13.9	77.8 ± 13.9	77.8 ± 13.9	51.9 ± 23.1

first 102 PTAs carried out before 1980 were not significantly different from the subsequent 882 PTAs (Wilcoxon = 5.121, $p = 0.02$; log-rank = 2.117, $p = 0.15$). The specialty of the referring doctor (vascular surgeon *vs.* other specialists) was not significant. Whether the PTA was performed for the first time or was a repeat PTA because of restenosis at the site of a previous PTA did not effect the long-term results. Neither the pre-PTA pressure gradient nor the residual post-PTA pressure gradient were related to the outcome. The ankle/brachial systolic blood pressure ratio was not a significant variable.

Multivariate Analysis of Results

As described in the following sections, the Cox regression model was used: (1) to determine which combination of the multiple variables was associated with success of the PTA and (2) to estimate the chance of success for all the combinations of the significant variables. Only iliac, femoral, and popliteal PTAs were included in this model and consequently of the original 984 cases, the number available for analysis totaled 915. If any variable had a missing value, the patient was excluded from analysis.

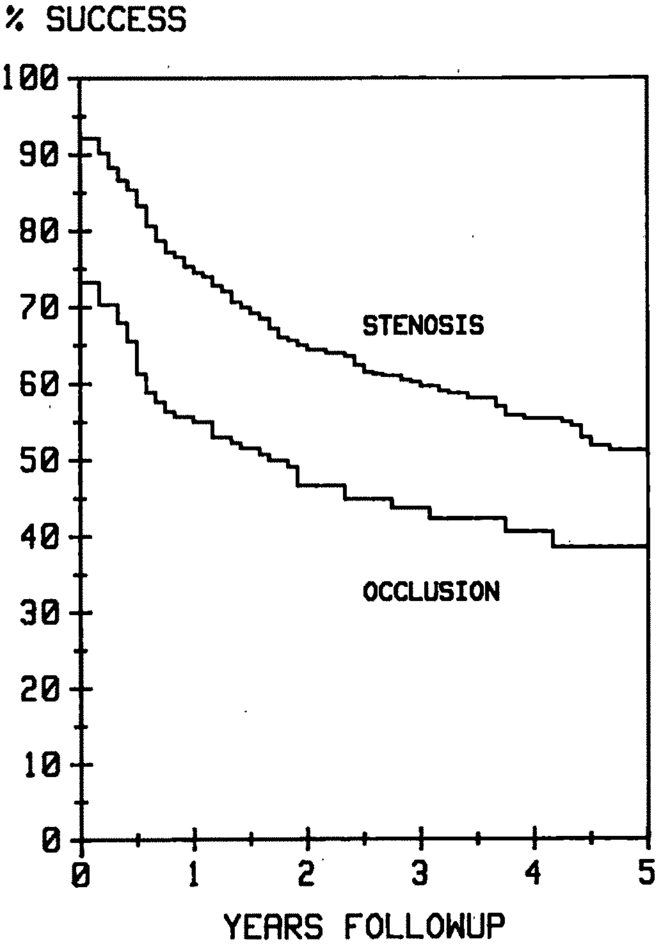

FIG. 4. Severity of lesion: stenosis *versus* occlusion. (Wilcoxon = 42.612, $p < 0.001$; log-rank = 24.459, $p < 0.001$).

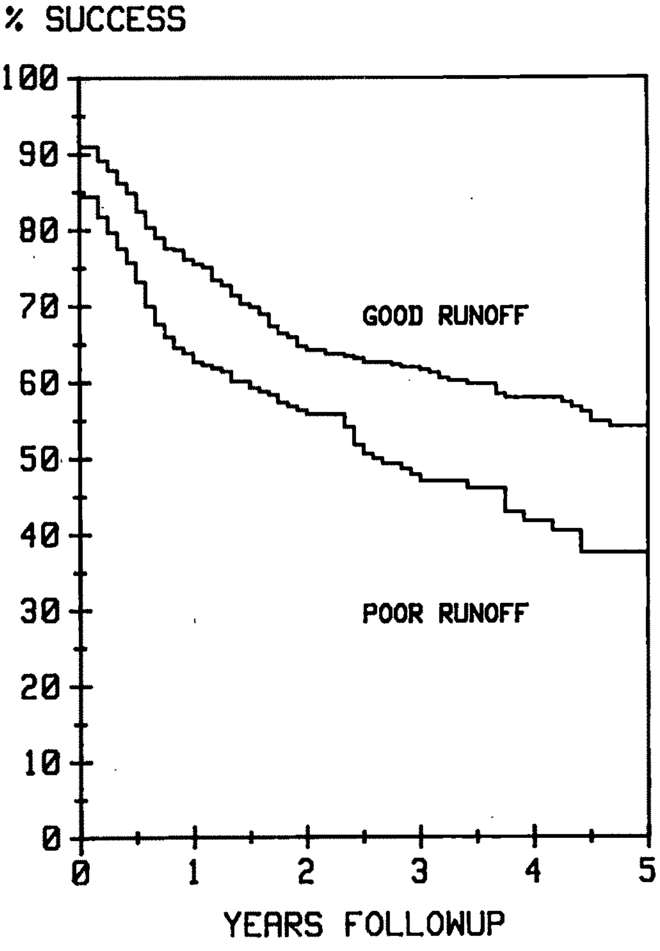

FIG. 5. Runoff: good *versus* poor. (Wilcoxon = 16.954, $p < 0.001$; log-rank = 21.923, $p < 0.001$).

Regression Analysis

A backwards stepwise regression procedure was used to identify the combination of variables that was related to success of PTA. The level of significance to enter the model was set at 0.05 to remove at 0.10. From the regression analysis, the resulting model (Table 4) was based on 870 cases with complete data and included the following combination of significant variables: (1) indication ($p = 0.0125$), (2) site ($p = 0.005$), (3) severity of lesion ($p = 0.0003$), and (4) runoff ($p = 0.0007$).

Plots of Success Rates

A microcomputer program was written to plot graphs of percentage chance of a successful PTA *versus* time for each combination of the four significant variables. At each point of time, the success rate was calculated from the estimated regression coefficients and the estimated baseline survivor function according to the following equation:

$$S(t;Z1,Z2,\ldots Zn) = S_0(t) \wedge EXP(B1*Z1 + B2*Z2 + \ldots BN*ZN)$$

where S(t;Z1,Z2,... ZN) is the success rate at time t, $S_0(t)$ is the baseline survivor function, B1,B2,... BN are the regression coefficients, and Z1,Z2, ... ZN are the coded values for the variables.

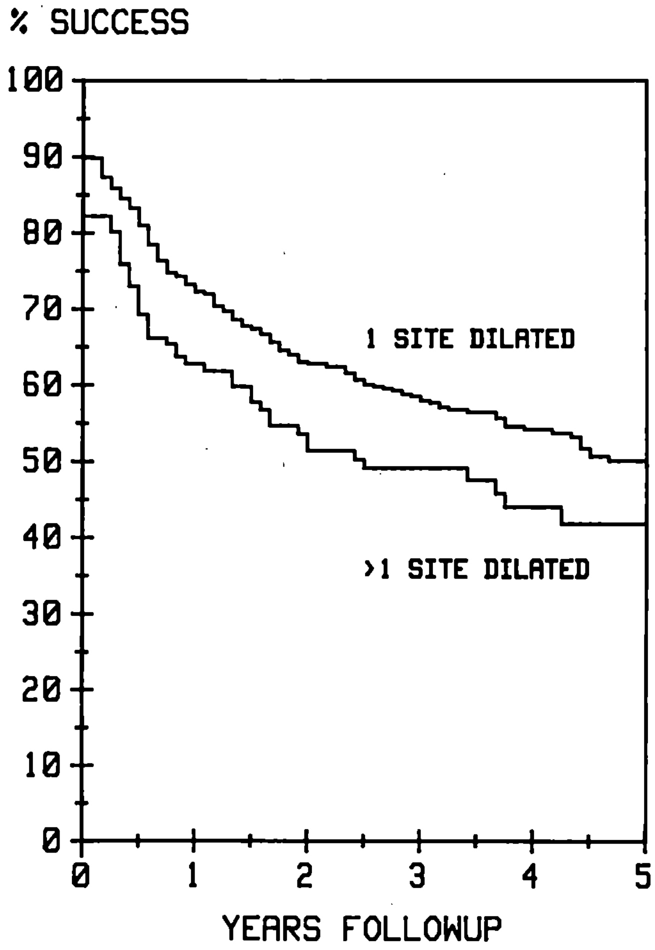

FIG. 6. Number of sites dilated: one *versus* two or more. (Wilcoxon = 9.142, p = 0.002; log-rank = 7.531, p = 0.006).

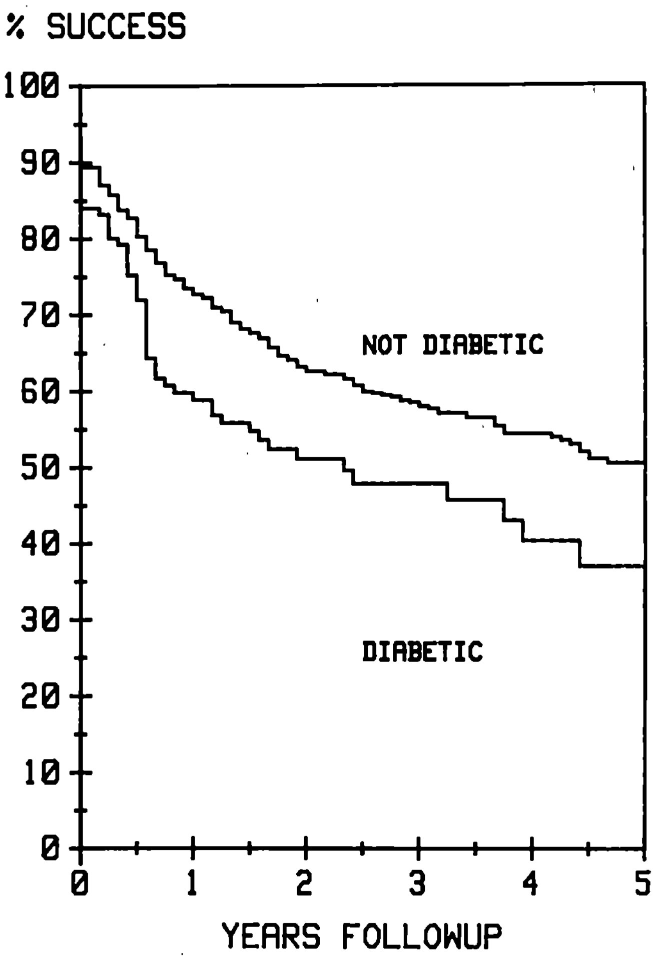

FIG. 7. Nondiabetics *versus* diabetics. (Wilcoxon = 9.348, p = 0.002; log-rank = 9.824, p = 0.002).

For the various combinations of the four significant variables, plots of the success rate *versus* time are shown in Figures 9 and 10 and the success rates are summarized in Table 5.

Discussion and Conclusions

Over the past decade, PTA has assumed an increasing role in the management of patients with peripheral arterial occlusive diseases since catheter technology has improved and the experience and competence of radiologists has increased. The low incidence of serious complications makes it an attractive alternative in the treatment of selected patients, especially if the symptoms are not disabling enough to warrant surgery or the patient is a high operative risk. However, since the over-

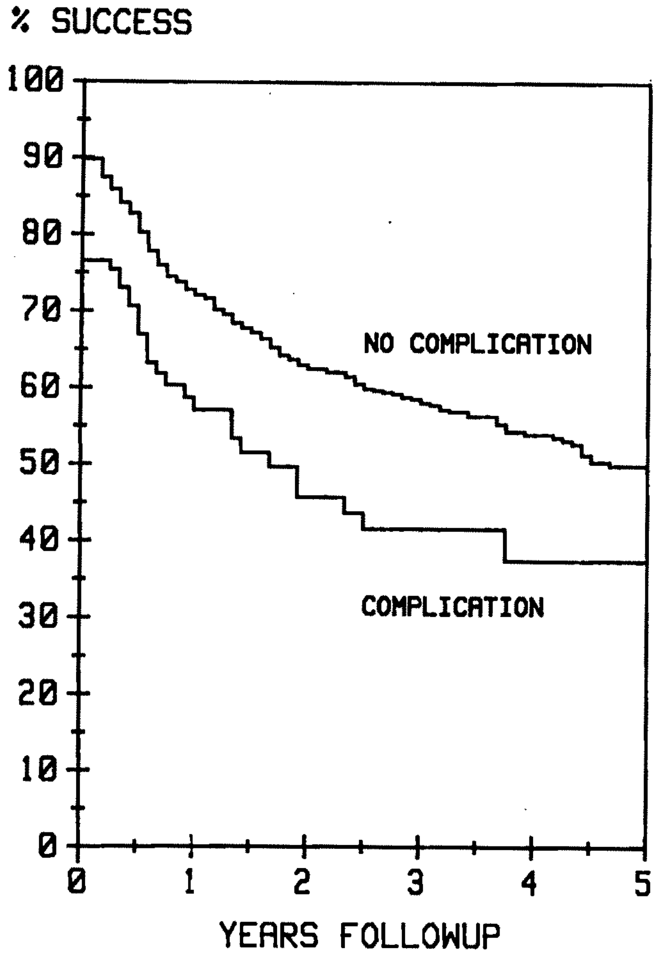

FIG. 8. No complication *versus* complication. (Wilcoxon = 13.033, p < 0.001; log-rank = 9.851, p = 0.002).

all success rate of PTA is generally believed to be lower than that reported for vascular reconstructive surgery, it is important to determine the variables that can be used to predict the long-term results of the procedure.

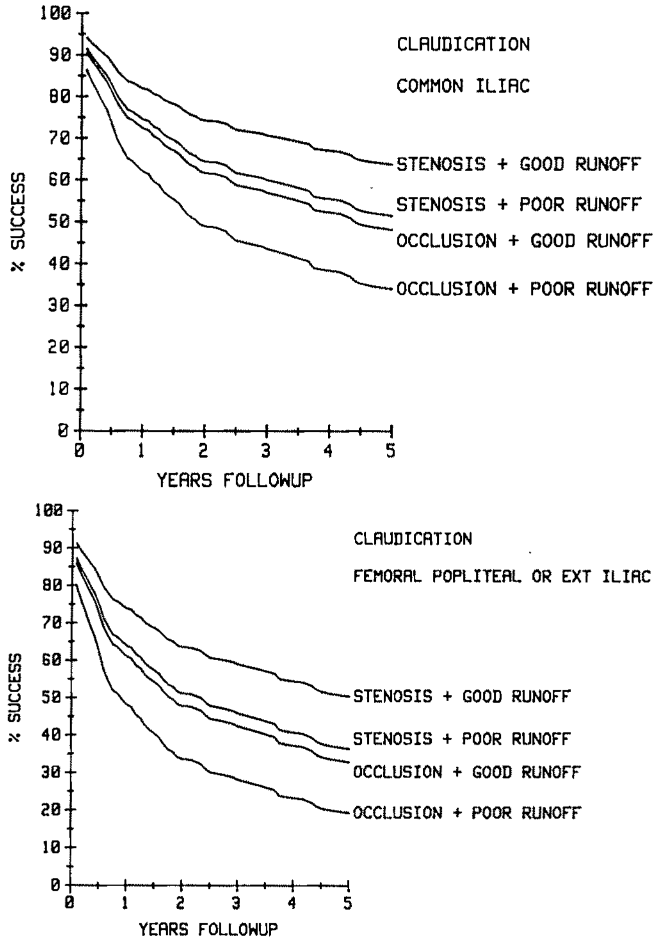

FIG. 9. Predicted results for patients with claudication and other combinations of the significant variables: site (common iliac or other), severity of lesion (stenosis or occlusion), and runoff (good or poor).

As described previously by Walden et al.,[7] the wide discrepancies in the reported results of PTA are due to differences in patient selection, criteria for evaluating

† Other = external iliac or femoral/popliteal.

the results, and methods of data analysis. In the study reported in this paper, a combination of clinical criteria and objective vascular laboratory criteria were used to determine if the procedure was a success or failure. Multiple regression techniques were used to describe the important variables that are predictive of success and to develop a model of the results.

Univariate Analysis

When the variables were analyzed one at a time, the predictors of success were found to be similar to previous reports.[8,9] The results are best when the indication for the procedure is claudication, the common iliac segment is dilated, the artery is stenosed and not occluded, the runoff is good, only one site is dilated, the patient does not have diabetes, and no complication occurred at the time of the PTA. The pressure gradient measured across the stenosis before or after the PTA was not related to outcome. In contrast to our earlier report,[10] in the model reported in this paper, we found that a repeat PTA at the same site did not have an effect on the outcome. It is important to recognize that the importance of certain variables such as smoking and length and morphologic characteristics of the lesion were not analyzed.

Multivariate Analysis

The Cox proportional hazards model was used to determine the variables that can be used to predict if a PTA is likely to be successful and to quantify the relationship between long-term success and these significant variables.[11] By using a stepwise multiple regression procedure, the combination of variables associated with

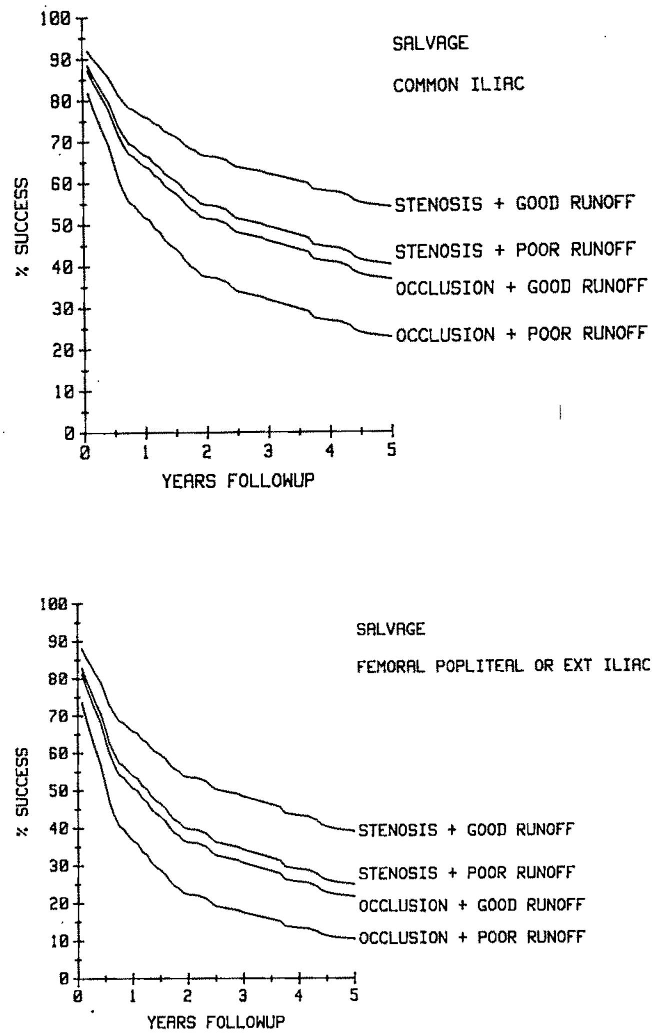

FIG. 10. Predicted results for patients having PTA for salvage.

			Poor	80	48	28	19
	FP and external iliac	Stenosis	Good	88	65	48	38
			Poor	82	53	34	24
		Occlusion	Good	81	50	30	21
			Poor	73	36	17	10

FP = femoral/popliteal.

success was determined. Based on a model that incorporated the significant variables together, plots of the percentage success *versus* time have been made.

In conclusion, the risks associated with PTA are low and the chances of success can be predicted from a knowledge of four significant variables: the indication for the PTA, site of the PTA, severity of the lesion, and runoff. Thus, in deciding on the management of an individual patient, the risks and benefits of PTA can be evaluated relative to conservative management or surgery.

DISCUSSION

DR. ROBERT B. RUTHERFORD (Denver, Colorado): Dr. Johnston and his colleagues are to be complimented on an absolutely superb, long-term analysis of a large series of PTAs performed by experts. He has given us an overall 5-year success rate of 48% and a 65% success rate in the best scenario of common iliac stenoses with good runoff done for claudication, yet currently there are three reports by radiologists in the literature of 5-year success rates for iliac PTAs ranging between 84 and 90%.

I want to point out that the difference here is simply a matter of the criteria for success. Dr. Johnston and his colleagues do *not* exclude initial failures or include redilations and, importantly, they demand both objective evidence of persisting hemodynamic benefit *and* categoric improvement.

Using similar criteria, our 5-year patency rates were 71% for iliac dilations and only 19% for femoropopliteal PTAs, but when we analyzed our data for publication at 3 years, we found that with using the differing criteria that were in the literature, we could vary the success rate on our iliac PTAs from 52% up to 86%.

In the Einover, Holland series, which reports a 90% 5-year patency for the dilation of iliac stenoses, the criteria for success were palpable femoral pulses, which the patient had before the dilation, and subjective improvement in patients who were mostly claudicators and were now 5 years older.

Clearly, we need hard data like those reported here if we are going to be able to judge the true value of PTA to our patients.

I have one question for Dr. Johnston. You previously reported that less than 10% of dilations were hemodynamically or symptomatically worse when they failed, and yet I notice a 0.4% mortality rate and a 7.8% amputation rate in this series in which 84% of the patients were claudicators.

Has this figure of less than 10% being worse off when the dilation fails held up in this larger experience that you are now reporting, and if possible, could you tell us if worsening with failure correlates with any of the variables that you have analyzed, for example, limb salvage, distal lesion, or poor runoff?

DR. JOHN J. BERGAN (Chicago, Illinois): This paper from the Toronto General Hospital is important. It is an objective summation of an experience with a treatment method that is useful to all of us who treat vascular disease, and the manuscript, as Dr. Rutherford has indicated, contains a wealth of information.

I would like to address my two remarks and single question to the rather sophisticated statistical analysis that Dr. Johnston has applied.

The number of 1000 cases gives enormous statistical power and, therefore, this study and its conclusions become a notable contribution.

Some surprisingly simple conclusions derive from his paper: one fourth of the patients in Ontario are being treated by PTA. That is certainly not our experience at Northwestern or the Chicago area. I believe that probably fewer PTA patients should be treated, certainly not those with distal occlusive disease.

Second, the complications of PTA in the study are significant. They are everywhere, even in experienced hands. They include, as has been said and I want to reemphasize, major hematomas, hemorrhage, and some of these leading to death as has been indicated by Dr. Johnston.

Similarly, in the univariant analysis, it is surprising in this study that nondiabetics fare better than diabetics because this is not true as we analyze the results of femoral distal occlusive disease operations.

It is also surprising that an early experience compared with a later experience is not different.

It is also surprising that a second dilation does not yield inferior results to the first dilation. Those are the surprising univariant results.

The multivariant analysis of 870 cases is of particular interest. Dr. Johnston is an experienced statistician. He has enormous experience, and I believe that his contribution may be of great value to us in the future because we deal with extremely complex patient problems.

Historically, vascular surgery has contributed several methods of analysis that have improved reporting in various surgical fields. I think of Harvey Butcher's contribution of introducing the life table method in analyzing patency of femoral-popliteal reconstruction.

Strandness in Seattle and Jimmy Yao, then in London, were among the first to use objective documentation of vascular reconstruction, which Dr. Johnston has employed.

I believe Dr. Johnston has given us a model, the Cox regression model, for a computer program that can make a great deal of contribution in surgery, and that is why I want to ask him a question about this.

The stepwise regression, with four variables, describes the results of his interventions. As you could see the results of his paper give support to current practice. That is, PTA is prescribed instead of surgery for common iliac stenosis in patients with claudication. Surgery instead of PTA is better for total occlusions of major arteries, especially those distal to the femoral artery.

Having said all that, Dr. Johnston, I must be critical of your study. Given the powerful statistical tool that you have developed, I am disappointed at the superficial nature of the conclusions. PTA for stenosis with good runoff is good. PTA for occlusion with no runoff is bad.

Given this tool, which, as I said, is a major contribution and may be of historic importance, therefore, how can you teach us to apply this to the next level of surgical information that we now lack?

DR. FRANK J. VEITH (New York, New York): I, too, commend Dr. Johnston for this clear, accurate analysis of angioplasty results. It is one of the few in the literature.

Based on experience with more than 600 angioplasties for limb-threatening ischemia, we continue to be enthusiastic about this treatment. Our results generally parallel those presented by Dr. Johnston.

Of importance to surgeons, we find that in most instances, angioplasty and surgery are complementary rather than competitive methods of treatment. Approximately two thirds of our patients who have angioplasty for limb-threatening ischemia ultimately require a vascular operation. One third require a complementary operation proximal or distal to their angioplasty or because the angioplasty is unsuccessful or has a complication. The other third require the operation because our successful angioplasties, like those of Dr. Johnston's group, are often palliative. That is, they often fail some time in the postangioplasty period. When these late angioplasty failures occur, patients often require a vascular operation.

Interestingly, as we showed in 1984, the downside risk of angioplasty is minimal if a appropriate close collaboration with a vascular surgeon is available. When an operation was required after an angioplasty was unsuccessful, had a complication, or failed, the operation was almost always of reasonable extent and successful.

For example, although complications that required operative correction occurred in approximately 7% of our limb salvage angioplasties, the extent of that urgent or emergent operation was usually equal to or less than the operation that would have been required if the angioplasty had not been performed.

In only 2% of all our angioplasty patients was a more extensive operation required than would have been needed without the angioplasty, and in only 0.4% of our angioplasty patients did a complication occur that precluded salvage of life and limb. It is this low downside risk that can be achieved with angioplasty that adds to its appeal, even though its benefits may not be durable and close cooperation between the angiographer and the surgeon are required to deal with problems and to achieve optimal results.

I ask Dr. Johnston if his experience with angioplasty failures and complications has been similar to ours. Were such problems almost always correctable by appropriate vascular operations?

DR. JOHN A. MANNICK (Boston, Massachusetts): I am afraid that I have nothing substantive to add to that which has already been brought up by the other discussants. However, I cannot resist one philosophical comment about this paper.

Surgeons and vascular surgeons, in particular, have recently been subjected to a barrage of criticism by medical and neurological colleagues for overly optimistic reporting of their operative results. I believe that might have been a justifiable criticism 20 years ago, but it seems to me that in this day and age it is a bum rap. It is very difficult to find in a peer review surgical journal a report of a clincal series that has not been subjected to actuarial analysis.

I believe it is ironic that invasive radiologists and interventionist cardiologists have not subjected their own work to the kind of scrutiny that surgeons are currently in the habit of doing. One sees over and over again enthusiastic endorsements of procedures from these groups based on very small numbers of patients observed for very short periods with no clear definition of what success is and no attempt at all to apply Kaplan-Meier statistics to analysis of the outcome.

I believe it is further ironic that it has taken a group of surgeons to finally evaluate adequately a large group of angioplasty patients, observed over a protracted period.

DR. K. WAYNE JOHNSTON (Closing discussion): I am honored to have had this paper reviewed in detail, and I will address the questions posed by the discussants.

Dr. Rutherford, I agree that hard end points are absolutely essential in all our studies. In peripheral vascular surgery, we have the advantage of quantitative data available from the noninvasive laboratory.

As reported previously, if the PTA fails, 10% of the patients are worse. The amputations all occurred in patients in whom prime indication for the procedure was limb salvage, and, therefore, we did not consider that they had, in fact, been worsened if the PTA failed.

Dr. Bergan mentioned a few surprising observations. Differences between our results and previous reports can likely be explained by the fact that our data were recorded prospectively and not retrospectively.

You have re-emphasized the importance of Cox regression analysis since it can correct for the confounding effect of the variables and at the same time take into account the effect of the time since the PTA.

Your criticism of the conclusions is valid. This is a descriptive, cohort study, and as such, has limitations. I agree that the causes of late failure would have been strengthened if we had examined the effects of thrombogenicity, platelet function, smoking, and other factors. Perhaps this should form the basis for future studies of patients having PTA. However, the objective of this study was to define the clinical criteria associated with success. Our results have two important applications. First, in the management of the individual patient, we now know the variables that will help us more rationally decide when PTA is indicated and to choose between conservative therapy, PTA, and surgery. Second, knowing the variables associated with a successful PTA, it should be possible to compare the results of PTA with a comparable surgical group.

Dr. Veith, our experience is quite different from yours. The majority of your patients had PTA for limb salvage, whereas 85% of our patients were claudicants. Clearly, we have corrected for this difference in our analysis; however, such observations as the consequences of failure and subsequent treatment will differ significantly. Two thirds of your patients with a failed PTA subsequently had surgery; only 25% of our failures had surgery. I agree that collaboration with the radiologist is very important.

Dr. Mannick also stressed the importance of hard end points and of the methods of statistical analysis in studies of this type.

Experimental and Clinical Results with Proximal End-to-End Duodenojejunostomy for Pathologic Duodenogastric Reflux

TOM R. DEMEESTER, M.D., KARL H. FUCHS, M.D., CHRIS S. BALL, M.D., MARIO ALBERTUCCI, M.D.,
TOM C. SMYRK, M.D.,* and JOSEPH N. MARCUS, M.D.*

From the Departments of Surgery and Pathology, Creighton University, School of Medicine, Omaha, Nebraska*

Existing Roux-en-Y bile diversion procedures for duodenogastric reflux coupled with distal gastric resection or antrectomy and vagotomy have varied success due to interruption of the physiologic relationships between stomach and duodenum, the reduction of the gastric reservoir, the side effects of vagotomy, and the effect of the Roux limb on gastric emptying. A new bile diversion procedure, suprapapillary Roux-en-Y duodenojejunostomy, was studied, which eliminates the need for gastric resection to prevent jejunal ulcers by preserving duodenal inhibition of gastric acid secretion and the protective effects of duodenal secretion on the surrounding mucosa. Experimentally, the incidence of jejunal ulceration was significantly decreased by the preservation of the proximal duodenum. Clinically, bile diversion by suprapapillary Roux-en-Y duodenojejunostomy alleviates symptoms of duodenogastric reflux disease without being ulcerogenic (in the presence of normal gastric secretion) or prolonging gastric emptying.

ALKALINE REFLUX GASTRITIS is a recognized complication after operations on the stomach that distort or remove the pylorus.[1-3] It may also occur as a consequence of altered pyloric or duodenal function in patients who have not had gastric surgery.[4-6] There is evidence that the regurgitation of duodenal juice into the stomach is associated with gastric mucosal damage[7-9] and can cause symptoms of epigastric pain, nausea, and bilious vomiting.[6,10-12] Conservative therapy of the condition has been largely ineffective,[13] and in its severe form a Roux-en-Y biliary diversion procedure or a jejunal interposition is usually necessary for relief of symptoms.[2] When the former is used in patients without previous gastric resection, an antrectomy and vagotomy are required to protect against the development of jejunal ulcers. This interrupts the physiologic relationship between the stomach and duodenum, reduces the gastric reservoir, and gives rise to side effects associated with a vagotomy.[14] In addition, the Roux-en-Y limb can severely delay gastric emptying.[15,16] For these reasons, the success of a Roux-en-Y biliary diversion in improving symptoms has been only 50–80% and the incidence of jejunal ulceration has been 10–15%.[12,17-19] Consequently, a new surgical approach is needed for patients with pathologic duodenogastric reflux, especially those who have not had previous gastric surgery or whose previous surgery did not include a resection. The current study reports on the experimental development and the clinical evaluation of a new biliary diversion procedure, namely a suprapapillary Roux-en-Y duodenojejunostomy succinctly called a "duodenal switch."

Experimental Study

The purpose of this study was to determine if duodenal inhibition of gastric acid secretion and the protective effect of duodenal secretion on the surrounding mucosa could be maintained in a bile diversion procedure that preserved only the proximal duodenum in continuity with the stomach. To do so, an attempt was made to reduce the 95% incidence of jejunal ulcer formation after the Mann-Williamson preparation[20] by performing a suprapapillary duodenojejunostomy instead of a pylorojejunostomy.

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

Supported in part by a Health Future Foundation Grant for "Establishment of the Creighton University Gastrointestinal Diagnostic and Research Core Center."

Reprint requests and correspondence: Tom R. DeMeester, M.D., Department of Surgery, Creighton University, School of Medicine, 601 North 30th Street, Omaha, NE 68131.

Submitted for publication: April 24, 1987.

Method

Under general anesthesia, 29 adult mongrel dogs were subjected to one of four different arrangements of Roux-en-Y biliary diversion (Fig. 1). Seven dogs had an end-to-end pylorojejunostomy with an end-to-side jejunoileostomy 10 cm proximal to the ileocecal valve (classic Mann-Williamson preparation: group A). Five dogs had an end-to-end pylorojejunostomy with an end-to-side jejunojejunostomy 40 cm down the jejunum (group B). Seven dogs had an end-to-end suprapapillary duodenojejunostomy with an end-to-side jejunoileostomy 10 cm proximal to the ileocecal valve (group C). Ten dogs had an end-to-end suprapapillary duodenojejunostomy with an end-to-side jejunojejunostomy 40 cm down the jejunum (duodenal switch procedure: group D). All dogs were given the same diet and were weighed and had endoscopy at monthly intervals for up to 1 year or until death. All dogs were autopsied with inspection and removal of both surgical anastomoses. Statistical differences in the incidence of ulcer formation and degree of weight loss were determined using the Student's t-test.

Results

The incidence of ulcer formation, ulcer perforation, and degree of weight loss is shown in Figure 1. Dogs with jejunoileostomy showed profound malnutrition. When the proximal duodenum was preserved, the incidence of ulceration was dramatically reduced. The results showed that the end-to-side jejunojejunostomy was necessary to maintain nutrition, and preservation of the proximal duodenum in the acid stream was necessary to protect against ulceration. Dogs without both of these components died of either malnutrition or ulceration within 3 months.

Clinical Study

The purpose of this study was to determine if biliary diversion by a suprapapillary Roux-en-Y duodenojejunostomy for pathologic duodenogastric reflux can: (1) provide symptomatic improvement; (2) heal endoscopic gastritis; (3) preserve normal gastric emptying; and (4) prevent jejunal ulceration wihtout vagotomy in patients with normal acid secretion.

Method

Patient Selection

Between January 1984 and January 1987, 202 patients were referred to the Creighton University Surgical Gastrointestinal Diagnostic and Research Unit for evaluation of foregut symptoms. Of these patients, 10 with epigastric pain, nausea, bilious vomiting, and endoscopic gastritis unresponsive to medical therapy for 2–20 years were selected for bile diversion. There were four men and six women with an age range of 28–57 years. Five patients had primary duodenogastric reflux and duodenogastric reflux developed in five patients after previous gastrointestinal surgery (Table 1). Of the three presenting complaints, epigastric pain was dominant in six of ten patients. In four patients it became worse with eating. The pain was described as burning by five patients, dull by three patients, and sharp by two patients. In six patients the pain radiated: to the chest in three, to the back in two, and to the lower abdomen in one. Nausea was the dominant symptom in two of ten patients. Nausea was associated with epigastric pain in four patients and the intake of food in two patients. Vomiting was the dominant symptom in two of ten patients, and was bilious in color in nine patients; one patient, who had a previous Nissen fundoplication, only retched. Vomiting produced relief of the epigastric pain in three patients.

In each patient the symptomatic and endoscopic evidence of duodenogastric reflux was supported by one or more of three objective tests: DISIDA cholescintigraphy, alkaline pH shift on 24-hour gastric monitoring, and discriminant analysis of 24-hour gastric pH data (Table 2). Twenty healthy volunteers who were asymptomatic for gastrointestinal disease and had normal upper gastrointestinal barium studies provided a control group for the normal parameters of these tests.

DISIDA cholescintigraphy. Five μCi of Tc-99m labeled disofenin was given by intravenous injection in the fasting state. Gamma camera imaging commenced immediately and at 5-minute intervals for 60 minutes. The images acquired were stored by computer. If no duodenogastric reflux was observed during the first 60 minutes, imaging was continued for an additional 60 minutes, after which cholecystokinin was given intravenously in a dose of 0.02 μg/kg body weight over 1 minute in an attempt to provoke reflux. The timing and degree of spontaneous or provoked reflux of isotope into the stomach was noted along with abnormalities of the biliary tract and the symptoms experienced by the patient after injection of cholecystokinin. When performed on 20 control subjects, four (20%) showed evidence of duodenogastric reflux. In three controls, reflux was spontaneous and in one control it was provoked by cholecystokinin.

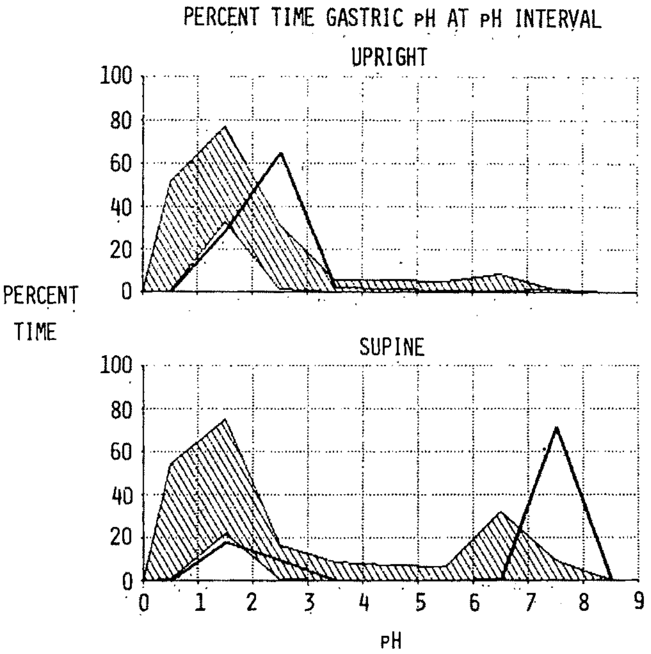

FIG. 2. Graphic display of percentage of time the gastric pH was at a whole pH interval. Control 95th and 5th percentile ranges are the shaded area. Patient data are represented by the solid line.

Twenty-four-hour pH monitoring. Outpatient monitoring of esophageal and gastric pH was performed using a computerized portable recording unit connected to combined glass probes, positioned transnasally 5 cm above and below the manometrically defined distal esophageal sphincter. The probes were calibrated in standard buffer solution at pH 7 and pH 1 before and after monitoring. The patient or volunteers were sent home and instructed to remain in the upright or sitting position until they retired for the evening, avoid strenuous exertion, and follow a diet restricted to three meals composed of food with a pH between 5 and 7. Only water was permitted between meals. A diary was kept of food and fluid intake, symptoms experienced during the monitored period, the time a supine position was assumed in preparation for sleep, and the time of rising in the morning. The patient's gastric pH data were displayed graphically as the percentage of time the pH was at a whole pH interval against a background of control data to detect an alkaline pH shift (Fig. 2). The pH data were further evaluated by a computerized discriminant analysis program developed in our unit to identify pH changes with a high probability of resulting from pathologic duodenogastric reflux. Comparison of patients with control subjects for this analysis is shown in Fig. 3.

Operative Procedure

Through an upper midline incision, the duodenum is kocherized sufficiently to allow it and the head of the pancreas to be swung freely for exposure of their posterior surfaces, and the position of the ampulla is palpated through the duodenal wall. With the thumb and index finger encircling the duodenum, it is possible to feel their close approximation at a point along the medial duodenal border just proximal to the site of the ampulla and about 2–3 cm distal to the pylorus. At this location the duodenum is dissected free of the pancreatic head by dividing the small vessels coursing between the two. This dissection is done alternately on the anterior and posterior surface taking small bites of tissue with delicate clamps. Care must be taken to avoid damage to the pancreatic portion of the common bile duct. It lies embedded just beneath the posterior surface of the pancreatic head and is identified by its linear appearance compared with the more globular adjacent pancreatic tissue. The dissection is continued until the index finger can be freely passed between the duodenum and pancreas.

At the distal end of the dissection the duodenum is divided using a GIA stapler. A pursestring suture is placed around the lateral corner of the stapled distal duodenal closure and the corner is opened. The flow of bile from this opening on compression of the liver confirms the suprapapillary transection of the duodenum. The pursestring is tied and the distal duodenal closure is oversewn (Fig. 4).

The jejunum, 25 cm distal to the ligament of Treitz, is brought through an opening in the transverse mesocolon to the right of the midcolic vessels. Its mesenteric border is freed for a distance of 2 cm and the bowel is divided between clamps (Fig. 5). Further division of the mesentery is avoided to preserve innervation.

The distal jejunal limb is anastomosed end-to-end to the proximal duodenum using an interrupted single-layer suturing technique (Fig. 6), and the proximal jejunal limb is withdrawn back through the opening in the mesocolon. This maneuver can be facilitated by initially applying the proximal jejunal clamp through the mesenteric opening before dividing the bowel. The proximal jejunal limb is anastomosed end-to-side to the distal jejunal limb 55 cm caudal to the duodenojejunal anastomosis (Fig. 7). The opening in the mesocolon is closed by suturing the margins to the circumference of the duodenojejunal anastomosis. The complete "duodenal switch" is shown in Figure 8.

This procedure was performed on the 10 patients in the study. In three patients, one of whom had a previously failed antireflux procedure, a Nissen fundoplication was added for coexisting gastroesophageal reflux disease. One patient who had gastric hypersecretion had a concomitant limited proximal gastric vegotomy to reduce acid secretion. One patient had a cholecystectomy added for cholelithiasis. Two patients had a temporary rise in their serum amylase level during the immediate postoperative recovery period. The average length of hospital stay was 13 days with a range of 9–31 days.

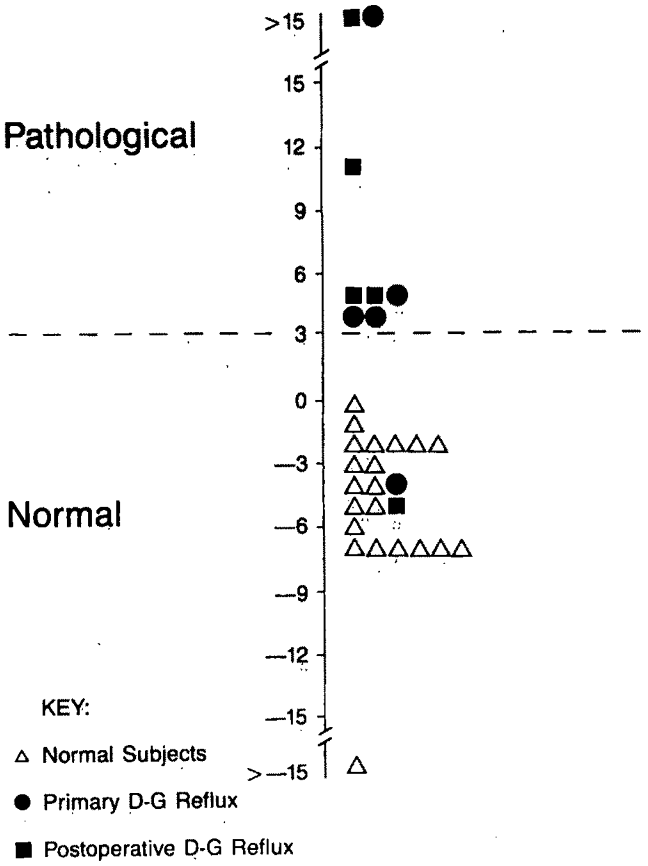

FIG. 3. Discriminant analysis of gastric pH data in duodenogastric reflux patients and controls.

Evaluation of the Operation

All patients had a preoperative and postoperative scoring of their symptoms and endoscopic evaluation of their stomach and duodenum. With few exceptions all had gastric biopsy, gastric emptying scan, gastric secretion analysis, and a serum gastrin assay before and after bile diversion. The postoperative evaluation was performed 10–33 months (median: 24 months) after operation. Student's t-test was used to determine statistical significance between preoperative and postoperative data when applicable.

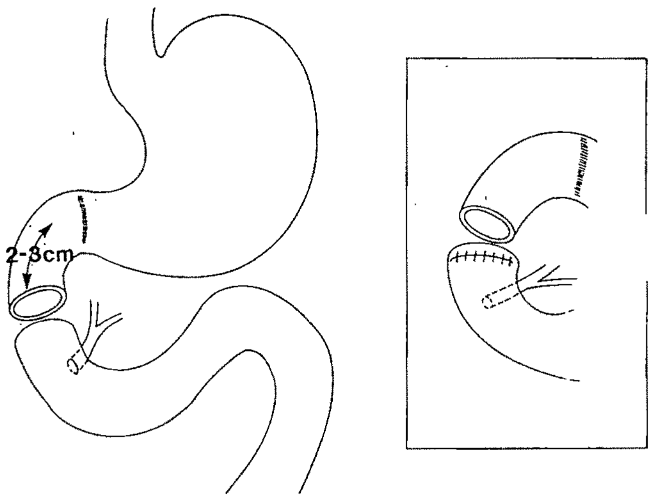

FIG. 4. Schematic diagram showing the suprapapillary transection of the duodenum 2–3 cm distal to the pylorus. Insert shows closure of the distal duodenum.

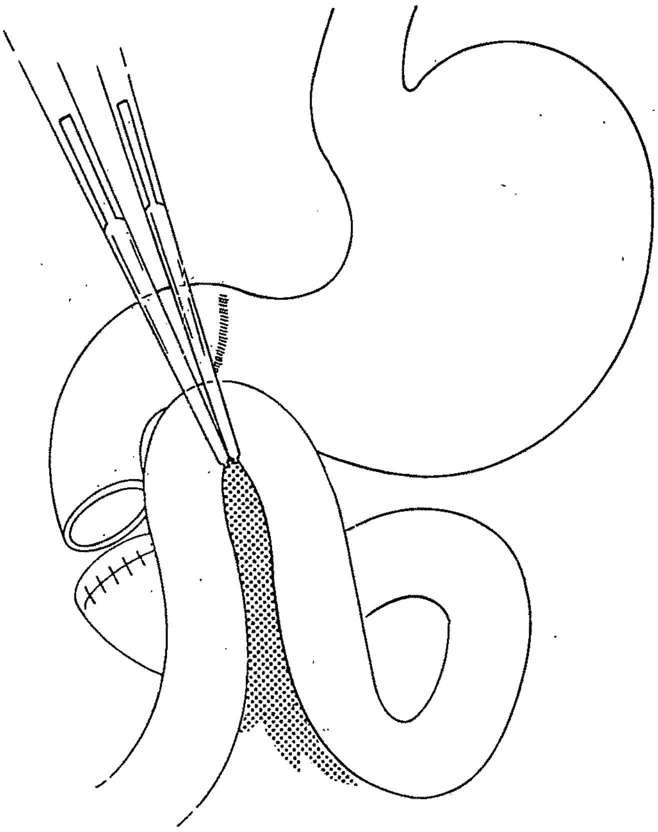

FIG. 5. Schematic diagram showing the initial construction of the Roux-en-Y in juxtaposition to the duodenum. This position is obtained by passing the loop through an opening in the mesocolon and allows construction of the Roux-en-Y without division of the mesentery.

Symptom scoring. Symptoms were scored using a detailed questionnaire completed by one of the authors. A scoring system shown in Table 3 was used to quantitate the symptoms of epigastric pain, nausea, and bilious vomiting. An overall symptom score was obtained by summing the scores for each symptom. The maximum score obtainable was 18.

Gastric biopsy. Multiple endoscopic biopsies were taken from the gastric antrum and body, fixed in formalin, and stained with hematoxylin and eosin. A scoring system was used to evaluate severity of gastritis.[21] A score of 0 to 4 was given for inflammation, 0 to 4 for corkscrew appearance of gastric tubules, and 0 to 4 for surface hyperplasia. The maximum score obtainable was 12.

Gastric emptying scan. A meal was given in the fasting state consisting of 56 g of instant oatmeal, 6 g of sugar, and 175 mL of water, mixed with 500 μCi Tc-99m sulfur colloid and followed by 240 mL of 2% milk. Caloric values of the test meal are shown in Table 4. Gamma camera counts were taken in the upright anterior and posterior projections for 40 seconds at the completion of the meal and every 15 minutes for 120 minutes. Counts per minute were adjusted to account for the decay of Tc-99m. The percentage of the initial count was plotted against time for the anterior projection, posterior projection, one-half times the sum of both projections and for a calculated geometric mean. The curve was displayed against the 95 and 5 percentile limit obtained from the 20 control subjects. In the early part of the study only the anterior projection was obtained.

Gastric analysis and serum gastrin levels. Gastric juice was aspirated using a Salem sump nasogastric tube (Sherwood Medical, St. Louis, MO) after an overnight fast. The first 15-minute sample was saved as residual basal secretion, and the following 60-minute aspirate was considered a representative basal sample. Pentagastrin was given subcutaneously in a dose of 6 μg/kg body weight and stimulated samples were obtained continuously for 15- and 60-minute periods. Hydrogen ion concentration was measured by a colorimetric titration, and the basal acid output (BAO) and maximum acid

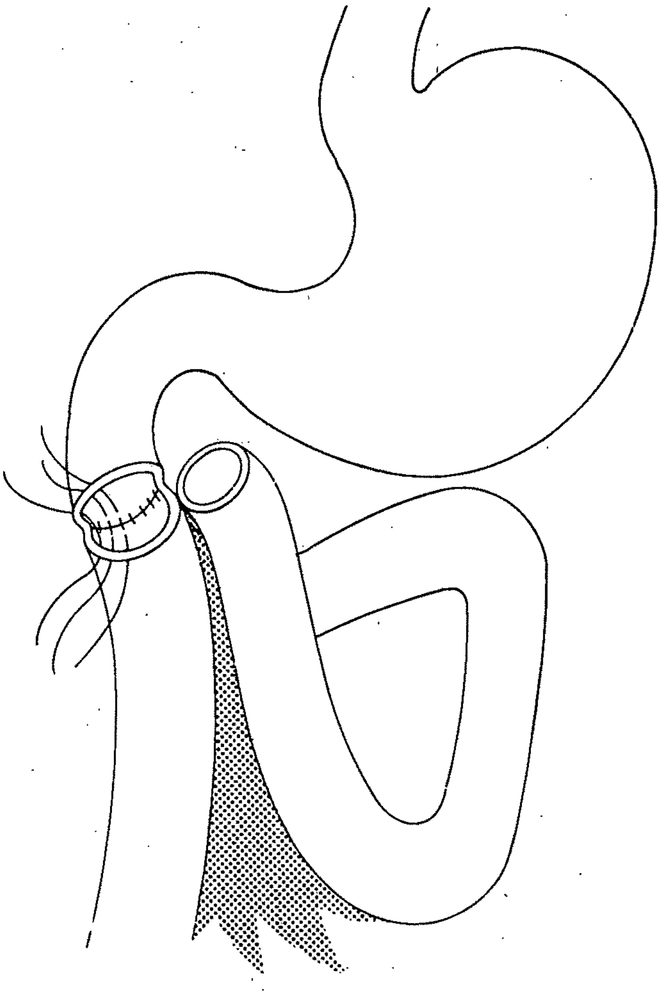

FIG. 6. Schematic diagram showing the end-to-end anastomosis of the distal jejunal limb to the duodenum.

output (MAO) in mEq/h were calculated. Hypersecretion was diagnosed when BAO was above 5 mEq/h and MAO was greater than 35 mEq/h. Fasting serum gastrin levels were measured by a radioimmune assay and recorded in picograms per milliliter.

Results

Symptoms

The preoperative and postoperative scoring of each symptom is shown in Figures 9 and 10. Bile diversion by a suprapapillary Roux-en-Y duodenojejunostomy statistically improved the overall symptom score for the five patients with primary duodenogastric reflux ($p < 0.05$), but no statistical improvement occurred in the five patients with postsurgical duodenogastric reflux. In the one patient who had persistent symptoms in the primary group, a postoperative jejunal ulcer developed that was healed completely by H2 antagonists in 6 weeks. This patient had preoperatively borderline gastric hypersecretion. In the postsurgical group, two patients had persistent symptoms. One patient had a previous colon interposition for severe reflux esophagitis after a Heller myotomy and Belsey antireflux procedure. The other patient had an esophageal myotomy and pyloroplasty for an esophageal motility disorder. Consequently, it was difficult to determine the cause of their continuing symptoms. When each patient was asked

whether he or she would have the operation if faced with the choice again, nine of ten said yes.

Endoscopy

Table 5 shows the preoperative and postoperative endoscopic findings. Before operation, all patients had endoscopic gastritis and no evidence of esophageal or duodenal mucosal abnormalities. After operation, the endoscopic gastritis healed in all but one patient who had atrophic gastritis associated with pernicious anemia. The duodenojejunal anastomosis was normal in all patients and no bile was seen in the stomach. One of the 10 patients had a jejunal ulcer that, as mentioned earlier, healed completely with H2 antagonists in 6 weeks.

Histology

Gastric biopsy was done in six preoperative and ten postoperative patients. Histologic scores of the biopsies are shown in Table 6. Despite the improvement in endoscopic gastritis, the histologic changes persisted in five patients (score: >1), although they were only minor in three patients. The two patients with the score of seven had intestinal metaplasia that persisted over follow-up periods of 21 and 33 months. Overall, there was no statistical improvement in the postoperative histologic scores.

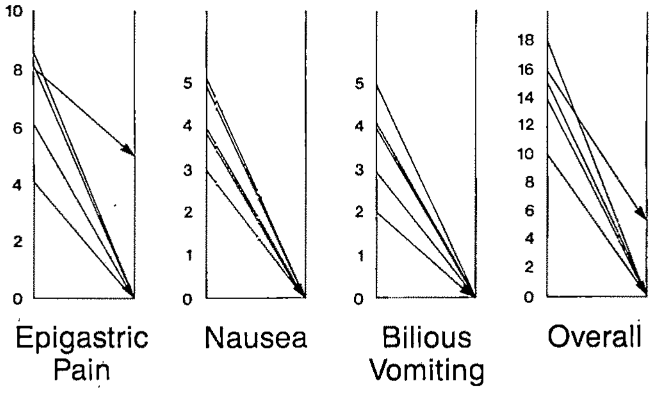

FIG. 9. Comparison of preoperative and postoperative symptoms in patients with primary duodenogastric reflux.

Gastric Emptying

Preoperative and postoperative gastric emptying curves are shown in Figure 11. All patients with primary duodenogastric reflux had normal preoperative gastric emptying. Two patients with postsurgical duodenogastric reflux had preoperatively rapid gastric emptying and in one patient the half-time was less than 15 minutes. Both patients had a previous pyloroplasty and the patient with particularly rapid emptying had a previous truncal vagotomy. With one exception, postoperative curves for both groups fell within the normal range as defined from scans on healthy volunteers and demonstrates that suprapapillary Roux-en-Y duodenojejunostomy does not retard gastric emptying. The one exception is a patient whose postoperative emptying became slightly rapid. When the postoperative geometric mean curves from seven patients were analyzed, the finding was similar.

Gastric Analysis and Serum Gastrin Levels

Table 7 shows preoperative and postoperative values for basal acid output, maximal acid output, and serum

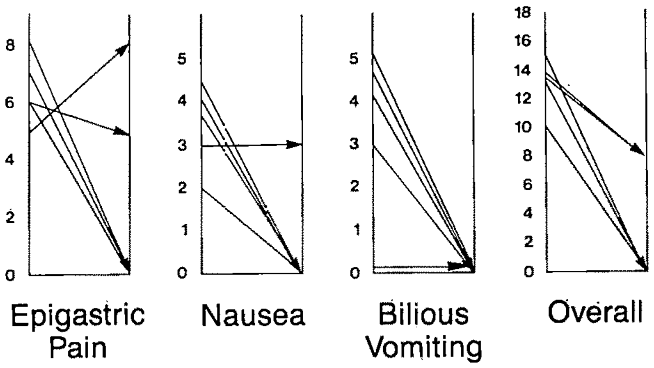

FIG. 10. Comparison of pre- and postoperative symptoms in patients with postsurgical duodenogastric reflux.

gastrin level. One patient (number 3 in the primary group) had hypersecretion before operation with elevated values for both basal and stimulated secretion. A limited proximal gastric vagotomy at the time of duodenal switch restored her acid output to within the normal range. A second patient (number 4 in the primary group) had acid secretion at the upper limit of normal range. After operation, her values crossed the upper limit and a jejunal ulcer developed that responded to H2 blockers.

Two patients with primary duodenogastric reflux had high preoperative serum gastrin levels, both of which remained elevated after operation. One patient had pernicious anemia and the other patient had normal gastric acid production and a normal secretin test.

TABLE 5. *Endoscopic Findings*

Body Weight

There was no statistically significant change in body weight after surgery.

Discussion

Suprapapillary Roux-en-Y duodenojejunostomy was designed to provide diversion of bile and pancreatic juice while leaving the proximal duodenum, pylorus, and stomach undisturbed. Conceptually, this has benefits over the classical Roux-en-Y gastrojejunostomy diversion procedure: it allows preservation of a normal gastric reservoir, antral and pyloric function, duodenal inhibition of acid secretion, and stimulation of the duodenal mucosa by chyme. An important part of the latter is the release of gastrointestinal hormones and digestive gland secretion. These functions are lost after the classical operation and result in early satiety, delayed gastric emptying, dumping, and the occurrence of jejunal ulcers. The latter has been reported to be as high as 10–15%. The incidence of ulcers can be reduced by the addition of vagotomy,[18] but this is not without its own side effects. Even with vagotomy, the possibility of jejunal ulceration still exists.[17]

The fear of performing a proximal duodenojejunostomy is the possibility of a high incidence of jejunal ulcers since the jejunum is exposed to the full barrage of gastric acidity without neutralization by biliary and pancreatic secretions. This fear may be unwarranted because of two physiologic factors. First is the observation that instillation of acid into the proximal duodenum suppresses basal and stimulated gastric acid secretions This effect was first shown in dogs by Sokalov[22] and widely confirmed by others.[23–29] The same mechanism

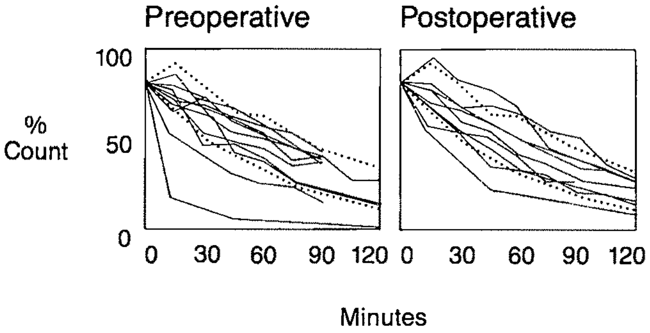

FIG. 11. Comparison of preoperative and postoperative gastric emptying scans taken in the anterior projection in patients who have undergone a duodenal switch procedure. The dotted line represents the 95th and 5th percentile limits measured in control subjects.

was shown in humans by Griffiths[30] and Shay et al.[31] Second is the observation in animals[32] and humans[33] that the proximal duodenum secretes bicarbonate, which, along with the overlying layer of mucus, provides a barrier to protect the surrounding mucosa from acid and peptic damage.

The current study indicates that these factors remain operational when the proximal duodenum is preserved in continuity with the stomach after diversion of biliary and pancreatic secretions. In the animal studies, there was a significant reduction in the incidence of jejunal ulceration compared with that observed with a direct pylorojejunostomy. In the human studies, jejunal ulceration did not occur unless gastric hypersecretion was present.

The advantage of a suprapapillary Roux-en-Y duodenojejunostomy is that a vagotomy and alteration of gastric or pyloric anatomy are not necessary to prevent jejunal ulceration. This allows preservation of normal gastric function and avoids the complications associated with vagotomy and resection.[12,34,35] Critchlow et al. reported an experience with a similar procedure in three patients for the treatment of symptomatic duodenal diverticula.[36] No jejunal ulceration occurred and the patients remained symptom free on subsequent follow-up. An important observation is that patients do not have delayed gastric emptying after a "duodenal switch" as reported after a Roux-en-Y gastrojejunostomy and vagotomy. Consequently, this delay must be due to either the vagotomy or denervation of the Roux limb. For this reason, we avoid dividing the mesentery to preserve the nerve supply to the jejunum when constructing the Roux-en-Y.

The endoscopic gastritis observed in patients with duodenogastric reflux is believed to be due to regurgitated bile and pancreatic enzymes. Both have been shown experimentally to be capable of damaging the gastric mucosa in animals,[37,38] and in humans, the presence of both in the stomach has been associated with gastric ulcer.[39,40] The "duodenal switch" procedure effectively diverted bile and pancreatic secretion and resulted in endoscopic healing of gastritis.

The histologic gastritis observed before operation rarely resolved. Persistence of intestinal metaplasia after bile diversion appears to account for elevated postoperative histologic scores. This phenomenon may be analogous to the development of Barrett's epithelium with gastroesophageal reflux and, like Barrett's, a return of the mucosa to normal histology, after removal of the stimulus to its production, may never occur or may take many years.

In humans, duodenogastric reflux occurs sporadically.[41] Increased duodenogastric reflux has been measured in patients with esophagitis, gastric ulcer, cholelithiasis, and previous cholecystectomy.[6,9,42–44] We reported five patients with the primary abnormality discovered during an evaluation of foregut symptoms. All complained of epigastric pain, nausea, and bilious vomiting. Two patients had documented gastroesophageal reflux disease, none had cholelithiasis, but all had endoscopic gastritis. Four of these patients had an alkaline gastric pH shift when measured over 24 hours.

When subjected to a discriminant analysis, the alkaline change had a high probability of being caused by excessive duodenogastric reflux. One patient, with gastric hypersecretion, did not show an alkaline shift or a positive discriminant analysis, but duodenogastric reflux was confirmed by radionuclide scanning. It may be that patients who have duodenogastric reflux after an acid-reducing procedure, initially had the primary disease, which was masked by hypersecretion. A clue that duodenogastric reflux might be present in a patient with hypersecretion is the persistance of bile reflux symptoms while the patient is receiving H2 blockers. Such patients are likely to have persistence of symptoms after vagotomy, and the addition of a duodenal switch to the initial procedure may be, as in our patient, beneficial to the successful control of symptoms.

The mechanism by which reflux occurs in the patient who is not operated on is poorly understood but probably related to a functional abnormality of the duodenum or pylorus.[5,41] The abnormality does not appear to affect gastric emptying in that all our patients who did not have previous surgery showed normal emptying curves.

Lawson showed in animals that severe duodenogastric reflux can cause a reduction in the number of parietal and chief cells in the gastric fundus.[38] In humans, a decrease in acid production has been observed with duodenogastric reflux and was ascribed to the loss of parietal cells or back diffusion of hydrogen ions. In severe forms, this can cause alkalinization of the antrum and elevated serum gastrin levels. Two of our patients with primary disease had a high serum gastrin level, one of whom had pernicious anemia. It may be that pernicious anemia is the end stage of duodenogastric reflux.

Of the five patients with postsurgical duodenogastric reflux, two had persistent epigastric pain and nausea after the biliary diversion procedure. Both patients had a history of esophageal motility disorder requiring a myotomy for relief of dysphagia, and one patient had an esophagectomy and colon interposition for intractable symptoms. This history may account for some of their current complaints.

In two patients with primary disease, a concomitant Nissen fundoplication was done to correct coexisting documented gastroesophageal reflux. All patients with postsurgical disease had a prior esophageal procedure: three had esophageal myotomy, and two had an antireflux operation. Thus the overall incidence of esophageal disease in our patients with duodenogastric reflux was 70% (7 of 10), suggesting that an underlying diffuse foregut disorder exists. Initially, the symptoms of duodenogastric reflux, gastroesophageal reflux, or an esophageal motor disorder may predominate. Correction of the predominant component may allow the symptoms of the other components, if present, to emerge. This emphasizes the importance of a careful preoperative and postoperative evaluation of patients with benign foregut disease. What might be considered a failure of a previous procedure to improve symptoms is, in reality, the emergence of symptoms due to another abnormality not appreciated before the operation.

Prolonged medical therapy consisting of H2 antagonists, antacids, and sucralfate did not relieve symptoms of epigastric pain, nausea, and bilious vomiting, and was the driving force for surgical therapy. Our experience indicates that if the patient has preoperatively marginal or definite hypersecretion, a limited proximal gastric vagotomy should be performed with the initial operation. Patients with normal and low gastric acid secretion do not need a vagotomy to remain free from jejunal ulceration.

In summary, bile diversion by "duodenal switch" preserves the suprapapillary duodenum. Experimentally, this causes a significant decrease in the incidence of jejunal ulceration. Clinically, the operation corrects pathologic duodenogastric reflux, alleviates the symptoms of the primary disease, improves the symptoms of the postsurgical disease, heals endoscopic gastritis, does not delay gastric emptying, and is, in the presence of normal acid secretion, not ulcerogenic.

DISCUSSION

DR. JOHN L. SAWYERS (Nashville, Tennessee): In 1965, Toye and Williams in the United Kingdom described a new postgastrectomy syndrome, which was reflux gastritis, and differentiated this from chronic afferent loop syndrome, which had been confused with alkaline gastritis. They treated this "new syndrome" by inserting an isoperistaltic jejunal segment between the gastric pouch and the duodenum. In 1974, Dr. Herrington and I presented at the American Surgical Association results of an isoperistaltic jejunal segment *versus* Roux-en-Y gastrojejunostomy for alkaline reflux gastritis and concluded that the latter was superior.

We currently have 110 patients followed from a minimum of 1 to more than 10 years with a Visick I or II clinical grading, *i.e.*, a satisfactory clinical result, in 79% of the patients. The 21% of patients with less than a satisfactory result have no evidence of bile reflux gastritis into their stomach, but they have motility problems of slow gastric emptying or Roux limb syndrome. In two of the 110 patients, a marginal ulcer developed despite what we believed was a complete truncal vagotomy.

Is Dr. DeMeester's new operation of a duodenal switch an improvement over Roux-en-Y gastrojejunostomy? There are a few things that bother me about the technique, and I wish he would elaborate to us how he locates the exact point in the second part of the duodenum where he puts his GI stapler and avoids injury to the distal end of the common bile duct and accurately locates the ampulla. It is my impression from reading the manuscript that the duodenum is not open to locate the ampulla.

Gastric emptying was almost normal in all of his 10 patients. This is contrary to results that we have seen, and others have reported, after pyloric sparing pancreaticoduodenectomy operations in which about one third of the patients have delayed gastric emptying, at least for a while.

Dr. DeMeester, is this difference due to sparing the duodenal pacemaker because you divide the duodenum more distally in your duodenal switch operation?

Five of his patients who had remedial operation had no previous gastric operation. I have never done a remedial operation on anyone for primary duodenogastric reflux. I am concerned that there is an increasing number of patients diagnosed as having reflux gastritis with insufficient evidence to substantiate the diagnosis. Concern exists that some surgeons may be too eager to do remedial operations on patients with reflux gastritis.

Dr. DeMeester, however, has carefully studied his patients to document reflux, and I am sure that they all were symptomatic.

Although I am enthusiastic about operations to spare the pylorus, I am concerned about postoperative jejunal ulcer developing after this procedure. One of his ten patients has already had a jejunal ulcer, and I would like to ask him why he does not add proximal gastric vagotomy to all these patients since it is a safe type of vagotomy with minimal side effects.

DR. WILLIAM SILEN (Boston, Massachusetts): My colleague, Dr. Jonathan Critchlow, and I about 1 year ago described an identical procedure in the *Annals of Surgery*, but using that procedure for a different purpose. We have now used this same procedure in five patients who had recurrent cholangitis and pancreatitis associated with the accumulation of food and debris in a juxtapapillary duodenal diverticulum, with excellent results in all cases. Peptic ulceration has not developed in any patient, and although two of them have had early transient delay in gastric emptying, the long-term results have shown no problems with gastric emptying in patients followed for up to 5 years.

I recommend this procedure to avoid a difficult and potentially hazardous dissection of a duodenal diverticulum if one needs to come to grips with that problem. For the indication I am describing, the defunctionalized limb includes the second, third, and fourth parts of the duodenum, and therefore the jejunum can be transected about 20 cm distal to the ligament of Treitz, but the end-to-side jejunal jejunostomy can be made very close to the end-to-end duodenal jejunostomy, thus allowing adequate mixing of food with bile and pancreatic juice, which in our opinion is the most important factor in preventing peptic ulceration.

There are abundant data in the literature that indicate that if one interferes with adequate fat digestion by whatever means, that is diversion of bile and pancreatic juice *far* distally in the small intestine by ligation of the pancreatic duct or by extensive resection of the small intestine, the well-known inhibitory effects of adequately digested and micellerized fat in the small intestine are lost. In the procedure that we have described to divert gastric content away from the diverticulum, mixing and fat digestion can proceed virtually normally because the end-to-side jejunostomy can be placed close to the end-to-end jejunostomy.

Whether the more distal displacement of bile and pancreatic juice for diversion of duodenal content away from the stomach, as required for the indications proposed by Dr. DeMeester and his colleagues, will eliminate the well-known enterogastrone inhibitory effects of fat, remains to be seen. It is going to depend on whether 55 cm is enough to interfere with adequate fat digestion and inhibition of acid secretion by micellerized and digested fat.

Finally, I believe, as alluded to by Dr. Sawyers, one must exercise great caution in the diagnosis of pathologic duodenal gastric reflux because the criteria for this entity are far from precise.

DR. C. THOMAS BOMBECK, III (Chicago, Illinois): I, too, was privileged to read this manuscript last night and would commend it to all of your attention. It is an excellent review of what is a very difficult and fortunately uncommon subject. The information in this paper could well be measured by the pound rather than by the page.

There are two outstanding or somewhat remarkable findings in this paper, and the first of them is the construction of a Roux loop drainage procedure that essentially has no component of the Roux Loop syndrome. That is, 100% incidence of a perfectly functioning Roux loop drainage procedure.

The authors attribute that to preservation of the innervation of that Roux loop, although it is placed somewhat down the duodenum. There are many other explanations for that, and I wonder if they have pursued any of them, for instance, measuring duodenal hormone levels with various stimuli in both the patients and in the animals.

The second remarkable finding is the incidence of improvement in bile gastritis. As all of you know, and has already been mentioned two or three times, the selection criteria for patients with bile gastritis for eventual surgical treatment are not at all clear. Many people have attempted to use the identity of the refluxed material: what composes it, how much bile salt there is present, how much trypsin, and so forth. There has not been any adequate explanation for this.

The authors use two methods of selection of these patients. In the first they say that they simply selected 10 of 202 patients from this patient population. I wonder what criteria they used to do that with.

Secondly, they investigated all these patients using one relatively new modality, which was the alkaline shift method using 24-hour intragastric pH measurements. That is relatively unusual and may account for their high incidence of success. I wonder what they do attribute that to.

Finally, I would echo everyone's concern about the omission of vagotomy in this group of patients. Both in the human and in the dog series, I notice now, the incidence of jejunal ulceration was 10%. The addition of a limited highly selective vagotomy to this group of patients would require no more than about 30 minutes more in the operation with essentially no complications, and it would seem to me to be a worthwhile thing to do, at least until many more patients are accumulated.

DR. EDWARD WOODWARD (Gainesville, Florida): The Roux-en-Y syndrome of delayed gastric emptying is certainly not either well understood or completely solved. Most of the patients we see with alkaline reflux gastritis have had a truncal vagotomy and a Billroth II antrectomy. If one transects the afferent limb and implants it 60 cm down the efferent jejunum, only one fourth of such patients will have a satisfactory result. Another one fourth will be completely disabled by severe delay in emptying of the gastric remnant. We have found that those patients who will tolerate Roux-en-Y duodenal diversion can be delineated by a measurement of solid phase gastric emptying. We use technetium-99 incorporated in a poached egg. If 50% of the isotope has emptied from the stomach in the first 30 minutes, the patient will tolerate the operation outlined above. In those patients with delayed solid phase emptying, we have used extensive subtotal gastrectomy with the Roux-en-Y procedure. Although the results seem to be somewhat better, they are certainly not uniformly so. In about three fourths of such patients, the Roux-Y limb of jejunum is itself involved in delayed transit.

The authors have demonstrated both in the experimental animal and in humans that preserving the first portion of the duodenum in continuity will minimize marginal ulcer formation, presumably by inhibiting gastric acid secretion. They are to be congratulated on these excellent observations, and the operation they present for use in patients would certainly preclude the necessity for truncal vagotomy to avoid marginal ulcer. The 10% incidence of ulceration they observed, however, would seem that parietal cell vagotomy would be needed. However, it seems there would be a limited patient population in whom the procedure could be used. The authors have found five patients with primary reflux alkaline gastritis in the presence of an intact stomach and intact vagal innervation. I find this surprising indeed since we have seen only three such patients in 20 years.

DR. TOM R. DEMEESTER (Closing discussion): I would like to thank the discussants for their comments and thought-provoking questions.

First I will answer Dr. Sawyers' question about locating the papilla. After kocherization, the papilla can often be palpated through the wall of the duodenum between the forefinger and thumb, the former on the posterior and the latter on the anterior duodenal wall. In addition, a point can be localized along the medial border of the duodenum where the thumb and forefinger approximate each other. A 1-cm hole between the medial border of the duodenum and the pancreas can be made at this point by careful dissection using small clamps. Initially, we used to open the duodenum and press on the liver to encourage bile flow to assure ourselves that we were proximal to the papilla. Now that we have gained confidence, we use the GIA stapler to divide the duodenum, opening only the proximal staple line to make the anastomosis.

Dr. Bombeck and Dr. Sawyers both asked about delayed gastric emptying and why it did not occur in our patients. There are at least three possible answers to this question and probably many more opinions, since this is currently an area of intense interest.

First, five of our patients had a normal anatomical stomach and pylorus and five had a previous pyloroplasty. None had a gastric resection, and that may play a role.

Second, we took great care not to denervate the Roux limb by dividing the mesentery. The whole operation is actually done in the area of the duodenum without cutting the mesentery except for 2 cm along the mesenteric border of the jejunum where the anastomoses are done. This may retain normal motility in the Roux limb.

Third, we retained the first portion of the duodenum so that the chyme coming out of the stomach passed over the duodenal mucosa. There may be yet unknown or known hormones that affect the motility when that portion of the gut mucosa is stimulated by chyme. There are a host of possibilities to investigate that may shed some light on the physiology of gastric emptying. The fact that we preserve the duodenal pacemaker has also occurred to us, but this may be of limited value since there is the duodenojejunostomy anastomosis 2–3 cm distal to the pacemaker.

Many of the discussants focused their questions on how we documented the presence of duodenal gastric reflux. First, these 10 patients were selected from 202 patients referred to us specifically with complex foregut symptoms because of our interest in 24-hour pH monitoring. They all complained of nausea, epigastric pain made worse with eating, and bilious vomiting. They all had endoscopic gastritis. All of them had been treated for at least 2 years with a variety of drugs, including H_2 blockers, sucralfate, and/or cholestyramine, and were not adequately relieved of their symptoms in their opinion and ours. It was symptoms that drove the operation.

Because documentation of the disease is such a critical point, I would ask the moderator if I may show two slides. The first slide demonstrates the pH distribution according to time in the stomach (Figure 2 in the manuscript) for normals and one of the patients. Compared with normal subjects, represented by the shaded area, the patient had a shift in the pH of the stomach toward an alkaline side, both during the day and at night. The second slide (Figure 3 in the manuscript) shows the result of a computer-performed discriminant analysis of the pH data to determine the probability that the change in pH was due to duodenal gastric regurgitation and not secondary to a change in gastric motility or acid production. Eight of the 10 patients scored in the pathologic range. It is our belief that this type of technology adds objectivity to the diagnosis of duodenal gastric reflux in patients who have symptoms suggestive of the disease.

Dr. Silen, I appreciate your support by commenting on the long-term follow-up on three patients who had a similar procedure done for treatment of symptomatic duodenal diverticula. The lack of postsurgical ulceration in your patients would support our theory that retention of the proximal duodenum protects against ulcer formation.

Dr. Woodward commented on our measurement of gastric emptying. Our test using oatmeal mixed with a radionucleotide has been standardized against the "gold standard" technique of gastric emptying, that is using livers from chickens injected with the radionucleotide during life. We have found that oatmeal, more than any other substance, correlates closest to the gold standard and is easy to use in the clinic. As you know, it is inconvenient to keep live chickens around to support a routine test.

Lastly, there were a number of comments questioning the existence of duodenal gastric reflux in a primary form. I would like to emphasize that the story of gastric ulcer has never been completed. About two thirds of patients with gastric ulcers have normal or low gastric acidity. The possibility that duodenogastric reflux is a pregastric ulcer condition has been made before. To us it seems that there is a great similarity between this disease and gastroesophageal reflux. Initially, both can have symptoms with little histologic changes; chronically both can cause mucosa changes, ulceration, metaplasia, and neoplasm.

Compazine®

Injection 5 mg./ml.

brand of
prochlorperazine

Available in 25 mg. suppositories, too.

Do not use 'Compazine' in pediatric surgery.

©SmithKline Beckman Corporation, 1985

See brief summary of prescribing information on adjacent page.

The antiemetic physicians prescribe most*

COMPAZINE®

brand of

prochlorperazine

See complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: For control of severe nausea and vomiting.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; pediatric surgery; use in children under 2 years of age or under 20 lbs.; use in children for conditions for which dosage has not been established.

Warnings: The extrapyramidal symptoms which can occur secondary to 'Compazine' may be confused with the central nervous system signs of an undiagnosed primary disease responsible for the vomiting, e.g., Reye's syndrome or other encephalopathy. The use of 'Compazine' and other potential hepatotoxins should be avoided in children and adolescents whose signs and symptoms suggest Reye's syndrome.

May cause tardive dyskinesia in some patients on neuroleptic (antipsychotic) therapy, usually long-term. This syndrome consists of potentially irreversible, involuntary dyskinetic movements. The risk of tardive dyskinesia and likelihood of irreversibility are thought related to duration of treatment and total cumulative dose of neuroleptic drugs.

Use in patients with bone marrow depression only when potential benefits outweigh risks. Patients who develop a hypersensitivity reaction (e.g., blood dyscrasias or jaundice) to a phenothiazine generally should not be reexposed to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Prochlorperazine may intensify or prolong the action of other C.N.S. depressants.

Use in pregnancy is not recommended except in cases so serious and intractable that, in the physician's judgment, drug intervention is required and potential benefits outweigh possible hazards. There have been instances of prolonged jaundice, extrapyramidal signs, hyperreflexia or hyporeflexia in newborn infants whose mothers received phenothiazines. There is evidence that phenothiazines are excreted in the breast milk of nursing mothers.

Precautions: The antiemetic action of 'Compazine' may mask the signs and symptoms of overdosage of other drugs and may obscure the diagnosis and treatment of other conditions such as intestinal obstruction, brain tumor and Reye's syndrome (See Warnings). Postoperative aspiration of vomitus has occurred in a few surgical patients who received prochlorperazine as an antiemetic. When used concomitantly with cancer chemotherapeutic drugs, may obscure vomiting as a sign of these agents' toxicity. Deep sleep and coma have been reported with prochlorperazine, usually with overdosage.

Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent *in vitro*, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Permanently stop neuroleptic therapy if neuromuscular reactions occur in pregnant women or in children.

In children with acute illnesses or dehydration, use only under close supervision. Avoid high doses and parenteral administration when cardiovascular system is impaired since hypotension has occurred. Use cautiously in patients with glaucoma. Use with caution in persons who will be exposed to extreme heat since phenothiazines may interfere with thermoregulatory mechanisms. Phenothiazines can diminish the effect of oral anticoagulants. Phenothiazines can produce alpha-adrenergic blockade. Thiazide diuretics may accentuate orthostatic hypotension that may occur with phenothiazines. Antihypertensive effects of guanethidine and related compounds may be counteracted when phenothiazines are used concomitantly. Concomitant administration of phenothiazines with propranolol results in increased plasma levels of both drugs and may also precipitate phenytoin toxicity. Phenothiazines may lower the convulsive threshold; dosage adjustments of anticonvulsants may be necessary. Presence of phenothiazines may produce false positive phenylketonuria (PKU) test results. Patients should not receive 'Compazine' 48 hours before or 24 hours after myelography with the contrast medium metrizamide.

Adverse Reactions: Drowsiness, dizziness, amenorrhea, blurred vision, skin reactions. Hypotension. Cholestatic jaundice, leukopenia, agranulocytosis. Fatty changes in the liver have been observed in a few patients who died while receiving the drug (no causal relationship has been established). Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, tardive dyskinesia, and a variant, tardive dystonia. Contact dermatitis is a possibility if 'Compazine' Injection (solution) inadvertently gets on hands or clothing.

Other adverse reactions reported with 'Compazine' or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., severe hypotension in mitral insufficiency or pheochromocytoma). Grand mal and petit mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat and organophosphorus insecticides; dryness of mouth, nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, ejaculatory disorders/impotence, priapism, atonic colon, urinary retention, miosis and mydriasis; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; pancytopenia, thrombocytopenic purpura, eosinophilia, hemolytic anemia, aplastic anemia; biliary stasis; hyperglycemia, hypoglycemia, glycosuria; lactation, galactorrhea, gynecomastia, menstrual irregularities, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; mild fever after large I.M. doses; increased appetite; increased weight; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; neuroleptic malignant syndrome, which may be fatal; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits.

EKG changes have been reported. Discontinue long-term, high-dose therapy gradually.

Note: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported.

Supplied: Tablets—5, 10 and 25 mg., in bottles of 100; Spansule® capsules—10, 15 and 30 mg., in bottles of 50; Injection—5 mg./ml. in 2 ml. ampuls, 10 ml. vials and 2 ml. disposable syringes; Suppositories—2½, 5 and 25 mg.; Syrup—5 mg./5 ml.; Single Unit Packages of 100 (intended for institutional use only)—5 and 10 mg. tablets; 10, 15 and 30 mg. 'Spansule' capsules.

The Gut Origin Septic States in Blunt Multiple Trauma (ISS = 40) in the ICU

JOHN R. BORDER, M.D., JAMES HASSETT, M.D., JOHN LADUCA, M.D., ROGER SEIBEL, M.D.,
STEVEN STEINBERG, M.D., BARBARA MILLS, B.A., R.N., PATRICIA LOSI, R.N., B.S.N., AND DONNA BORDER, M.A.

The association between support elements (ventilator days = Vd, enteral protein = EnP, number of antibiotics per day = AB/d) and the magnitude of the septic state (SSS) and its bacteriologic manifestations (bacti. log) in 66 patients with blunt multiple trauma (mean HTI-ISS = 40) over 1649 days have been studied restrospectively. SSS is measured by summing the standard deviation units of change in the septic direction for the 16 measurements taken every day in the intensive care unit. Increasing Vd is tightly associated with an increasing SSS ($r = +0.52$), after day 10 an increasing bacti. log ($r = +0.21$ to $+0.32$), and an increasing AB/d ($r = +0.26$) (all $p < 0.001$, $N = 1615 - 1626$). The independent variables that best predicted Vd were delayed operations (DORS), day of rising EnP, and total positive blood cultures (TPC) (adj. R sq. = 0.84, F = 104, dF = 3/59). An increasing AB/d was associated with an increasing SSS ($r = +0.38$), increasing Vd ($r = +0.26$), and an increased bacti. log ($r = +0.14$ to $+0.18$) (all $p < 0.001$, $N = 1615$). Only an increased EnP was consistently associated with a reduced SSS ($r = -0.38$) and a reduction in bacti. log ($r = -0.10$ to -0.21) (all $p < 0.001$, $N = 1626$–1636). The independent variables Vd, EnP, AB/d, and TPC best predicted SSS for all surviving patients (adj. R sq. = 0.42, F = 268, dF = 4/1496). The patients who died of sepsis were not different in terms of bacti. log from those with equal Vd but were distinguished by zero EnP, high AB/d, and persistent ventilatory support. In conclusion, DORS is tightly associated with increased Vd, SSS, AB/d, and zero EnP. If Vd exceeds 10, there is an increasing bacti. log and evidence of infection probably from the gut. This responds only to increased EnP and not to AB/d. Death due to sepsis is not associated with increased bacti. log but with zero EnP and high AB/d and their consequences.

From The Department of Surgery, The Erie County Medical Center, and the State University of New York at Buffalo, Buffalo, New York

A CRITICALLY INJURED patient after initial treatment seems to become stable or improve for 2–3 days. A severe septic response may then develop with failure of several organs, especially the lung. This is typically treated with broad-spectrum antibiotics on the assumption that hidden infection is present. At about 10 days, bacteriologic evidence of infection develops, which seems to confirm the use of antibiotics earlier. The magnitude of the septic state then largely stabilizes while the bacteriologic evidence of infection gets worse. Repeated changes and additions of antibiotics seem to have little effect on the patient's course. The longer the course, the more likely the patient will die. A large variety of human and animal studies have shown excessive escape of normally confined wound destructive processes in patients and animals with major wounds and sepsis in association with suppression of the normal antibacterial systems (trauma immunology and polymorphonuclear cell literature) and the pulmonary failure (ARDS literature) in a way that suggests cause and effect. These combined observations have tended to confirm the course of the patient with blunt multiple trauma as outlined and to cause almost everyone to accept it as the normal course.

We would suggest that this is not the case and that there are good reasons to believe that the management these patients received in the initial surgical intervention and the subsequent 10 days in the intensive care unit (ICU) causes the pulmonary failure septic state to persist and directly induces the subsequent bacteriologically confirmed infections.[1] We will discuss evidence that bears on this point.

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

Submitted for publication: April 24, 1987.

Methods

This study consists of 66 retrospectively studied patients with blunt multiple trauma (ages 16–60 years) with an injury severity score (ISS) greater than 22 and no documented pre-existing cardiopulmonary hepatic disease who had 2.4 megabytes of data entered for 1649 patient days. This group of patients comprised patients from our study of the effects of fracture fixation on cardiopulmonary metabolic failure in blunt multiple trauma, all blunt multiple trauma patients who stayed in the ICU 14 days or more since 1979, and one patient with detailed metabolic studies who died in 1974. These patients were treated by the physician authors of this paper. All data were entered into the computer for each patient for the entire ICU stay plus data from floor care until the patient was clearly stable. The data consisted of all fluid intake and its contents, all fluid output and its source, all laboratory tests, and all diagnoses and procedures. The day of the hospital stay was used as the key time marker for such entries. All laboratory tests that were repeated within 24 hours were averaged to obtain a single value to characterize the day. At times when a laboratory test was not done, the values of the preceding and following days were averaged and that value was entered for the missing value. All bacteriologic data were entered by source and bacteria cultured for the day the culture was taken. All use and changes of use of antibiotics were recorded by hospital day (AB/d). The conditions of ventilatory support were recorded by hospital day together with the inspired oxygen and positive end expiratory pressure. All delayed operations were recorded by hospital day.

The data were recovered from the chart by three individuals who have had extensive experience recovering data from ICU patient records. These consisted of an experienced ICU head nurse who had worked with these patients (PL), an experienced nurse who has done many such chart reviews and who is also expert in the use of computers (BM), and another person who has 4 years of experience in such chart reviews and the use of the computer (DB). All data were entered into a computer with software specifically designed for the purpose at hand. This data base management system (Datamat®, Transtime Technologies, Tonawanda, NY) allowed conversion of the fluid intake and its components into grams of protein per kilogram per day with a subdivision into route of administration as to intravenous or enteral. The amino acid or protein content entered was based on the label on the substance given and on discussions with the dietitians in charge.

A sepsis severity score (SSS) was then calculated based on the standard deviations of change in the septic direction of the measured variable. The normal range was taken as the mean value plus or minus two standard deviations. The normal range was then divided by four to obtain a standard deviation. The mean normal value was then subtracted from the observed value and the difference divided by a standard deviation to obtain standard deviation units of change. A septic direction of change was defined for each variable. Only the standard deviational units of change in the septic direction were counted in the SSS.

The preceding process was done for each of the 16 observations commonly made every day in the ICU on every patient. The temperature used was the maximum temperature of the day. The other observations were electrolytes, blood gases, creatinine, glucose, bilirubin, WBC, platelets, and positive end expiratory pressure (PEEP). PEEP was entered directly as centimeters of water. The alveolar arterial oxygen tension difference ($A\text{-}aD_{O2}$) was calculated from the inspired oxygen and the arterial oxygen tension and then corrected for standard deviational units by the increase in $A\text{-}aD_{O2}$ that occurs in the normal lung with an increase in the inspired oxygen. Since the lung was characterized in terms of the septic response by three characteristics (PO_2, $A\text{-}aD_{O2}$, and PEEP), the contribution of the lung to the septic response was triple weighted.

The standard deviations in the septic direction for each of the 16 observations considered were then summed to give the SSS. No weight was given to changes in an observation from the mean in the direction opposite to the septic direction. Thus, leukopenia, for instance, was not considered.

Some observations have narrow normal ranges and some have wide normal ranges. This characteristic resulted in some observations giving a far smaller contribution in standard deviations (*e.g.,* temperature) than the weight the clinician would give such an observation and other observations giving far more standard deviations than the weight the clinician would give such an observation (*e.g.,* creatinine and bilirubin). Constant multipliers and dividers were then introduced until each observation for a patient with maximal sepsis had approximately the same weight in standard deviations.

The normal range of SSS is from 0 (all 16 variables at the proper mean value) to 32 (all 16 variables at the outer limit of normal).

The patients were divided into groups based on their duration of stay in the ICU. Group 1 stayed 3–7 days, Group 2 stayed 8–14 days, Group 3 stayed 15–21 days, Group 4 stayed 22–28 days, Group 5 stayed 29–135 days, and all patients in Group 6 died of sepsis at 22–43 days in the ICU. This division produced roughly equal numbers for the various groups (Group 1, N = 11; Group 2, N = 14; Group 3, N = 12; Group 4, N = 13; Group 5, N = 12; and Group 6, N = 4). To maintain a

constant N for statistical comparison of the groups, the study period was ended when half of the patients had been discharged from the ICU. Mean values were then used to fill the data base from the time of earliest discharge to the time when one half of the patients had been discharged. Data without this mean value fill are shown in many places subsequently (see especially Tables 10–16 and Figures 1–3, 6, 12, and 14). This procedure was followed only for those patients who continued to do well and did not return to the ICU for further care. In those patients who were discharged from the ICU and returned for further critical care, the patient was entered into the group that corresponded to his final discharge from the ICU, and no attempt was made to fill missing data.

Results

Table 1 shows the characteristics of the patients in means and standard deviations for all 66 patients as a single group and for each of the subgroups. The mean age is 29 years mean ISS is 40, mean number of diagnoses is 14, mean number of procedures is 12, mean days on the ventilator is 17, and mean days in the ICU is 25. At the bottom of the table is the analysis of variance between the groups. By this statistic, the groups are identical in age, ISS, sex, and the number of diagnoses and procedures, and differ at a statistically significant level in ventilator days (Vd), ICU days (TICUd), hospital days (THd), total cultures taken (TCT), total positive cultures (TPC), total blood cultures taken (TBCT), and total positive blood cultures (TPBC). The primary determinants of increased TICUd are the number of delayed operations, the day of rising enteral protein intake (REI), and the TPC (see Fig. 15). The correlation between ICU days and ventilator days is +0.92 ($p < 0.001$).

Table 2 shows the Pearson cross-correlations for the SSS to its components arranged by the magnitude of r for all observations on all 66 patients. It is to be noted that platelets have a nonsignificant correlation.

Table 3 shows the changing relationships with time of SSS to its components as judged by Pearson correlations. The time scale is 0–3 days, 3–10 days, and the period of REI for Groups 1–5. It is to be noted that the SSS components A-aD_{O2}, plate., CO_2v, glucose, creatinine, Vd, do not have a changing relationship with time to SSS. The SSS components and support variables that do not have a significant correlation on days 0–3 that later have significant correlations are PO_2, Na+, Cl−, bilirubin, albumin, EnP, IVP, TBCT, TPC, and TPBC. These abbreviations are as follows: (1) EnP = enteral protein in grams per kilogram per day and (2) IVP = intravenous protein or amino acids for the same dimension as EnP. The variables that develop an increasingly significant correlation and magnitude of correlation with the passage of time are EnP, PEEP, albumin, Cl−, Na+, WBC, pH, PO_2, TCT, TBCT, TPC, and TPBC. PCO_2 and K+ have a progressive negative relationship with the passage of time, whereas bilirubin has a biphasic relationship to time.

Table 4 shows the results of a stepwise linear regression of SSS to its components. Only 10 of 16 variables

REI Group 1 Days 3–7, Group 2 Days 5–14, Group 3 Days 6–21, Group 4 Days 5–28, Group 5 Days 11–50.

Variables whose coefficients remained significantly high ($p < 0.001$), throughout all time periods: A-aD_{O2}, venous CO_2, glucose, creatinine, temperature, and ventilator days.
Platelets remained insignificant throughout.

are required to reach an adjusted R2 of 0.986 and an F of 10,604. The variables not in the equation at step 10 are CO_2v, K+, Plate., pH, pCO_2, and PO_2. This analysis states that we could have adequately measured SSS by the use of the 10 remaining variables and that in this group of variables the leading role is played by PEEP, creatinine, glucose, bilirubin, A-aD_{O2} and WBC. It also shows that statistically we were able to maintain oxygen transport.

Table 5 shows the Pearson cross-correlations between the SSS for all days on all patients for EnP, Vd, IVP, TBCT, TPBC, TCT, and total nasogastric suction volume (TNG). SSS is tightly and positively correlated with all measures except EnP, which is negatively correlated. Finally, nasogastric suction volume increases with an increasing SSS as most clinicians would have suspected.

Table 6 compares the Pearson cross-correlations for EnP and Vd with the bacteriology log, Vd, FFP, and TRBC. All EnP correlations are highly significant and negative, whereas all Vd correlations are highly significant and positive. Increasing EnP is associated with decreasing use of red cells (TRBC) and fresh frozen plasma (FFP), whereas increasing Vd is associated with increasing use of these support elements. EnP has a negative correlation with Vd. Table 7 compares the Pearson cross-correlations of EnP and Vd for all patients with SSS and the seven major components of SSS. Again, all EnP correlations are highly significant and negative, whereas all Vd correlations are equally significant and positive.

Table 8 shows the Pearson correlations of the number of antibiotics per day (AB/d). There are positive highly significant correlations with SSS, Vd, IVP, and the components of the bacteriology log, and only EnP has a highly significant negative correlation. The bacteriology correlations are of smaller magnitude than the other correlations. If antibiotics were effective in the presumed way, the bacteriology log correlations should be negative. Table 9 shows the Pearson correlations to TPC of SSS, the bacteriology log, and AB/d. These are all highly significant and positive, with the smallest numerical value for AB/d. Again, the AB/d correlations should be negative if they had the effect desired.

Table 10 shows the initial characteristics for a patient grouping based on the first 20 days with no enteral protein (N = 10), minimal enteral protein (N = 9), and the rest of the patients in the ICU the same length of time (N = 8). The initial characteristics of those patients are not statistically different by ANOVA, but they differ significantly for Vd per group with the greatest number for the group with no enteral protein.

Table 11 shows the associations between no enteral protein, minimal enteral protein, and normal enteral protein for the first 20 days of the hospital course expressed for the table as the mean per patient day. These comparisons exclude the patients in the ICU less than 20 days. The reference group (A) has 0.61 g protein/kg/day plus 0.48 g intravenous protein/kg/day (total 1.09), whereas the minimal enteral protein group (B) has 0.110 + 1.40 (total 1.51) and the no enteral protein group (C) has 0.01 + 1.820 (total 1.82). Thus, total protein intake per kilogram per day increases as enteral protein intake decreases. In association with these changes, SSS increases from group A (48) to group B (55.5) to group C (73.6) at a highly significant level statistically ($p < 0.0001$). In addition, all bacteriology log measurements increase at a highly significant level statistically from group A to C and total positive blood cultures from group A to B or C. Figure 1 shows SSS by day as the mean per group for the reference group (A) and the no enteral protein group (C) plus mean daily EnP and total protein (TP) for a 6–21-day period. The two groups begin at the same SSS and the difference in SSS continually evolves over the 20 days of observation. Thus, the absence of enteral protein intake is associated with progressively more septic behavior by all criteria, and this is not compensated for by increased intravenous protein support, which provides almost twice as much protein.

Table 12 shows the characteristics of a group of patients left in femoral traction for 21 days relative to a control group of patients who had open reduction and internal fixation of their fractures initially or after femur traction up to 9 days. There is no statistically significant

* ANOVA reveals statistically significant differences between groups for all comparisons at p < 0.000.

difference in the groups for age, ISS, or the number of diagnoses or procedures.

Table 13 shows the effect of 21 days of traction on these patients in terms of mean values per patient day for 21 days. SSS is statistically significantly higher (72 *vs.* 47, p < 0.000), whereas EnP is lower (0.14 *vs.* 0.39, p < 0.000) and IVP (0.87 *vs.* 1.11) and TP (1.00 *vs.* 1.49) are also significantly lower (p < 0.04 and 0.000). The components of the bacteriology log and SSS are all increased with traction at a significant level (p < 0.006). Figure 2 shows SSS by day per group for these two groups and the mean EnP and TP for days 6–21. It is apparent that SSS for the group in traction progressively rises, whereas SSS is stable for the group with ORIF and no traction.

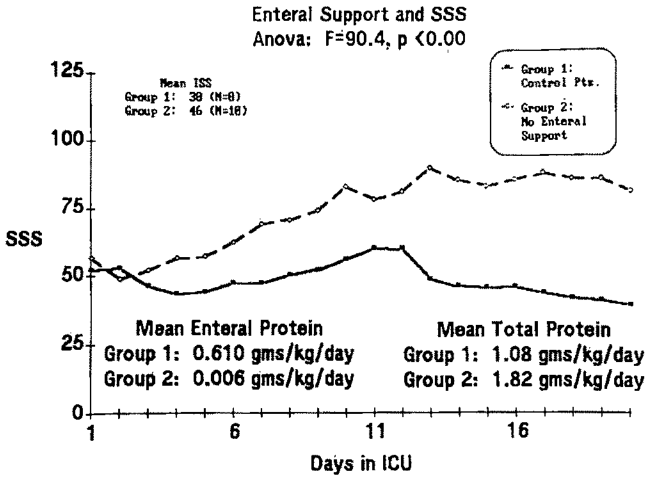

FIG. 1. A comparison of the associations of zero EnP or 0.61 g of EnP with SSS on a group daily mean basis. See Tables 10 and 11 for further details. The group with zero EnP has a progressively rising SSS, whereas the group with 0.61 g of EnP has a stable to falling SSS over the 21 days of observations. The group with zero EnP receives much more total protein (1.82 *vs.* 1.08 g). There is no mean data fill in this comparison.

Table 14 shows the characteristics of groups of patients who have 0–2 delayed operations *versus* those who had 3 or more delayed operations. Age, ISS, and the number of diagnoses are statistically identical, whereas the number of procedures, ICU days, and Vd are increased at statistically significant levels (p < 0.02).

Table 15 shows the effect of delayed operations on these patients by mean values per patient day for SSS, EnP, IVP, and the components of the bacteriology log. Three or more delayed operations are associated with a higher SSS score (60.3 *vs.* 46.54), a lower EnP (0.24 *vs.* 0.41), a higher IVP (1.27 *vs.* 1.06), and an increase in all components of the bacteriology log (p < 0.001). Figure 3 shows SSS by day per group and mean EnP and TP for days 6–21. It is apparent that SSS for those with three or more delayed operations rises from days 1–10 relative to the other group and is then consistently greater.

SSS when analyzed for days 0–3 for all six groups is not statistically different among the groups by ANOVA (Fig. 4). The primary difference in SSS among groups arises in days 3–10. This changing relationship is further discussed in the section dealing with stepwise linear regression.

The relationships of IVP and SSS for the five surviving groups (constant N, mean data fill) are shown in Figure 4. The positive correlation between the magnitude of the septic state as judged by SSS and IVP per kilogram is in major part our therapeutic response to the septic state. Figure 5 shows the relationship of EnP to

TABLE 12. *Open Reduction and Internal Fixation of Femur Fractures (ORIF)* Versus *Traction for Femur Fractures: A Comparison of the Initial Characteristics of Each Group (Mean ± SD)**

Group	N	ISS	Age	No. of Diagnoses	No. of Procedures
ORIF femur fractures	47	40.0 ± 10.0	29.0 ± 12.2	13.8 ± 5.4	11.2 ± 16.8
Traction for femur fractures	4	42.5 ± 18.9	32.0 ± 18.0	17.0 ± 4.7	16.8 ± 10.8

* No statistically significant differences between the groups.

TABLE 13. *Effects of Traction* Versus *Open Reduction and Internal Fixation (ORIF) of Femur Fractures on the Following (Mean ± SD)**

					Mean per Patient Day			
Group	N	Enteral Protein (g/kg)	SSS	IV Protein (g/kg)	Cultures Taken	Blood Cultures Taken	Positive Cultures	+ Blood Cultures
ORIF femur fractures	47	0.39 ± 0.54	47.0 ± 14.4	1.11 ± 1.08	1.04 ± 1.88	0.30 ± 0.74	0.53 ± 1.19	0.08 ± 0.44

* Significant differences, all comparisons p < 0.006.

SSS for all five surviving groups (constant N, mean data fill). The tight association between falling SSS and REI is immediately obvious. Group 5 patients, who were the most septic for the longest time, received about 2.5 g total protein/kg/day in association with their survival. This intake was achieved with orders for 3.5–4 g of protein.

Figure 6 shows SSS as a function of days on the ventilator for each surviving group with variable N (no mean data fill) as they came off. It shows the values obtained only when the patient was on the ventilator and excludes all other values. The high SSS values, achieved in Groups 1–4 by day 10, remain stable and decline rather preciptiously near the end of the ICU stay. This does not occur in Group 5. In the lower panel, the declines in SSS are tightly associated with REI in Groups 2–4, even for those patients remaining on the ventilator. Even in Group 5 the expected relationship between EnP and SSS exists but there is no abrupt rise in EnP as there is in the other groups.

Figure 7 shows the effect of severe but survivable head injury in patients with multiple trauma on SSS, EnP, and IVP. It is apparent that in the first 4 days SSS is much higher than that shown in Figures 4 or 5, but that there is little effect after the first 4 days and that the relationship to enteral protein exists here as elsewhere.

Figure 8 shows the fluid volumes associated with this sort of exogenous protein support for all surviving patients by day with variable N. It is apparent that the typical patient receives about 4500 mL/day on all days, which is composed of an increasing enteral intake and decreasing intravenous intake. The same figure shows a urine output of about 3000 mL/day. Oliguric renal failure occurred in one surviving patient.

Tables 16 and 17 show the effect of a change in antibiotic on SSS and blood bacteria. The effect of a change in antibiotics was tested by excluding the first 10 days of the courses (rising SSS period and the period of REI [falling SSS period]). Twenty-seven comparisons of the 3 days of SSS before and after a change in antibiotics were conducted using a paired t-test on mean values. There was no significant change in SSS associated with the change in antibiotic, and at the same time there was no significant change in EnP, IVP, or temperature. Table 17 explores the effect of a change in antibiotic on the blood bacteria using a forward 3-day window to observe

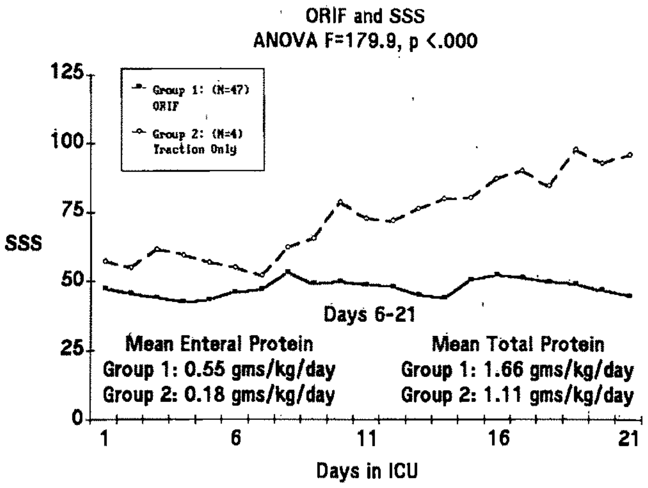

FIG 2. A comparison of the associations of femoral fracture internal fixation or femur traction over 21 days with the group daily mean SSS. See Tables 12 and 13 or more details. The group with femur traction has a progressively increasing SSS over the 21-day period relative to the stable or falling SSS of those with internal fixation. See also our previous report.[1] There is no mean data fill in this comparison.

TABLE 14. *Delayed Surgery: A Comparison of the Initial Characteristics of Each Group (Mean ± SD)*

Group	N	ISS	Age	No. of Diagnoses	No. of Procedures	ICU Days	Ventilator Days
0–2 delayed operations	39	39.5 ± 10.1	28.9 ± 12.4	14.1 ± 5.7	10.1 ± 5.6*	15.8 ± 9.5*	9.4 ± 8.5*
>3 delayed operations	27	42.6 ± 11.3	29.1 ± 11.7	14.9 ± 5.7	15.0 ± 9.2*	40.6 ± 29.9*	27.7 ± 28.2*

* Significantly different, $p < 0.02$.

TABLE 15. *The Effects of Delayed Operations (Mean ± SD)**

					Mean per Patient Day			
Group	N	Enteral Protein (g/kg)	SSS	IV Protein (g/kg)	Cultures Taken	Blood Cultures Taken	Positive Cultures	+ Blood Cultures
0–2 delayed operations	39	0.41 ± 0.54	46.5 ± 14.6	1.06 ± 1.17	0.98 ± 1.74	0.29 ± 0.75	0.42 ± 0.89	0.03 ± 0.19
>3 delayed operations	27	0.24 ± 0.43	60.3 ± 23.0	1.27 ± 0.95	1.55 ± 2.24	0.51 ± 0.94	0.82 ± 1.44	0.16 ± 0.57

* All comparisons significantly different at $p < 0.001$.

for change in the blood bacteria in the 30 patients who had positive blood cultures. A positive change was defined as the disappearance of bacteria within 3 days of an added antibiotic or the appearance of new bacteria within 3 days of stopping an antibiotic. A negative change was defined as the appearance of new bacteria in the presence of an added antibiotic within 3 days. This provides for twice as many positive as negative correlations. The data show that these patients have many changes of both antibiotics and bacteria, but that there is an equal association of positive and negative blood bacteria changes in a forward 3-day window with an antibiotic change. There is no evidence to support a beneficial effect of antibiotics on the septic state in terms of changes in blood bacteria in this particular cohort of patients.

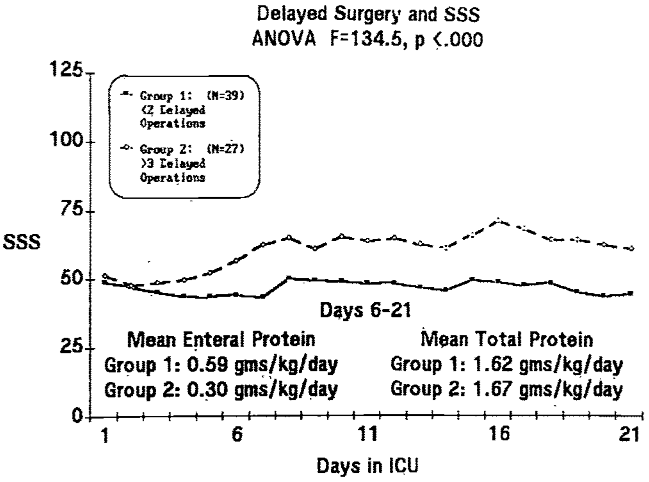

FIG. 3. A comparison of the association of various numbers of operations (0–2 *vs.* 3 or more) with SSS. See Tables 14 and 15 for more details. It is to be observed that 3 or more delayed operations are associated with a persistently higher SSS than 0–2 delayed operations. See Figure 14 for the effects of delayed operations on ICU days. ICU days correlates tightly ($r = 0.92$, $N = 62$, $p < 0.001$) with ventilator days. See Tables 5, 6, and 7 for the association of Vd with SSS, bacti. log, and components of SSS. There is no mean data fill in the comparison.

The patients who died of sepsis (Group 6) had a rise in SSS of 110 to 130 in association with an average of two positive blood cultures of 16 taken. The rise in SSS that led to death is shown for three of four patients in Figure 9 as a function of time. Two of these patients received large amounts of intravenous protein, and two received totally inadequate total protein by the standards of Group 5. Three of the four patients received no enteral protein support (shown in Fig. 9) and the fourth patient received little total protein support for a prolonged pe-

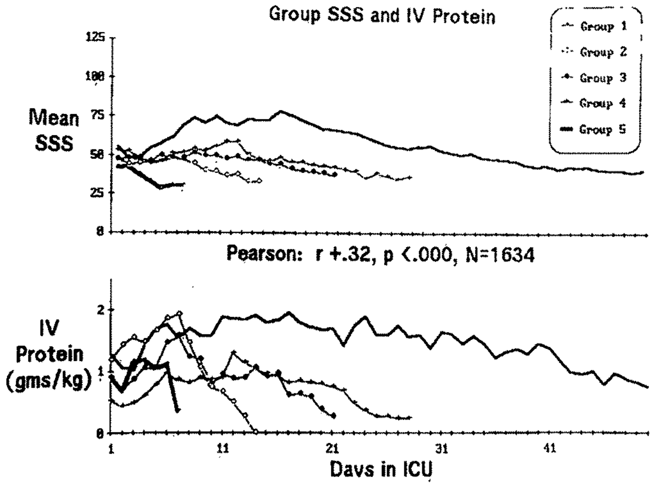

FIG. 4. A comparison of SSS by group to IVP by group daily mean. It is obvious that the two curves are parallel as shown by the Pearson correlation data. This is a result of our therapeutic response to the septic state.

riod and then increasing enteral protein in the premortem phase when her lungs were in severe failure. This patient was in traction at all times and was discharged from the ICU and then returned to the ICU. The results for this patient are shown in Figure 10. This patient had an ISS of 36 with an acetabular fracture that was treated in traction, operated on inadequately 7 days later, and as a result received continued traction until death. She received little protein *via* any route until she was close to death. She died of multiple systems organ failure due to severe protein malnutrition with failure of the lungs as an oxygen transport organ as a major component. She had four positive blood cultures for *Staphylococcus epidermidis* in her terminal phase. Figure 11 shows values for a patient who died in 1974.[16,17] The values for this patient are shown because we have reported on the patient's death metabolically in great detail. At day 10 his splanchnic extraction of glutamine went to zero and concurrently the SSS rapidly rose. At day 17, the splanchnic extraction of isoleucine and methionine also went to zero. From day 10 to day 17, the SSS continued to rise rapidly. This patient also received no enteral protein and grossly inadequate total protein. Death occurred from multiple systems organ failure.

The patients who died of sepsis had an average of two positive blood cultures, whereas the patients of Group 5, all of whom lived, had an average of eleven positive blood cultures. We have shown that increasing Vd is tightly associated with an increasing number of positive blood cultures. Figure 12 plots group mean positive blood cultures per patient ventilator day by group mean ventilator days to compensate for the different numbers

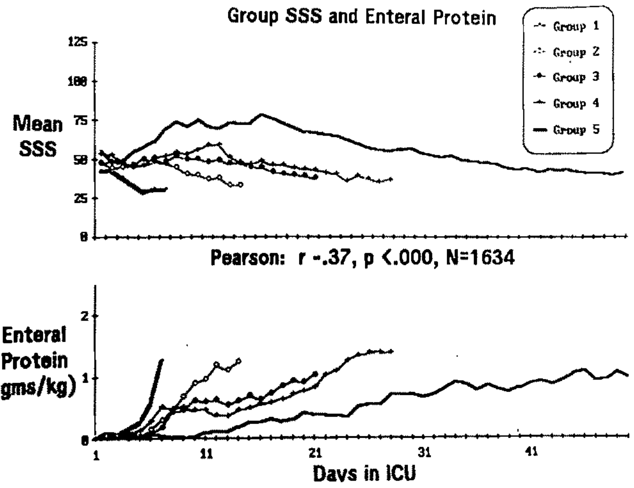

FIG. 5. A comparison of SSS by group daily mean to EnP by group daily mean. This data base has a constant N per group achieved with a mean data fill between the time of earliest ventilator weaning in a given group to the time when one half the patients had been discharged from the ICU. The relationship of a rising EnP to a falling SSS for each group is obvious and confirms the Pearson correlations.

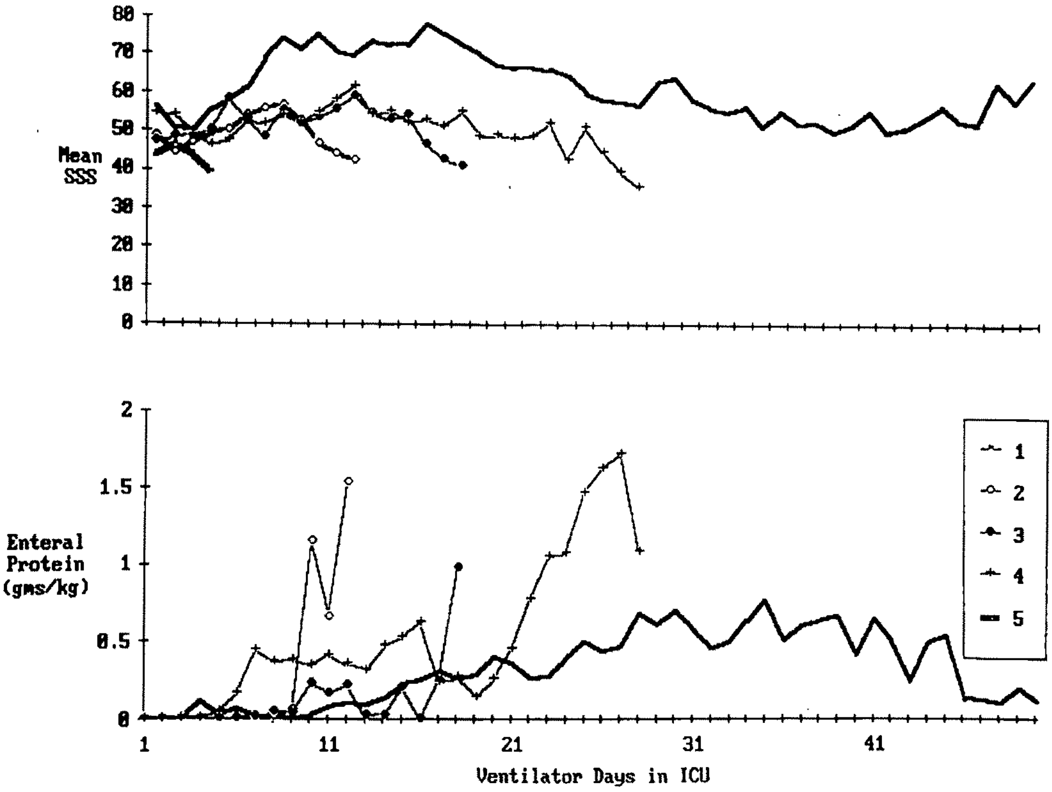

FIG. 6. A comparison by group of SSS and EnP daily mean values for those patients still on the ventilator. This produces a variable N as the patients are weaned but has no mean data fill. SSS in each group after the initial 10 days is stable and falls abruptly in Groups 2–4 as EnP rises rapidly. This occurs when they are gotten out of bed and sitting up while on the ventilator. Group 1 is sitting up out of bed at 2–3 days and the patients eat after coming off the ventilator. Group 5 has the expected reciprocal relationship between SSS and EnP but does not have the rapid rise in EnP that Groups 2–4 have.

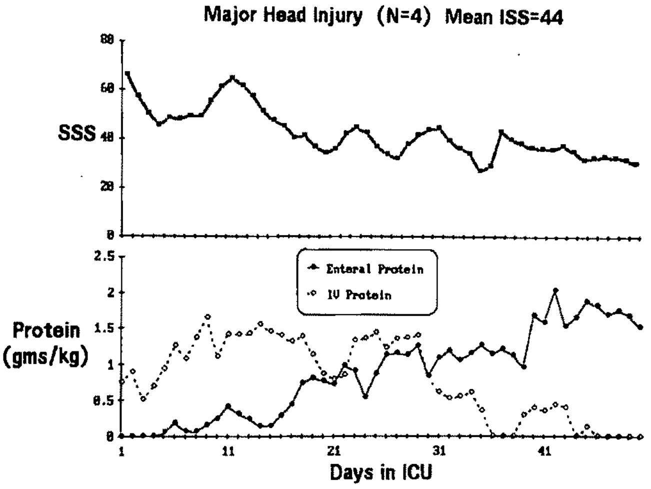

FIG. 7. Major but survivable head injury and its effects on SSS, IVP, and EnP. It is apparent that SSS is very high but declining in the first 4–5 days. After that time, the behavior of SSS and ENP is the same as the other groups.

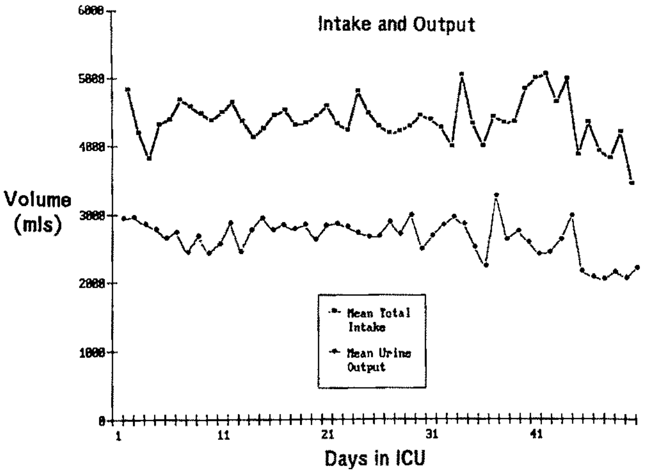

FIG. 8. Intake and output with variable N. These patients received 4500–5000 mL of fluid intake per day and had 2500–3000 mL of urine output per day. On this regimen, oxygen transport was well maintained statistically (see Table 4) and oliguric renal failure did not occur. This regimen results from the fluid volumes necessary to deliver 2–2.5 g protein/kg/day.

of ventilator days among groups. It is immediately apparent that an increasing number of ventilator days is tightly associated with an increasing number of positive blood cultures per patient ventilator day beginning at day 9 (Group 3) and that the group of patients that died of sepsis (Group 6) had the appropriate number of positive blood cultures for the number of days they spent on the ventilator as extrapolated from the surviving patients. Group 6 is not different from the surviving groups by this bacteriologic measure.

Table 18 shows SSS for a day of a positive blood culture, a day of a negative blood culture, and all days without a positive blood culture. SSS is statistically significantly greater on a day of a positive blood culture compared with a day of a negative blood culture or a day without a positive culture. The increase in SSS from a day of a negative blood culture to a positive blood culture is not a clinically significant increase, but the increase in SSS from no positive blood culture to a positive blood culture is both statistically and clinically significant.

One must deduce that blood cultures are taken in the septic patient, and that they are positive makes only a slight additional contribution to the septic state.

Table 19 lists the number of patients per group, the

TABLE 16. *A Comparison of 3 days before and 3 days after a Change in Antibiotic Therapy is Noted: Effects on Septic Severity Score, Temperature, Enteral and IV Protein Intake (Mean ± SD)**

	N	Septic Severity Score (SSS)	Enteral Protein (g/kg)	IV Protein (g/kg)	Temperature
3 days before change	27	74.5 ± 25.0	0.15 ± 0.28	1.79 ± 1.08	38.9 ± 0.8
3 days after change	27	71.5 ± 24.0	0.20 ± 0.34	1.89 ± 1.31	38.9 ± 0.8

* Days excluded: first 10 days and days of rising enteral intake. No significant differences observed.

TABLE 17. *The Effects of Changes in Antibiotic Therapy on Blood Bacteria in 30 Patients in a Forward 3-day Window (Mean ± SD)**

Mean antibiotic changes per patient		5.33 ± 3.38
Mean blood bacteria changes per patient		5.67 ± 6.29
Positive correlations	Number of times blood bacteria disappeared (as expected) when a new antibiotic was added *or* number of times blood bacteria appeared after an antibiotic was discontinued.	0.93 ± 1.26
Negative correlations	Number of times new bacteria appeared with the addition of a new antibiotic.	0.80 ± 1.00

* By definition, positive correlations have a probability of *2 times* negative correlations. No significant change observed.

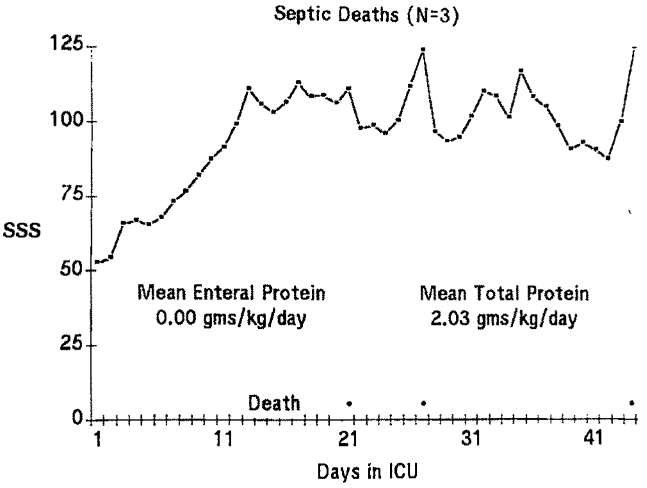

FIG. 9. This shows the behavior of SSS in the three patients who died with zero EnP. The hospital days of their deaths are noted at the bottom. Death is associated with an SSS between 100 and 125 and occurs earliest in the patient who received the least exogenous protein.

number of patients with positive blood cultures per group, the total blood cultures taken per patient in each group, the total positive blood cultures per patient per group, and the total match of blood bacteria to any other culture report from any other site per patient with a positive blood culture. We have excluded from the table those organisms most commonly believed to come from the gut, which are Candida, *S. epidermidis*, and Pseudomonas. The fraction of patients per group with a positive blood culture increases with increasing time in the ICU on the ventilator. In the 21–28-day period, this reaches 50% (Groups 3 and 4). In the period greater than 28 days, it reaches 100% (Group 5). Total blood cultures taken per patient also increase in direct proportion to the number of days in the ICU. The percentage of blood cultures taken that are positive remains consistently less than 35% but rises rapidly from Group 2 (4%) to Group 3 (12%) to group 4 (17%) to group 5 (35%). The match of the blood bacteria to other sites reported in a plus or minus 3-day window also rises rapidly from 0.2 in Group 3, (days 14–21), to 2.4 in Group 4, (days 21–28), to 4.1 in Group 5 (days 28–135). Thus, with increasing time on the ventilator, there is increasing bacteriologic evidence of infection in sites other than the blood as well as in the blood.

Group 6 comprised the patients who died of sepsis. These patients all had one to four positive blood cultures (mean: 2.2 of 16 taken) that were primarily obtained just before death. The number of positive blood cultures obtained per patient in this group was the number to be expected for the days these patients spent on the ventilator as extrapolated from the surviving patients (cf. Group 4 here and Figure 12). The match of the blood bacteria to any other site report in a plus or minus 3-day window is also that expected from Group 4 (1.5 *vs.* 2.4). In fact, compared with Group 4, the percentage of positive blood cultures of those taken is also approximately the same for Group 6 (13.7%; Group 4, 17.3%).

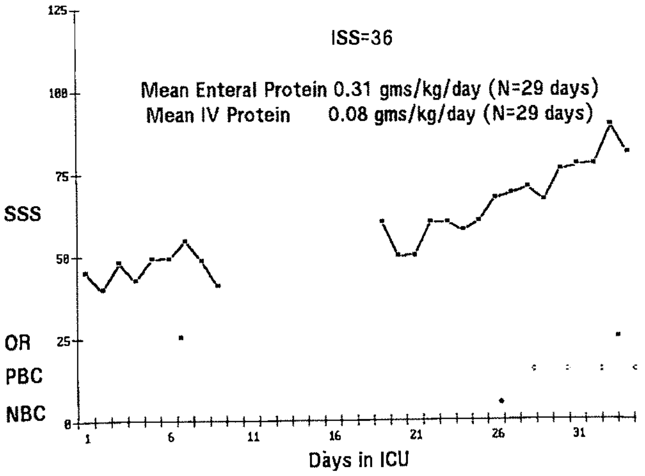

FIG. 10. This shows the SSS of the patient who died in association with continued femoral traction for an acetabular fracture. It represents a typical late septic death from conservative fracture management. The patient seems to get better and is discharged from the ICU. The doctors assumed that the patient is doing well, whereas the nurses' notes are filled with reports of the patient not eating. She receives no nutritional support for almost 26 days after injury and several days after she re-enters the ICU in crisis. As she is dying of failure of her lungs as an oxygen transport organ and multiple systems organ failure, she is given enteral protein when it is too late. OR = operation, NBC = negative blood culture, PBC = positive blood culture.

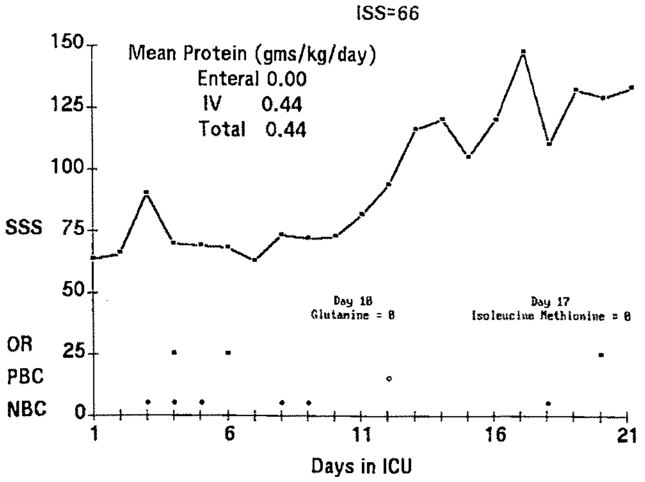

FIG. 11. The association of SSS in a patient who died of sepsis with zero EnP and very small total protein intake with splanchnic extraction. We have reported on this patient in great detail metabolically.[16,17] We therefore thought we should construct a SSS to compare with these metabolic measurements. SSS rises abruptly as glutamine extraction goes to zero on day 10 (see text for discussion) and then continues to rise as isoleucine and methionine extraction go to zero at day 17. These falling splanchnic extractions of glutamine and isoleucine are based on very low plasma concentrations produced by changes in muscle metabolism. OR = operation, NBC = negative blood culture, PBC = positive blood culture.

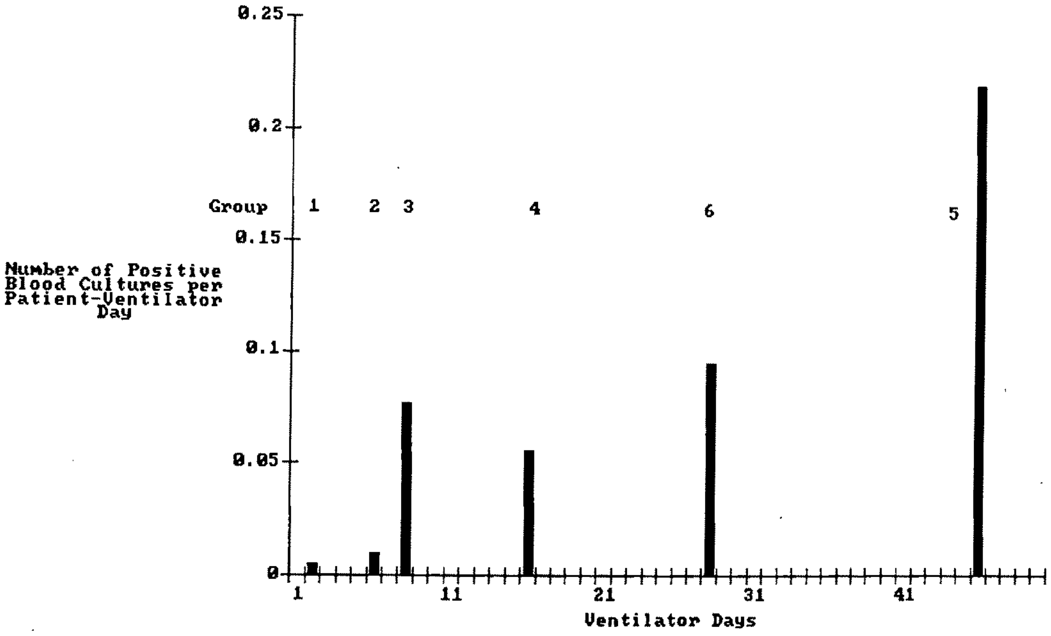

FIG. 12. The association between ventilator days and blood bacteria expressed by group as number of positive blood cultures per patient ventilator day and plotted as the group mean ventilator days. It is apparent that after 8–9 days on the ventilator the number of positive blood cultures per patient ventilator day rapidly increases and continues to increase up to ventilator day 46. The patients in group 6 died of sepsis and have the expected number of positive blood cultures for the days they spent on the ventilator as extrapolated from the surviving patients. This group is not different from the surviving patients by this measure.

Group 6 has no distinguishing bacteriologic evidence to suggest excessive infection relative to those who survived.

The most common organisms isolated from the blood of these patients were, in order of frequency: *S. epidermidis,* Candida, and Pseudomonas. These patients commonly had blood cultures positive for multiple organisms. If one bacterium was repeatedly cultured and the correct antibiotic chosen, then that bacteria commonly disappeared only to be immediately replaced by a bacterium resistant to the antibiotic used. The successful use of an antibiotic at most changed the name of the bacteria in the blood.

Table 20 lists a series of stepwise multiple linear regressions for SSS under different time conditions (0–3 days, 3–10 days, period of REI), for all surviving patients over all days, and all patients over all days. These regressions are not used as time series and do not predict SSS by day. The following independent variables are for condition: (1) Vd and EnP; (2) Vd, EnP, AB/d, (3) Vd, EnP, AB/d, and TPC, and (4) others. In days 0–3, the variables used are Vd and TCT (total cultures taken), and the adjusted R2 reaches only 0.125 and an F of 15.

TABLE 18. *Blood Cultures and the Septic Severity Score (SSS)*

	N	Septic Severity Score (Mean ± SD)
Days of positive blood cultures	107	67.4 ± 19.7*†
Days of negative blood cultures	274	62.8 ± 19.9*
Days of no positive blood culture	1536	53.6 ± 19.6†

* Statistically significant at $p < 0.04$.

† Statistically significant at $p < 0.000$.

We are unable to find satisfactory correlates of SSS in this period. This is the period when SSS falls, the groups are the same by ANOVA, and Pearson correlations show many nonsignificant correlations of SSS to its components. The correlation with SSS in this period is not improved with the use of ISS or the fluid volume given in the first 48 hours. These two variables have strong cross-correlations between themselves as might be expected.

Patients in Group 1 (Figs. 4 and 5) have all surgery done the night of admission including fractures. This group is largely synonymous with Group 1 in our earlier publication.[1] Because of total surgical care the night of admission, patients in Group 1 can sit up on the second to third day, are off the ventilator largely on that day, are spontaneously eating, and are discharged from the ICU by 7 days. Group 1 has the same ISS as the other groups. This same response occurs whenever the patients are gotten out of bed sitting up (Fig. 4) even though they are still on the ventilator (Fig. 6).

Days 3–10 for Groups 2–6 are a time of stable to rapidly rising SSS (especially Groups 5 and 6). In this period, reasonably good adjusted R2s (0.321 and 0.344) and Fs (102 and 76) for regressions in which SSS is dependent and the independent variables are AB/d and Vd or AB/d, Vd and TPC are obtained. All coefficients are positive and highly significant as opposed to zero. Adding TPC to AB/d and Vd produces only a slight rise in adjusted R2 and a considerable fall in F. TPC therefore does not add any large amount of new information to AB/d and Vd. This is a period in Group 2–6 of largely zero EnP and the enforced supine position, and, therefore, this variable is not entered.

TABLE 19. *Match of Blood Bacteria to other Sites in Groups**

	Group 1 (N = 11)	Group 2 (N = 14)	Group 3 (N = 12)	Group 4 (N = 13)	Group 5 (N = 12)	Group 6 (N = 4)	All (N = 66)
Number of patients with positive blood cultures	0	1	5	6	12	4	28
Mean number of blood cultures obtained per patient	1.5	2.6	6.6	11.0	31.0	16.0	11.0
Mean number of positive blood cultures per patient	0.0	0.1	0.8	1.9	11.0	2.2	2.6
Mean number of times blood bacteria matched bacteria cultured from other sites (±3 days) in patients with positive blood cultures	0.0	0.0	0.2	2.4	4.1	1.5	2.4

* Excluded: Candida, *S. epidermidis*, and Pseudomonas.

The time period REI is defined in Figure 5 for each group. This period varies in its beginning from Group 1 (day 3) to Groups 2, 3, and 4 (days 4–5) to Group 5 (day 11) and extends to the end of the study period for each group (day 7, Group 1; day 14, Group 2; day 21, Group 3; day 28, Group 4; and day 50, Group 5). It is this period in which the highest adjusted R2s (0.319 to 0.439) and Fs (234 to 278) are combined. The most basic relationship occurs with Vd and EnP, but the addition of AB/d and TPC clearly improves greatly the strength of the regression as judged by the change in adjusted R2 and a small decrease in F. Thus, these variables contribute new information.

This same improvement is seen when the data base derived from the whole course of all surviving patients (Groups 1–5) is used for regression. In this data base, addition of AB/d to Vd and EnP as an independent variable improves greatly the adjusted R2 (0.273 to 0.376) and F (285 to 302). Thus, AB/d includes considerable new information. The addition of TPC improves adjusted R2 (0.376 to 0.417) but decreases F (302 to 268). TPC adds some new information but not a large amount like AB/d.

The entry of all data on all patients (*i.e.*, including the deaths) causes some deterioration of the regression analysis characteristics since both adjusted R2 (0.417) to 0.366) and F (268 to 234) drop under identical conditions (Vd, AB/d, TPC, and EnP as independent variables), whereas N increases (1496 to 1611).

This problem is best examined in Group 6. Overall the regression of SSS on Vd and EnP for those four patients gives an adjusted R2 of 0.153 and an F of 11.5. AB/d and TPC when offered in this regression are not used because their coefficients are not significantly different from zero.

For Group 6, we are unable to do a satisfactory regression analysis with the variables that work fairly well for those patients who survived. One patient in the

Vd = Ventilator days.
ABd = Antibiotics/day.
EnP = Enteral protein (g/kg).
TPC = Total positive cultures.

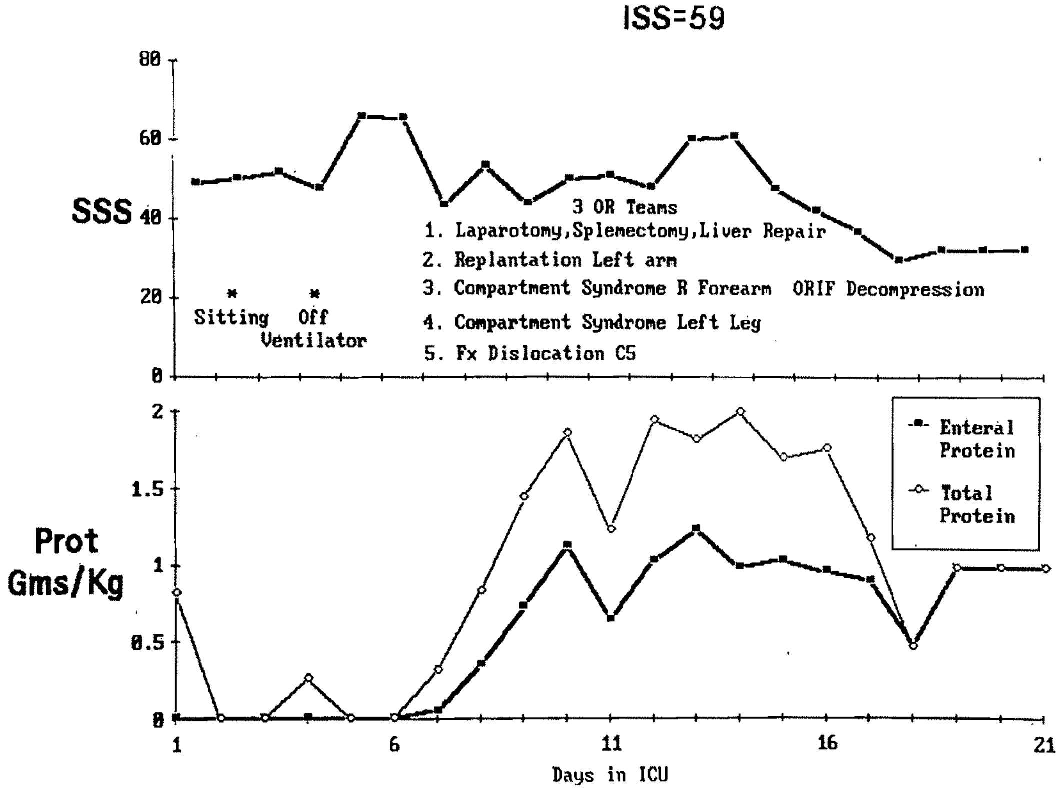

FIG. 13. The effects of initial total operative care followed by getting the patient out of bed and sitting up the next day on SSS, EnP, and IVP. This patient had severe life-threatening injuries and was left in shock with inadequate fluids for about 2 hours before being transferred to our hospital. He was an ideal candidate for the prolonged pulmonary failure septic state and perhaps death. Oxygen transport was vigorously restored and maintained throughout the operation. Three operating teams worked simultaneously in the first shift and two in the second shift. At the conclusion of the surgery, the patient could sit up out of bed the next day. He was off the ventilator on days 3–4 and had increasing EnP on day 6. His ICU course was short and without incident. This objective can be repeatedly achieved if simultaneous operating teams are used the first night.[1,10,14]

group had a different time course for SSS than the other patients (cf. Figs. 10 and 11). Excluding this patient did not improve our regression analysis. The dominant observations in this group are the lack of enteral protein intake and the lack of any bacteriologic differentiation from those who were in the ICU on the ventilator a comparable period.

The essential point of the regression analysis is that the variables found to be important individually in Pearson correlations are found to be important as an organized body of overall information by regression analysis. This analysis confirms the signs of variables previously found and shows that AB/d is again entered as a positive coefficient for SSS and not as the negative coefficient we would expect if the antibiotics were doing the job we desire. This analysis shows that increased numbers of antibiotics per day are associated with the patient getting worse.

Figure 13 shows the course of a severely injured young man (ISS = 59) who was initially taken to another hospital where he was allowed to be in moderate to severe shock for about 2 hours. He had a ruptured spleen and liver, amputation of the left arm above the elbow, a fracture of C5 with subluxation, a severe head injury, a comminuted fracture of the right forearm with a compartment syndrome that limited circulation to the right hand, and a compartment syndrome of the left leg without fracture that limited circulation to the foot. Oxygen transport resuscitation was achieved rapidly and the patient was operated on with oxygen tensions in the 150–200 mmHg range and urine outputs above 150 mL/h. The cervical spine was immobilized by traction. Three operating teams were employed: one for the abdomen, one for the left arm replantation, and one for the right arm decompression with open reduction and internal fixation of the fractures. The left leg was done after the abdomen and at the same time a halo vest was applied. With this management, the patient was sitting up and out of bed the day after his injury, he was off the ventilator at 4 days, and began enteral intake at day 7. The increase in SSS after weaning probably means he was weaned from the ventilator a day or two early. He was kept in the ICU for days 10–17 primarily to observe the circulation in his arm. On days 13 and 14 he had a septic response for which no bacteriologic site was ever found. This case illustrates management of night of admission that prevents the prolonged pulmonary failure septic state and the subsequent gut origin septic states we have been discussing. This objective can be achieved reproducibly as we have previously shown.[1]

Figure 14 shows the duration of stay of the individual patients in the ICU. The individual time varied from 3 to 135 days to form a logarithmically decreasing curve. It also shows the regression equation that best predicts TICUd based on the individual patient characteristics. The independent values that best predict the curve are

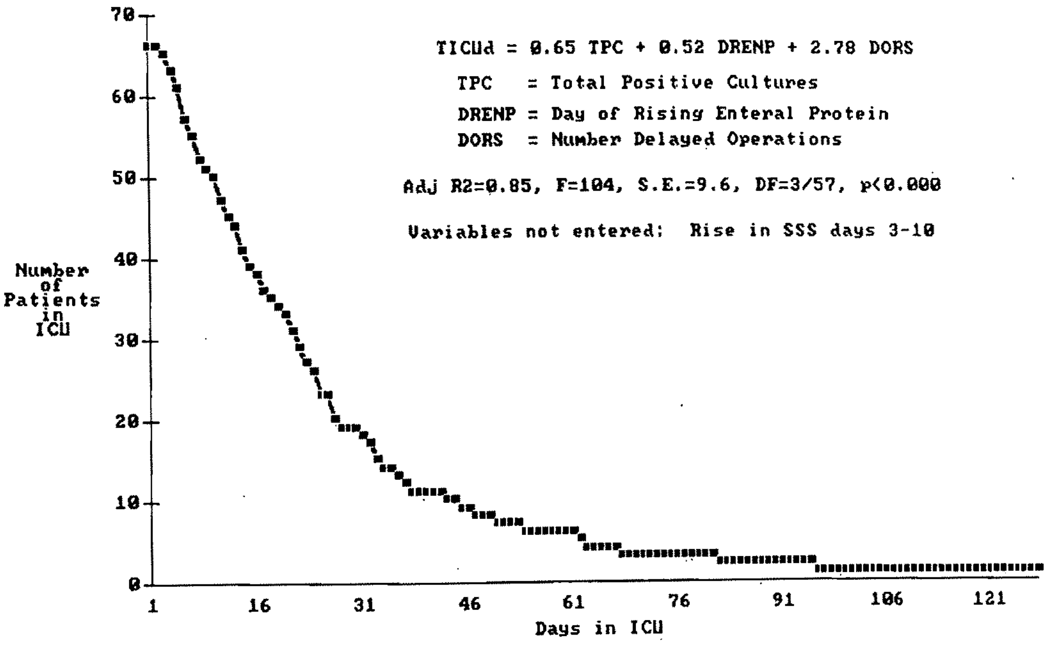

FIG. 14. A plot of ICU days and number of patients in the ICU each day shows a logarithmically decreasing curve. Total ICU days is best predicted with the independent variables: number of delayed operations (DORS), day of rising enteral protein (DREnP), and total positive cultures (TPC) (adj. R sq. = 0.84, F = 104, dF = 3/59). The variable of greatest importance is DORS and the next greatest is DREnP. TPC is highly correlated with both of these variables but does contain some new information.

number of delayed operations, TPC, and day of REI defined as the day it exceeded 0.3 g. Adjusted R2 is high at 0.85, whereas F at 104 is reasonable for the degrees of freedom. This regression is of extreme importance. All previous statistical comparisons have been based on the arbitrarily chosen groups and have been for intensive or daily variables. This analysis is based on individual patient characteristics and is for extensive variables. It therefore has an entirely different basis. The fact that it is using largely the same variables confirms the importance of the associations previously observed. Incomplete operative care the night of admission seen here as number of delayed operations is of dominant importance for the duration of stay in the ICU (TICUd). We have previously shown that TICUd is tightly correlated with TVd (Pearson r = 0.92, $p < 0.001$, N = 62) and that the bacteriologic evidence of infection is tightly correlated with TVd after day 9. In figures 1, 2, and 3 we show the effect of no enteral protein, traction, and three or more delayed operations on SSS and EnP. The effects are also shown in Tables 10, 11, 12, 13, 14, and 15. The essential point is that delayed operations of all kinds (not just fractures) are associated tightly with prolonged ventilator support and reduced enteral protein (see discussion for consideration of emergency operation). If these factors prolong ventilator support and reduced enteral protein beyond day 9, then bacteriologic evidence of infection and the gut origin septic states develop.

Discussion

We would suggest that the primary determinant of the magnitude of the septic state and the duration of stay in the ICU is incomplete surgical care the night of admission. We would further suggest that incomplete surgical care the night of admission leads to greater use of analgesics, prolonged use of broad-spectrum antibiotics and other drugs, intravenous lines, monitoring and drainage lines, ventilator lines, and patient care that produces the enforced supine position. Traction for fractures is only one method of producing the enforced supine position.[1] Secondary to the enforced supine position in the patient with multiple trauma, the viscera presses continuously against the diaphragm to produce a failure to deep breathe and therefore cough with resultant atelectasis and retained secretions. These activate the pulmonary alveolar macrophage to produce the septic state. In addition, the same position causes high capillary hydrostatic pressure and blood flow in the posterior dependent lung, which is not as accustomed to this as are the bases of the lungs. Concurrently, there is excessive escape of wound destructive processes such as complement split products, lysosomal destructive enzymes, procoagulant factors, oxygen free radicals, prostaglandin E (PGE2), and leukotrienes and escape of normally released products such as the interleukins. These are all macrophage products and their release begins after macrophage maturation and activation. This occurs about days 3–4 and accounts for the stable to falling SSS from days 0–3.

The excessive escape of wound destructive processes produces, when combined with the enforced supine position and its effect on pulmonary blood flow, damage to pulmonary tissue to enhance the pulmonary failure and to further activate the pulmonary alveolar macrophage.

The combined release of wound and pulmonary macrophage interleukins then accentuates the systemic septic state. This effect may be enhanced by entry of gut endotoxin to the systemic body to activate the hepatic macrophages. The excessive escape of wound destructive processes not only makes the pulmonary failure worse but also suppresses the immune system and the function of the polymorphonuclear cell. For the polymorphonuclear cell, this occurs by excessive escape of complement split products so that the cell is desensitized to a second exposure and thus has a reduction in all its functions.

The Lung, the Wound, and the Subsequent Bacteriologic Evidence of Infection

PGE2 in the wound normally suppresses immune function by inhibiting production of interleukin 2 (IL2) and therefore generation of T-helper inducer cells.[2,3] With a normal lung, all PGE2 is cleared from pulmonary artery blood by the lung so that none enters the systemic body.[4] This allows locally generated PGE2 to be utilized widely in the systemic body as a microregulator of metabolism and function. The existence of major wounds and macrophage activation greatly increases the load of PGE2 presented to the lung. The enforced supine position and its associated pulmonary failure probably reduces the capacity of the lung to clear PGE2. In addition, pulmonary damage produced by a variety of mechanisms plus the embolic material presented to the lung (activated aggregates of white cells and platelets, fat emboli) under these conditions all activate the pulmonary alveolar macrophage. This macrophage then becomes a source of PGE2. We speculate these combined events allow PGE2 to enter the systemic body to suppress T-cell mediated immunity generally and the secretory IgA system of the mucous membranes specifically.[2,3] This effect plus the absence of enteral food intake and the effect of prolonged broad-spectrum antibiotics on the commensal bacteria then produce the tight association between ventilator days and the bacteriologic evidence of infection if they last beyond 10 days.[5-9]

Normal Function of the Upper Airway, Oropharyngeal, and Upper Gut Antibacterial Systems

The secretory IgA system is of dominant importance for the oropharynx, the airways of the lung, and the gut. Secretory IgA after synthesis is delivered directly to the surface of the mucous membranes in mucus, *via* salivary gland secretions for the oropharynx, and *via* biliary tract secretions for the upper gut. Secretory IgA does not kill bacteria but rather binds to them and thus prevents binding of the bacteria to cells of the mucous surface. It works in conjunction with the commensal bacteria of the gut, which bind to cells of the mucous membrane where they consume nutrients and release metabolites toxic to many pathogenic bacteria. These metabolites operate in the oropharynx in conjunction with lysozyme, another product of the salivary gland.

The bacteriocidal mechanism of the upper gut, oropharynx, and airways is stomach digestion of bacteria and the secretory IgA bacterial complex. This depends on the ciliary ladder of the airways to deliver mucus to the pharynx and the physical movement of saliva from its point of secretion to the pharynx. This combined material is then swallowed for stomach digestion. The dominant factor that causes the whole system to operate properly is food ingestion. This stimulates secretion of the salivary glands, liver, and stomach while physically cleaning the oropharynx and esophagus and locally supporting growth of the commensal bacteria. Food ingestion at the same time specifically stimulates growth and replication of the enterocytes, secretion of mucus, the gut associated lymphoid tissue and immune system, the secretion of bile salts to neutralize endotoxin, and subsequently, defecation to reduce the penetration of bacteria and endotoxin in the colon. As a result of these functions, the upper gut below the oropharynx is largely sterile and the barrier function of the mucosa is well maintained.

Origin of the Bacteriologic Phase of the Septic Response

Largely due to the enforced supine position, these patients remain in pulmonary failure requiring intubation and ventilatory support with all of its associated management and become more septic or at least remain the same. In response to these problems, they receive a large number of medications that keep them lethargic. They remain in the enforced supine position (horizontal crucifixion position) because of this and the many lines for support, monitoring, drainage, and the need for delayed planned operations. These medications may also inhibit salivary, biliary, and gastric secretions. At the same time, the stomachs of these patients are alkalinized to prevent stress ulcers. Because the patients are septic, they receive prolonged broad-spectrum antibiotics that kill the commensal bacteria and help the gut to evolve antibiotic-resistant bacteria. The endotracheal tube and the medications largely prevent enteral food intake, while also preventing movement of the mucus of the airways into the pharynx and maintaining a partially open mouth so that the oropharynx dries out. The endotracheal tube provides a pathway for bacteria from the oropharynx to the airway of the lungs.

In addition, these patients have a generalized suppression of T-cell mediated immunity with a speculated suppression of the secretory IgA system, and a PGE2 systemically altered metabolism.[2,3] While these are occurring, the absence of food intake progressively decreases the function of the gut mucosa as a barrier, while the enforced supine position augments the gastric and colonic stasis of the basic ileus. This provides more time for bacterial growth and penetration in the stomach and inhibits defecation to maintain a high colonic penetration pressure for endotoxin and bacteria.

Death from sepsis does not occur from the bacteria unless they produce destruction of the lung (?pneumonia) that prevents oxygen transport (two patients). The bacteria are merely markers of advanced organ failure generally but especially of the gut mucosa. All patients who died of sepsis had no enteral protein intake or a prolonged period of no enteral protein intake and were in the enforced supine position. Death from sepsis probably occurs from entry of gut endotoxin into the body to damage the function of all organs. It is probably also true that the hepatic damage that occurs reduces bile salt secretion to detoxify endotoxin so that the endotoxin in the gut is more toxic.

The essential point is that the treatment of the pulmonary failure septic state of the first 10 days in an inappropriate way based partly on an assumption of a bacterial origin directly inhibits practically every aspect of function of the normal antibacterial system of the oropharynx, airways, and upper gut. Secondary to this, the gut origin bacteriologic septic states begin around 10 days of critical illness with ventilator support. After this, the problem becomes increasingly one of bacteriologic sepsis due to the antibiotic-resistant bacteria generated in the first 10 days.

Van Saene et al. from Groningen have defined the normal commensal bacteria of the gut.[8] They showed that with increasing days of ventilatory support with conventional prolonged broad-spectrum antibiotic use in the trauma patient, this flora becomes increasingly pathogenic and antibiotic resistant. The oropharyngeal flora was then found in the upper airways and stomach and finally in the blood, pneumonia, urinary tract, and wounds.[9] They then tried to define a group of antibiotics that were active against pathogenic bacteria and largely commensal bacteria neutral. They used these antibiotics to selective decontaminate the gut with special emphasis on the oropharynx. They showed with their approach but with historic controls a considerable reduction in infection (80% to 15%) and mortality (5 of 47 to 0 of 51).[6,7] Marshall et al. from Montreal have reported a very high mortality in association with the same antibiotic-resistant bacteria in infections in patients in the ICU and the appearance of the same bacteria in the stomach.[5]

This hypothesized course best explains the positive correlation and coefficients obtained for SSS that are strongest and most positive for ventilator days, next for antibiotics per day, and weakest for total positive cultures. The same rationale explains the strong negative correlations and coefficients for EnP that strongly supports all of the normal antibacterial mechanisms of the oropharynx, airways, and upper gut and encourages defecation for the lower gut. These same concepts clearly apply to the duration of stay in the ICU correlations and coefficients where the independent variable of greatest importance is the number of delayed operations, which is positive. The variable of next greatest importance is a rise in enteral protein intake above 0.3 g protein/kg/day.

The data presented here are completely consistent with preceding data on this topic. Thus, the entire blunt multiple trauma fracture literature states unanimously that conservative management with femoral traction of fractures of the femur, acetabulum, and weight-bearing pelvis relative to immediate operative management is associated with a considerable increase in the magnitude and duration of the pulmonary failure septic state that follows blunt multiple trauma and in the number of late septic deaths.[1,10–14,33] These same data also show the increased bacteriologic phase beginning at 10 days.[1] These are probably all gut origin septic state deaths and bacteremias. The duration of the pulmonary failure septic state in our previous work had no statistical relationship to the magnitude of the original injury as judged by the Hospital Trauma Index–Injury Severity Score (HTI–ISS) but was tightly associated by every criterion with the days of femoral traction.[1] Despite the fact that HTI–ISS should reflect the total magnitude of devitalized tissue present, we had chosen to interpret the pulmonary failure septic state as resulting from the action of the macrophage on fracture hematoma and devitalized tissue since this was resected with our open internal fixations.[1]

This is no longer a feasible interpretation. Thus, femur fractures may be internally fixed open (resection of hematomas and devitalized tissue) as we did or closed (hematoma and devitalized tissue left in place) as Bone et al. did in their prospective randomized study.[1,10] Both techniques result in the same beneficial effect in terms of reducing the duration and magnitude of the pulmonary failure septic state, and both allow the patient to be out of traction so that he can sit up relatively pain free a day or two after injury. We must therefore conclude that in the patient with blunt multiple trauma, the enforced supine position produced by traction by itself increases the magnitude and duration of the pulmonary failure septic state. This is also consistent with no relation of HTI–ISS to the magnitude and duration of the pulmonary failure septic state.

This is an important conclusion since the patient may be in the enforced supine position (horizontal crucifixion position) for many other reasons, such as the medications required to keep the endotracheal tube in place, the need for several delayed planned operations, and the multiple lines required for intravenous support, monitoring, drainage, and ventilatory support. This problem is well illustrated by our data on traction, delayed operations, and no enteral protein support in addition to the correlations with three or more delayed operations. It is this particular factor that makes days on the ventilator such an important variable.

The data on EnP fits exactly into our previous work,[15-17] the work of Clowes and associates,[18-21] the work of Alexander and associates,[22-24] the work of Antonacci et al.,[25] and some work of Wilmore and Souba.[26-28]

Wilmore and colleagues demonstrated that at least from the vascular side, the gut uses little glucose for energy and consumes predominantly ketone bodies and glutamine.[27,28] The septic response largely shuts off ketogenesis leaving the predominant fuel of the gut as glutamine.[15,29,30] We have shown in this paper that the patient we studied and reported on in great detail much earlier became much more septic as the gut plus liver glutamine extraction went to zero and then continued to get much more septic as the extraction of isoleucine and methionine went to zero. Our previous paper showed that these changes were secondary to a very low concentration of glutamine and isoleucine.[16,17] Glutamine is unstable and is not contained in intravenous amino acids. The patient receiving intravenous hyperalimentation uses muscle to convert valine to glutamine to support the enterocyte. One of the markers of impending death from sepsis is that the plasma valine concentration rises and valine begins to behave as an hepatic catabolized amino acid.[29,31] That observation is the counterpart of the low glutamine and zero glutamine extraction shown here and elsewhere. The infusion of glutaminase causes glutamine to go to zero in the experimental animal with the development of multiple gut mucosa lesions and death of the animal.[27] Hwang et al. have shown that addition of glutamine to conventional amino acids in experimental animals is associated with a thicker gut mucosa.[26] Thus, glutamine is clearly of considerable importance as a fuel to support the enterocyte. Ingested intact protein contains glutamine since it is stable under these correlations but more importantly contains a large number of amino acids that can easily be converted to glutamine.

Clowes and colleagues have shown in a number of papers that reduced central plasma clearance of amino acids is a marker of impending death in the septic patient.[18-21] Technically, central plasma clearance includes amino acid extraction by all organs other than muscle. It is clearly increased by intravenous amino acid infusion at the same time muscle amino acid release is reduced.[18] Those patients who eventually die have a much smaller increase in central plasma clearance when amino acids are infused than those who survive.[21] Practically, the dominant organs measured by central plasma amino acid clearance are clearly the gut and liver. These observations are entirely consistent with our observations but both are made on intravenous support.

Alexander and associates showed in a prospective randomized trial that in severely burned children an increase in enteral protein intake of 25–50% relative to recommended intake was associated with a considerable reduction in mortality rate, septic behavior as judged by antibiotic days, and the use of red cells and plasma.[22] They then showed in burned guinea pigs that enteral protein intake relative to intravenous, begun within hours of the burn, produced a much thicker gut mucosa in association with largely shutting off the septic neuroendocrine response.[24] Subsequently, they showed that intact protein was much more effective than an equivalent amino acid mixture.[23,32] Antonacci et al. repeated Alexander's prospective randomized study in severely burned adults and made the same observations of reduced mortality rate despite more severe burns in the high protein group. They also observed that nitrogen balance was not improved, whereas several aspects of immune function were greatly improved.[25]

All of this literature is entirely consistent with our observations of a very special effect of enteral protein in reducing the magnitude of the septic state and the bacteriologic evidence of the septic state in a way that cannot be achieved with intravenous protein or amino acids no matter how much is given. It is probably true that high intravenous amino acids are important in allowing survival while extreme septic states persist.[15] This is probably a direct cause of our high survival rate. That is an entirely different issue from reducing the magnitude of the septic state and its bacteriologic evidence. The evidence presented here and the background on which it is presented seems to show rather clearly that the conventional prolonged use of multiple broad-spectrum antibiotics does not benefit these patients and that it almost undoubtedly directly contributes to the gut origin septic states that lead to death.[6-9] Short-term selective antibiotics for specific problems probably have considerable beneficial effects. We have not investigated that problem. Finally, it seems equally clear from these data and those of others that the traditional surgical incomplete operative management the night of admission with its traditional associated ICU care and delayed operations (horizontal crucifixion position), directly contributes to and probably produces the prolonged pulmonary failure septic state that produces the antibiotic management that later produces the gut origin septic states.[1-13,33]

These combined events probably result in many of the emergency operations these patients require, which are probably direct products of their gut origin septic states (*e.g.*, tracheostomy, subphrenic abscess, wound infections, laparotomies to search for abscess, sinus abscesses, parotitis, prostatic abscesses). We have demonstrated rather clearly in our preceding paper that this whole complex can be avoided by total surgical care including fractures the night of admission followed by getting the patient out of bed, sitting up, and off the ventilator a day or two later.[1] The data presented here support that paper but point out that the same effect occurs with all delayed surgery, femur tractions simply being the most obvious and perhaps most potent example.

DISCUSSION

DR. MARTIN ALLGÖWER (Basel, Switzerland): Thank you for the privilege of discussing this most stimulating paper. I may point out a few things that support what Dr. Border said.

Since 1958, for us, fractures have been an emergency, particularly in multiply injured patients. It so happens that in 250 multiply injured patients by a combination of this aggressive total care to the body cavities along with the fractures of the long bones and with adequate ventilation under PEEP, the so-called fat embolism syndrome has practically disappeared and looks like a ghost of the past.

One day in Switzerland we had a surgical meeting where two neighboring cities presented their results with about the same number of multiply injured patients. Our neighbor city was complaining of a series of fatal fat embolism, whereas none occurred in our patient series.

We put our results together, submitted them to the *Journal of Trauma,* but it was not a prospective study and, therefore, it was turned down. We were so convinced of our approach that we did not ethically feel justified to make a prospective study.

I believe it is most noteworthy that we owe to John Border the insight that many so-called sequellae of trauma are related to treatment modalities rather than to the trauma as such. Studying the alveoloarterial O_2 difference in two patient groups, one in prolonged supine position with their fractures in traction, the other with the immediate total care, including operative fixation of long bone fractures, one finds the alveoloarterial O_2 difference normalized within 3 days in the aggressively treated group. The conservatively treated group needs 10 days on the average and does not even completely normalize its pulmonary physiology, demonstrating that prolongation of this pulmonary insufficiency is clearly treatment related.

One thing that was quite impressive to us was that at entrance to the hospital, the circulatory state seems to be of some prognostic importance. It may be appreciated by looking at the quotient of pulse rate over blood pressure, a value that we have proudly called "shock index." The impending danger appears at a value of 1 and becomes life threatening at 1.5. Evidence was supported by two groups of clinical findings. In 25 septic patients of a group of 250 multitrauma patients, the patients who were going to die had at entry to the hospital a shock index of 1.58 ± 0.52, whereas those who survived entered the hospital with a mean shock index of 1.17 ± 0.2. The same observation was true for a group of 84 patients with ruptured spleens in combination with other injuries. Those with a shock index of over 1 at entry to the hospital had twice the mortality rate of the group with a shock index below 1.

This simple and rather primitive parameter is valid only in the recently traumatized but seems to indicate that very early on some homeostatic mechanisms, even in reversible shock, get damaged. It would appear interesting to get more data concerning the simple parameter to evaluate recently traumatized patients. Incidentally, looking at this shock index in the four groups of patients recently published by Border, it completely agreed with his evaluation of the severity of injury.

Two questions to Dr. Border would interest me. We certainly should remember Jacob Fine who was pointing out clearly that susceptibility to any toxin, but particularly to endotoxin, is much increased even after a reversible shock episode. Is this mechanism instrumental in Dr. Border's observations?

The second question is how do you determine at what moment the ventilator becomes a hazard, or rather, how do you avoid it?

DR. GEORGE H. A. CLOWES, JR. (Boston, Massachusetts): Dr. Border kindly provided me with an up-to-date copy of his paper, which I believe will nicely supplement this talk.

The point I want to make is what Dr. Border has done for us. He has documented that the sicker the patient is, the worse his overall problem, and if his illness is substantially prolonged, he will die with probable overwhelming infection in what we term "multisystem failure."

I would like to point out that the basis for all this is what Dr. Border has partially pointed out, namely, protein synthesis. The immune system, as Wesley Alexander and others have clearly shown, does not work without protein metabolism going on. I presented data to this society 2 years ago in which we showed that people who died in multisystem failure with overwhelming infection did not respond to uptake of amino acids in their visceral tissues. The liver protein metabolism correlates with the amino acid uptake.

More recently, Dr. Bosari in our laboratory has conducted some experiments in which he showed that the protein synthetic rate in the small bowel increases significantly 24 hours after the onset of experimental infection.

Dr. Border has emphasized the need for the enteric nutrition, but if you look at his graphs, you will see that those people who were critically ill with abdominal problems, and consequently could not take enteric nutrition, also developed pulmonary complications and finally died. This is further documentation, although not definite, pointing to the gut as the origin of this infection that kills people.

The other point I want to emphasize is that the sooner we can begin administering enteric nutrition, such as in severely injured patients at risk of dying whom Dr. Border and I see at our respective hospitals, the better their chance for survival. This is evidenced by the fact that Dr. Border had only four deaths in 66 seriously injured patients, which says that he is doing something right.

I look forward to studying this manuscript in greater detail. It is a fine follow-up to what Dr. Carrico, Dr. Meakins, and others did recently in a symposium on multisystem failure where protein synthesis and pulmonary failure were emphasized.

DR. JOHN F. BURKE (Boston, Massachusetts): I rise to congratulate Dr. Border on the collection of a large and accurately compiled data base followed by an intensive statistical analysis of the data.

This area is important, and I believe the points made are of value to the management of massive injuries.

I have two questions. First, the evidence is, I believe convincing, that bacterial invasion at least in the early phases of recovery from injury are not a prominent cause of what you have called the septic state. If this state is not caused by bacteria, what mechanisms and what initiators of these mechanisms do you postulate cause this septic state?

Second, renal failure was conspicuously absent from all of your data. In your experience, is this because you have only looked at the patients who survived and not those who died, or is this related, at least partially, to the patients' age. Your patients were very young as the spectrum goes.

DR. J. WESLEY ALEXANDER (Cincinnati, Ohio): Dr. Border has given us a very complex analysis of a very complex problem.

He has brought into clear focus the fact that despite its relatively noxious content, we should no longer ignore the critical role of the intestine as a barrier. Nutrition has long been believed to be an important determinant for resistance to infection, but specific nutritional support of the intestine has been studied only recently.

(Slide) In a burned animal model, lack of enteral nutrition for only 24 hours can result in a 50% reduction in the jejunal mucosal mass, but this loss can be prevented by immediate feeding by the enteral route, although (Slide) not by the parenteral route. (Slide) Furthermore, intact protein in the diet prevents loss of mucosal mass better than crystalline amino acids of the same composition and amount as the intact protein.

In our studies with burned patients, there has consistently been a direct relationship between the amount of intravenous nutrition that the patients receive and the incidence of sepsis. (Slide) These studies and others have led us to the conclusion that both the septic state and hypermetabolism occur at least in part from a failure of the gut mucosal barrier and that the failure can be prevented by aggressive enteral nutrition with high protein diets, which is what Dr. Border is trying to show us.

I would like to ask Dr. Border three relevant questions. First, have you measured endotoxin levels in any of your patients, and is there a relationship to the septic severity score, or the amount of enteral protein given the patient? Second, is there a relationship between the septic severity score and the central nutritional proteins such as retinal binding protein, prealbumin, and transferrin, which in other studies have a close relationship to the development of sepsis? Third, in the patients studied, did it make any difference if the enteral protein was given as intact protein or as an amino acid solution?

DR. BENJAMIN F. RUSH, JR. (Newark, New Jersey): I simply cannot resist joining this symposium concerning Dr. Border's paper. I certainly congratulate him and his colleagues on a stimulating work and some controversial hypotheses.

John was kind enough to allow me to review the manuscript, and my first thought is that the flood of data derived from the daily management of patients in the intensive care unit is obviously overwhelming. This paper is an impressive example of number crunching in which a quarter of a billion bytes of data have been massaged to obtain meaningful correlations.

The most consistent finding is the correlation of an enteral protein diet with a decrease or absence of sepsis. Almost all other major parameters including parenteral protein without initial protein intake correlate positively with increased sepsis, with primarily enteral bacteria appearing in the blood in increasing numbers.

I have a comment and a question concerning this paper. The comment relates to our own work in a rat model of treated hemorrhagic shock.

In previous papers we have shown that if severe hemorrhagic shock in rats is treated vigorously, as we would treat shock in humans, that almost all animals survive the first hours or days of shock, but death occurs mainly in the second or third day, and if the rat survives past the third or fourth day, recovery seems complete. Death in these rats seems to correlate with the findings of positive blood cultures.

(Slide) Primarily, these cultures are of enteral bacteria. What we did in these animals was to tag some *Escherichia coli* with C-14 oleic acid and feed the animals on the C-14 radioactive compound. These are the radioactivity levels in shocked animals out to the third day. This is the radioactivity seen in unshocked controls.

(Slide) The interesting fact is that in 14 shocked animals, we had about a 50% survival rate. Of those animals who showed no radioactivity, only one animal died in the course of the 7-day follow-up. The mortality rate was 100% in those animals that showed radioactivity.

In most of these animals we were able to demonstrate positive cultures showing *E. coli* and other enteral bacteria.

Our conclusion from this was that the appearance of bacteria in the shocked animal is a very early event and that the source for the bacteria seemed to be almost certainly the gastrointestinal tract as demonstrated by the appearance of tagged bacteria from the gastrointestinal tract. That would, of course, fit with some of the comments made earlier by Dr. Allgower.

A question to Dr. Border is: how can he clearly eliminate the possibility that the ability to accept enteral feeding is not itself an index of the stronger, more resistant patient? Perhaps this question would best be answered by a prospective, randomized trial.

DR. ROBERT F. WILSON (Detroit, Michigan): I have a number of questions. What was the relationship between injury to the gut or brain and their effects on these data? Certainly if the gut is inovlved and you cannot use it for feeding for some time, this is going to change the results, and, obviously, head injury will also tend to make the outcome worse.

If, indeed, you can use the gut, it is certainly better than intravenous feeding. Is there any difference in the types of enteral feeding (gastrostomy *vs.* jejunostomy) that you should use and is there any optimal formula for enteral feeding?

Very often our sickest patients are those most apt to have negative blood cultures (because of fungi or viruses?) and get progressively more antibiotic-resistant organisms. Was there any particular relationship between the antibiotics used and the incidence of negative blood cultures and the types of antibiotic resistance?

Most people have found that there is a correlation between mortality rate and whether the initial empiric antibiotics were appropriate when the culture results eventually came back. Did that not pertain here?

Almost all of these critically ill patients with prolonged stays in the intensive care unit will have some degree of pneumonia at autopsy. Consequently, there is some question as to whether a persistent septic state without pus is due to pneumonia or a "gut septic state." I am not sure that the data presented here indicate that if the gut happens to be able to take nutrition, the gut is not the cause of the septic state. How did you determine that the gut could not be used; was it the amount of distension, nasogastric damage, or what? Most people agree that if you can use the gut for feeding, it should be used as much as possible.

We wonder what sort of attempt there will be to randomize the use of enteral nutrition to prove this particular point.

DR. JOSEPH M. CIVETTA (Miami, Florida): I have just three clarifications to ask from Dr. Border.

One, what is the definition of the gut septic state, and how is the diagnosis substantiated?

Second, what were the selection criteria used to choose between enteral or parenteral nutrition?

Third, I noted that there were four patients who died in septic states. Does that mean that the other 62 patients in the study were long-term survivors?

DR. JOHN R. BORDER (Closing discussion): We have established an objective septic severity score based on the 16 measurements made every day in the intensive care unit. This septic severity score works almost exactly as the experienced clinician does when evaluating the septic state. The statistical correlations in this retrospective study with the septic severity score are negative only for enteral protein intake and positive for all other therapeutic modalities including antibiotics. Thus, only an increase in enteral protein intake was associated with a reduced magnitude of the septic state. This statistical relationship existed at all times and under all conditions examined. When one reviews the previous literature on humans and the normal antibacterial antiendotoxin mechanisms of the gut, this relationship of increased enteral protein to a reduced magnitude of the septic state and clearance of bacteria from the blood makes good biological sense. There are now a large number of investigators who see the gut as a primary source of bacteria and endotoxin to the systemic body in chronically critically ill patients. We believe that this is largely a product of patient management. We have discussed this at some length in the primary paper.

Dr. Allgower wanted to know about the shock index. We did not calculate that variable. However, in principle, prolonged severe shock with subsequent resuscitation should lead to oxygen-free radical damage to the gut mucosa and liver and a much earlier onset of the gut origin septic states. This is in keeping with Jacob Fines' work and with Ben Rushes' work in terms of the effect of shock on the entry of endotoxin and bacteria into the systemic body.

Dr. Allgower also asked about weaning from the ventilator. The entire blunt multiple trauma literature is very consistent in that operative stabilization of fractures of the femur, acetabulum, and posterior pelvis the day of admission by allowing the patient to sit up relatively pain free shuts off the pulmonary failure septic state at 2–4 days. In contrast, femur traction produces a pulmonary failure septic state that lasts as long as the traction and which beginning at about 10 days gets rapidly worse. It is to be pointed out that our data show that femur traction is associated with a reduced enteral protein intake and a progressive increase in the magnitude of the septic state. This is also true of any kind of delayed operative therapy. We must deduce that the sitting position obtained by complete operative care the night of admission aids not only in the function of the lungs but also in the function of the gut probably in terms of both food intake and defecation.

Dr. Clowes used the words overwhelming infection. I do not agree with that because there should be bacteriologic evidence which we did not find. I believe he means overwhelming septic response. I agree with that but must point out that the septic response is a product of macrophage activation and that such activation may come from devitalized tissue as well as bacteria. Both Dr. Clowes and ourselves have shown that reduced amino acid extraction by the gut plus liver is a predictor of a septic death. Dr. Clowes' work on central plasma clearance fits exactly with our work. I wonder if the reduced gut plus liver extraction of amino acids reflects a greatly reduced mass of gut enterocytes. I would therefore speculate that perhaps enteral protein feeding could restore central plasma clearance of amino acids to normal.

Dr. Burke's question is based on nonbacterial causes of the septic state. It is clear from cell biology that any factor that activates the macrophage can produce release of the factors that produce the septic state. The factors that activate the macrophage are endotoxin (especially the hepatic macrophage) and phagocytosis of any material from latex beads, to colloidal gold, to devitalized tissue, to bacteria. I believe these patients were initially septic from phagocytosis of devitalized tissue secondary to wounds and the effect of the enforced supine position on the lung. Our treatment of this septic state with the ventilator and intubation, no food intake, alkalinization of the stomach, and broad-spectrum antibiotics then created by days 8–10 a bacterial endotoxin septic state with pathogenic antibiotic-resistant bacteria. The bacterial phase of this problem (and presumably the endoxin phase) then gets progressively worse from days 8–10 to at least day 28 when all patients are involved with multiple positive blood cultures. It is my opinion that aggressive protein support (2.5 g/kg/day), although it does not treat or reverse this septic state, does allow the patient to endure and survive until enteral protein intake is increased.

It is of considerable interest to me that oliguric renal falure did not occur except for one patient in the patients who survived. That one patient came very close to death and was not supported as the other patients were. I attribute this absence of oliguric renal failure to our fluid support, which maintained an average of 3600 mL of urine output per day. I suspect strongly that many patients who die in association with oliguric renal failure actually die of protein malnutrition and the gut origin septic states.

Bob Wilson wanted to know about feeding the injured gut. There are a wealth of papers that clearly show that patients can be fed almost immediately after bowel surgery; they can be fed with peritonitis, and they can be fed immediately after major intra-abdominal trauma. We must realize that an ileus is as gastric and colonic stasis and not a jejunoileal stasis. The upright chest position helps greatly (probably) in getting liquid foods through the stomach. It also greatly aids defecation, which is equally important. Alternatively the stomach may be placed on suction and the feeding given into the upper jejunum. Only bowel obstructions and high fistulas contraindicate such early enteral feeding.

How much enteral protein is enough to prevent the gut origin septic states? Enteral protein in the amount of 0.3 g/kg/day is clearly too little, 0.6 g may be enough, but 1.0 g is probably better. We have customarily given both enteral and intravenous protein support so that in critically ill humans we achieve about 2.5 g/kg/day. It is important to note that this is only achieved with orders for 3.5–4.0 g/kg/day since everyone seems to believe they have the right to withdraw nutritional support. It is further important to note that we could find no evidence for a beneficial effect of broad-spectrum antibiotics in treating these patients and, in fact, our correlation suggest harmful effects. The most important antibiotic in this study was clearly enteral protein.

The biggest question for this whole study is clearly whether the patient has more enteral protein intake because he is getting better (self-fulfilling prophecy), or whether he gets better because he has more enteral protein intake. We would suggest since the same relationship between enteral protein and reduced septic state is seen at all times and under all conditions, since there is a large background literature, and since it is consistent with basic biology, that the patient gets better because of more enteral protein. Other observers may believe differently.

against the *B. fragilis* group?

the facts *still* favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*.

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986*, Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

MSD

SHARP&
DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®# vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

Defective Glucose Utilization in Patients with Functioning β-Cell Tumors Persists after Tumor Excision

GREGORY S. McGEE, M.D., MAHMOUD M. KULAYLAT, M.D., AND NAJI N. ABUMRAD, M.D., F.A.C.S.

From the Department of Surgery, Vanderbilt University School of Medicine, Nashville, Tennessee

Glucose utilization was assessed before and after operation in five patients with insulin-secreting tumors using the euglycemic clamp. Two groups of age, sex, and weight-matched controls were studied under conditions of either acute (3 h, $N = 7$) or chronic (48–72 h, $N = 6$) hyperinsulinemia (46 ± 4 μU/mL). The rate of glucose infusion (M = mg/kg/min) required to maintain steady-state euglycemia was taken as index of glucose utilization. M was higher both in postoperative patients and in chronic controls than in preoperative patients (2.1 ± 0.1 and 1.8 ± 0.2 *vs.* 1.0 ± 0.2, $p < 0.01$), yet never achieved levels seen in acute controls (3.3 ± 0.3, $p < 0.01$). Also reported is one subject who had a predominantly proinsulin-producing tumor with little insulin secretion, who also manifested a similar defect in glucose utilization. Excision of this tumor resulted in partial reversal of the peripheral defect in glucose metabolism. In conclusion, chronic endogenous hyperinsulinemia (and hyperproinsulinemia) in humans is associated with a defect in peripheral glucose utilization that is only partially resolved 2 years after tumor removal.

HYPERINSULINEMIA and insulin resistance coexist in several pathologic conditions including obesity,[1] cirrhosis,[2] chronic renal failure,[3] and non–insulin-dependent diabetes mellitus.[4] Conflicting reports exist concerning the developmental sequence of hyperinsulinemia and insulin resistance.[5–9] It has been suggested that the elevated insulin levels represent compensatory pancreatic secretion in response to reduced insulin activity.[18] Most *in vitro* studies, however, indicate a role for insulin in regulating its own biologic response. Cultures of rat adipocytes,[10,11] rat hepatocytes,[12] and rat hepatoma cells[13] and of human skin fibroblast[14] exposed to insulin exhibit reduced insulin activity. The degree of this reduction is directly related both to the duration of insulin exposure and to the concentration of insulin in the media.[11] Possible explanations for this resistance include decreased coupling efficiency between glucose transport and receptor occupancy, receptor "down regulation," and postreceptor defects in insulin responsiveness.[11] The validity of applying conclusions based on these *in vitro* findings to the intact organism has not been established yet.

Chronic peripheral infusions of insulin achieving comparable insulin enrichments to those seen in insulin resistance states have been used to examine the effects of hyperinsulinemia on *in vivo* glucose metabolism. Generally, these infusions resulted in a reduction in target sensitivity to insulin.[15,16] Yet, physiologic portal-to-arterial insulin gradients are not maintained during such infusions, and thus their application to the study of endogenous hyperinsulinemia is still questionable. Patients with functioning β-cell tumors may represent a more accurate model for the study of primary endogenous hyperinsulinemia. Evaluating these patients before and after tumor removal may afford a view into the mechanisms of insulin resistance in humans.

The purpose of this study was to assess the effect of chronic hyperinsulinemia and its normalization on glucose utilization in humans. Glucose utilization was assessed in six patients before and after resection of their β-islet cell tumor using the euglycemic clamp technique originally proposed by DeFronzo et al.[17] The results were compared with those obtained from two groups of well-matched volunteers who served as controls. One group ($N = 7$) had a euglycemic clamp technique used during an acute infusion of human insulin. The second

* Predominantly a proinsulin-secreting tumor.

group (N = 6) had endogenous hyperinsulinemia produced by a 48–72-hour infusion of glucose, near the end of which a 3-hour euglycemic clamp was performed. Plasma insulin levels were similar in all study groups.

Materials and Methods

Subjects

From July 1981 to December 1985, eight subjects with evidence of inappropriate insulin secretion (concurrent plasma insulin level of >25 μU/mL and plasma glucose level of <50 mg/dL during fasting) were admitted to Vanderbilt University Medical Center. Additionally, one patient was admitted with elevated proinsulin levels and low-normal levels of plasma insulin and C-peptide, associated with hypoglycemic attacks. All patients subsequently had operative removal of a single, benign pancreatic β-cell tumor, which was done by tumor enucleation in five patients and distal pancreatectomy in four patients. After operation, no patients required glucose supplementation to maintain euglycemia.

Six of these nine patients had both a preoperative and postoperative euglycemic clamp. The interval from tumor removal to the postoperative study ranged from 7 days to 24 months. The ages of these six patients ranged from 18 to 76 years (Table 1). All recounted symptoms consistent with recurrent hypoglycemia varied from 2 months to 5 years in duration. One patient had been an insulin-dependent diabetic for 25 years and was well controlled with oral hypoglycemic agents. Another patient gave a positive family history of adult onset (non-insulin-dependent) diabetes. Three patients were being treated elsewhere for psychiatric disturbances, and three were taking antiepileptic medications.

Control subjects included 13 normal volunteers without family histories of diabetes mellitus who were matched for age, sex, height, and weight. Seven subjects received a 3-hour infusion of insulin (0.32 ± 0.02 μU/kg/min) and six subjects had a prolonged infusion of glucose for 48–72 hours.

Experimental Protocol

Studies of patients with islet cell tumors were done after an overnight fast. Patients were kept euglycemic with an infusion of glucose *via* an antecubital vein. Plasma glucose levels were monitored every 1–2 hours and maintained near 90 mg/dL by adjusting the infusion rate. The glucose infusion was stopped at 8:00 A.M. on the day of the study, and frequent (15–30-minute) glucose monitoring was continued until plasma glucose levels fell to 50–55 mg/dL. A 3-hour experimental period was begun, during which plasma glucose levels were monitored every 5 minutes and kept between 80 and 90 mg/dL by a variable glucose infusion. Blood for plasma insulin determination was drawn every 15 minutes during the study. In select patients, plasma samples were also obtained at 60-minute intervals for later assay of glucagon, epinephrine, norepinephrine, and cortisol.

The control subjects were also studied after an overnight fast. The placement of catheters (5 cm, 16–18 gauge) into a superficial hand vein (SHVC) and a contralateral forearm vein (FVC) was begun at 7:00 A.M. The hand with the SHVC was inserted into a box heated to 55 C to ensure complete arterialization of blood.[18] The FVC was used for infusion of insulin and glucose. The subjects were allowed to rest for 1 hour before a 3-hour experimental period was begun. Seven subjects received a primed continuous infusion of insulin (Humulin R, Eli Lilly and Co., Indianapolis, IN) at a rate calculated to achieve insulin enrichments in the arterialized hand vein equivalent to those noted in the tumor-bearing patients. Plasma glucose levels were monitored every 5 minutes and were maintained near 80–90 mg/dL by a variable infusion of glucose. This group of volunteers constituted the acute hyperinsulinemic controls. A similar study was performed in patients after tumor removal using exogenous insulin to re-establish preoperative levels of hyperinsulinemia. In the patient with proinsulin-secreting tumor, plasma insulin was raised in the postoperative study to levels noted in preoperative insulinoma patients.

TABLE 2. *Plasma Glucose, Insulin, the Rate of Glucose Infusion to Maintain Euglycemia (M) and Metabolic Clearance Rate (MCR_g) in Patients with Insulinomas and in Normal Control Subjects*

	Glucose (mg/dL)		Insulin (μU/mL)		M (mg/kg/min)	MCR_g (mL/kg/min)
	Basal	Experimental	Basal	Experimental		
Insulinoma patients						
Before operation	34 ± 3	94 ± 4	41 ± 5	47 ± 6	1.0 ± 0.17	1.1 ± 0.20
After operation	88 ± 3	93 ± 5	9 ± 1	39 ± 5	2.1 ± 0.13	2.3 ± 0.20
Control subjects + hyperinsulinemia						
Acute (3 h)	86 ± 2	86 ± 4	8 ± 0.2	44 ± 5	3.3 ± 0.26	3.9 ± 0.20
Chronic (48–72 h)	81 ± 3	83 ± 3	10 ± 0.1	45 ± 4	1.8 ± 0.20	2.3 ± 0.20

Another six control subjects were admitted for 3 days to the Clinical Research Center (CRC) at Vanderbilt. On the day of admission, blood for basal glucose and insulin was drawn and catheters were placed in forearm veins bilaterally to be used for glucose infusion and for blood sampling. Subjects consumed weight-balanced meals on the CRC until fasting was begun at 10 P.M. the night before the study. The glucose infusion was begun on the day of admission at 2.3 g/h and was escalated by 2.3 g/h for 5 hours. Blood samples were obtained every 1–2 hours for the measurement of plasma glucose levels, which were kept near 90 mg/dL by adjusting the glucose infusion rate. The infusions lasted from 48 to 72 hours. A 3-hour experimental period was begun at 8:00 A.M. after 10 hours of fasting. During this period plasma glucose levels were monitored every 5 minutes and kept near basal levels (range: 74–90 mg/dL) for each subject. Blood was obtained at 15-minute intervals for plasma insulin assay and at 30–60-minute intervals for later assays of plasma glucagon, epinephrine, norepinephrine, and cortisol.

In all control subjects and in one patient with β-islet cell tumor, the rate of glucose production was estimated using a primed continuous infusion of 3-[^{3}H]-glucose as previously described.[19,20]

All studies were approved by the Committee for the Protection of Human Subjects. All subjects gave informed written consent before participating in the study.

Analytical Methods

All infusions were performed with a geared motor driven pump (Harvard Infusion/Withdrawal Pump, Model #600–900, Harvard Apparatus, Co., Inc., Dover, MA) using 60-mL syringes. Plasma glucose levels were measured by the glucose oxidase method using a Beckman Glucose Analyzer II (Beckman Instruments, Fullerton, CA). Glucose specific activity in plasma was determined in samples deproteinized with 4.5% barium hydroxide and 4.5% zinc sulfate (1:10, v/v) as previously described.[18] Blood for insulin determination was collected in cold tubes containing EDTA, and plasma samples were stored with Trasylol (500 U/mL) at −70 C for later assay. The insulin assay[21] was performed using a Phadebas radioimmunoassay kit obtained from Pharmacia Laboratories (Pharmacia, Inc., Piscataway, NJ). The inter- and intra-assay coefficients of variation were 6.5% and 7.2%, respectively. The lower limits of the assay were 2–3 μU/mL, and the assay could not differentiate these levels from zero. The antibody used for insulin detection had a 75–90% cross-reactivity with proinsulin. Immunoreactive glucagon levels were assayed as previously described[22] using Unger's 30 K antibody obtained from Southwestern Medical Center (Dallas, TX). Plasma cortisol levels were determined by a Gammacoat RIA kits (Clinical Assays, Travenol-Gennentech Diagnostics, Cambridge, MA) and plasma catecholamines were measured using a radioenzymatic CAT-A-KIT assay kit (Upjohn Diagnostics, Kalamazoo, MI). Proinsulin levels were determined by radioimmunoassay as previously described.[23]

Calculations

In the control subjects and one subject with a β-cell tumor, calculation of the rates of hepatic glucose production (Ra, mg/kg/min) was based on a one compart-

TABLE 3. *Data from One Patient with a Proinsulinoma*

	Basal		Experimental Period	
	Before Operation	After Operation	Before Operation	After Operation
Glucose (mg/dL)	32	90	91	87
Insulin (μU/mL)	1.2	7.2	1.5	41
C-peptide (μU/mL)	<0.05	—	—	—
Proinsulin (μU/mL)	32	—	—	—
M (mg/kg/min)	—	—	1.3	1.9
MCR (mL/kg/min)	—	—	1.4	2.1

* The tumor content of insulin and C-peptide was undetectable.

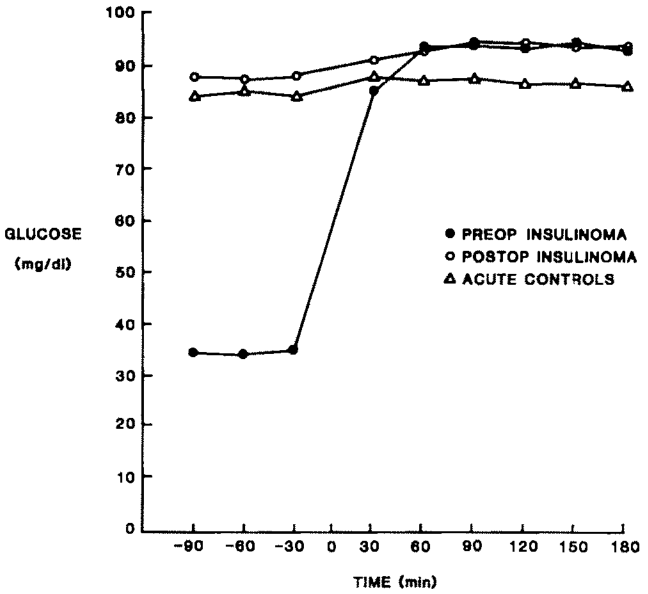

FIG. 1. This diagram represents the temporal changes in plasma glucose concentration during the basal state (−90 to −30 minutes) and during the experimental steady state (60–180 minutes). Basal plasma glucose was significantly depressed before operation (34 ± 3 mg/dL) when compared with any other study group ($p < 0.01$).

ment model as previously described.[19,20] This method has been validated for both insulin and glucose over wide ranges of deviations from steady state.[24,25] The rate of glucose infusion required to maintain euglycemia during the hyperinsulinemic states (endogenous or exogenous) was used as an index of peripheral glucose utilization. This rate was designated as M and expressed as mg/kg/min. The metabolic clearance rate of glucose (MCR_g, mL/kg/min) was calculated as M divided by steady-state plasma glucose (expressed in mg/mL).

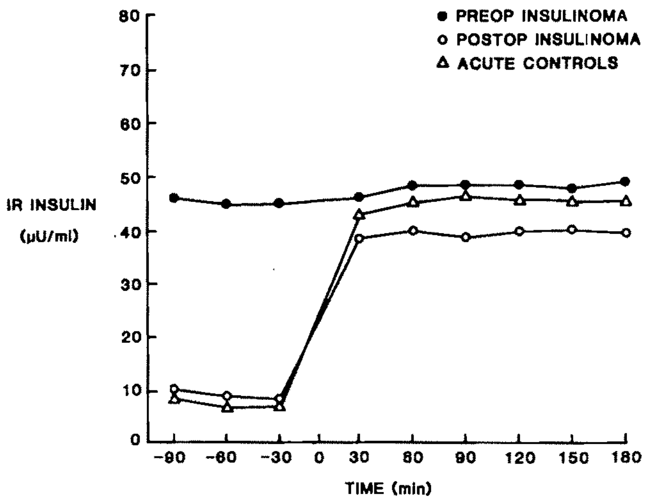

FIG. 2. This diagram represents the plasma immunoreactive insulin levels during the basal state (−90 to −30 minutes) and the experimental steady state (60–180 minutes). No significant difference in steady-state plasma insulin levels existed among the study groups.

Statistical analysis was done using nonpaired t-test, and where applicable, analysis of variance. Data in the Result section, tables, and figures are expressed as mean ± standard error of the mean (SEM), unless otherwise specified.

Results

Of the six patients studied with islet cell tumors, five had proven insulin-producing neoplasms, whereas one patient had a tumor secreting predominantly proinsulin. The results from the study of the patients with insulinomas are presented below and in Table 2. The data from the proinsulinoma patient are presented at the end of this section and in Table 3.

Initial fasting glucose levels were significantly lower in all patients before tumor removal than after tumor resection (34 ± 2.8 *vs.* 84.6 ± 6.2 mg/dL, $p < 0.001$). Glucose levels were maintained at approximately 90 ± 3 mg/dL in all four groups during the hyperinsulinemic euglycemic clamp (Fig. 1).

Basal plasma insulin levels were significantly higher in the insulin tumor-bearing patients than in any other group (Fig. 2). In the preoperative period, basal plasma insulin levels were 41 ± 4 µU/mL and increased slightly in response to the glucose infusion (to 47 ± 6 µU/mL). These levels, however, did not differ from those obtained during the experimental period in the acute or chronic control subjects or in the patients during the postoperative period.

The rate of glucose production was assessed by tracer methodology in one insulinoma patient during the preoperative period and was found to be severely suppressed (basal Ra was 1.6 mg/kg/min, and this value declined to 0.2 mg/kg/min after a 10-hour fast). The induction of hyperinsulinemia resulted in a similar suppression of Ra in the acute and chronic control subjects (Ra dropped from 2.4 ± 0.3 to 0.6 ± 0.2 mg/kg/min in the acute control subjects, and from 2.1 ± 0.4 to 0.4 ± 0.2 mg/kg/min in the chronic control subjects).

The rate of glucose infusion (M, mg/kg/min) required to achieve steady-state euglycemia in the preoperative study was significantly lower than the rate required in the postoperative clamp (1.0 ± 0.17 *vs.* 2.2 ± 0.13, $p < 0.001$). Yet, even after tumor removal, M remained significantly lower than in acute controls (2.2 ± 0.13 *vs.* 3.3 ± 0.26, $p < 0.01$). During chronic hyperinsulinemia induced by glucose infusion, M was found to approach levels noted in postoperative patients (Fig. 3).

In differences in the metabolic clearance rates of glucose (MCR_g), the four study groups mirrored differences noted in M. Thus, even 24 months after tumor resection, the MCR_g remained significantly below levels noted in acute controls (2.6 ± 0.25 *vs.* 3.9 ± 0.37, $p < 0.01$) (Fig. 4).

No consistent relationships existed between preoperative values for insulin and for M, or between duration of symptoms and preoperative M. Furthermore, no association between the absolute or relative changes in M (preoperative to postoperative) and preoperative insulin levels was uncovered.

The levels of the counter-regulatory hormones in the patients with insulin-secreting tumors did not differ from those in the control subjects. Plasma glucagon levels, measured in four patients before operation (145 ± 23 pg/mL), were similar to those measured in the postoperative clamp (106 ± 26 pg/mL) and did not differ from levels seen in control subjects. Similarly, plasma epinephrine (E) and norepinephrine (NE) levels, measured in two patients before operation (121 and 116 pg/mL, respectively) were not different from those seen in the postoperative period (126 and 93 pg/mL, respectively) or in control subjects (acute, E = 105 ± 8 pg/mL, NE = 118 ± 10 pg/mL; chronic, E = 118 ± 13 pg/mL and NE = 121 ± 16 pg/mL). Plasma cortisol levels in two patients with β-islet tumors averaged 4.8 μg/dL before operation, 5.5 μg/dL after operation compared with the acute (6.8 ± 0.9 μg/dL) and chronic (5.9 ± 0.8 μg/dL) controls.

The patient with a proinsulin-producing tumor had depressed fasting glucose levels before operation that stabilized at euglycemic levels after operation without glucose supplementation. Preoperative insulin levels were <2 μU/mL, whereas proinsulin levels were greater than 30-fold above basal. The tumor content of insulin and C-peptide was undetectable. Interestingly, postoperative insulin levels returned almost to normal.

During the preoperative euglycemic clamp, this patient exhibited reduced insulin-like activity (M = 1.3 mg/kg/min; MCR_g = 1.4 mL/kg/min) that improved after tumor removal (M = 1.9 mg/kg/min; MCR_g = 2.1 mL/kg/min). Yet, even after tumor excision, this patient had reduced insulin sensitivity when compared with acute controls (M = 2.1 *vs.* 3.3 mg/kg/min).

Discussion

This study investigated the insulin sensitivity of peripheral glucose utilization in insulinoma patients before and up to 2 years after tumor excision. A state of peripheral insulin resistance was observed in these patients that persisted, although in a milder form, 2 years after correction of the hyperinsulinemia by tumor removal. These findings confirm data recently reported by Rizza et al.[26] and Nankervis et al.[27] We further describe an unusual case of a proinsulinoma in a patient who manifested the same degree of peripheral insulin resistance seen in insulinoma patients. Ten days after removal of the proinsulin-producing tumor, an incomplete improvement was also observed.

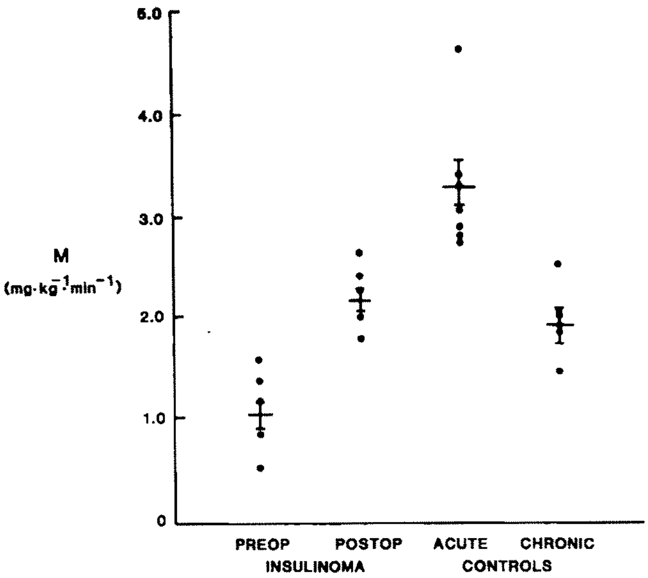

FIG. 3. This scatter diagram represents the values of M, the rate of glucose infused (mg/kg/min) to maintain euglycemia at insulin concentrations of 42 ± 5 μU/mL. Significant differences exist between the preoperative and postoperative M (1.0 ± 0.017 *vs.* 2.1 ± 0.13 mg/kg/min, $p < 0.01$), and between postoperative M or chronic control M and acute control M (2.1 ± 0.13 or 1.8 ± 0.20 *vs.* 3.3 ± 0.26 mg/kg/min, $p < 0.01$).

Insulin resistance was assessed by the hyperinsulinemic euglycemic clamp previously described.[28] This method assumed that the prevailing hyperinsulinemia completely suppressed hepatic glucose production and that the amount of glucose infused to maintain euglycemia reflected peripheral glucose utilization. Plasma insulin levels were identical during the experimental periods in all study groups. In our hyperinsulinemic control subjects and in one insulinoma patient, tracer-

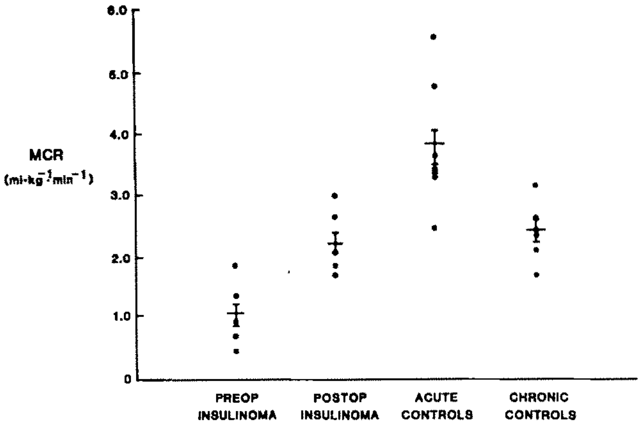

FIG. 4. This scatter diagram depicts the metabolic clearance rate of glucose (MCR_g) calculated as M divided by glucose concentration at steady state. A significant difference existed between the preoperative and postoperative MCR_g (1.1 ± 0.20 *vs.* 2.3 ± 0.20 mL/kg/min, $p < 0.01$) and postoperative and acute control MCR_g (2.3 ± 0.20 *vs.* 3.9 ± 0.20 mL/kg/min, $p < 0.01$).

measured hepatic glucose production was assessed and was found to be 75–80% suppressed by this degree of hyperinsulinemia (42 ± 5 μU/mL). Other studies have shown a comparable degree of suppression of hepatic glucose production occurring in insulinoma patients.[26,27]

Data from the current study also indicate that insulin resistance can be experimentally produced by chronic endogenous hyperinsulinemia resulting from glucose infusion. Hyperinsulinemia was achieved by a 48–72-hour infusion of glucose during which plasma glucose was kept at euglycemic levels. This experimental design, in contrast to previous reports using chronic infusions of insulin,[15,16] should simulate the 2–3-fold portal–arterial insulin gradient seen in normal subjects and in insulinoma patients.[29]

The mechanisms of the resistance to insulin-induced peripheral glucose utilization in insulinoma patients is not well understood. *In vitro* studies have produced conflicting data regarding the effect of high insulin levels on regulation of insulin's activity. Some studies have demonstrated increased insulin activity in tissues preexposed to high insulin levels both *in vivo*[30] and *in vitro.*[31,32] The majority of the reports, however, have shown an insulin-induced decrease in insulin's biologic activity.[11–14,33–36]

In vivo studies in humans[15,16] have shown that peripheral infusions of insulin to create chronic hyperinsulinemia resulted in defective insulin activity even in the presence of normal insulin receptors. Our data using chronic endogenous hyperinsulinemia in the control subjects demonstrated similar defects in insulin activity. Such defects could not be accounted for by changes in counter-regulatory hormones as no rise in circulating glucagon, catecholamines, or cortisol was noted in either control subjects or in select patients with β-cell tumors. Thus, these findings strengthen the possibility that insulin itself or other β-cell secretory products may have directly contributed to the development of insulin resistance.

It is currently believed that chronic hyperinsulinemia is associated with alterations in postreceptor events involved in glucose transport and metabolism in normal volunteers[15,16] and obese subjects[37] as well as in patients with insulinoma,[26,27] chronic renal failure,[37] cirrhosis,[37] and type II diabetes.[37] This conclusion is derived from observations of a reduction in the maximal responsiveness of glucose utilization to insulin that occurred in the presence of normal or mildly reduced insulin receptor number.

The patient with a purely proinsulin-secreting tumor afforded us a unique opportunity to examine the effect of other β-cell secretory products on insulin-like activity *in vivo.* This patient had a severe reduction in peripheral glucose utilization in the presence of low circulating insulin. This finding indicates that the abnormally high levels of proinsulin observed in this patient must have contributed to the development of his insulin resistance. It has been well established that plasma proinsulin levels are elevated in patients with insulinoma and can vary between 30 and 90% of the circulating plasma immunoreactive insulin.[38,39] Thus, elevated proinsulin levels may have contributed also to the insulin resistance seen before operation in insulinoma patients. In addition, proinsulin, once considered to have minimal physiologic activity,[40,41] has recently been shown to have potent insulin-like action in reducing hepatic glucose output in patients with non–insulin-dependent diabetes mellitus.[37] This raises the possibility that the elevated levels of proinsulin in patients with β-islet cell tumors may contribute significantly to the observed reduction in hepatic glucose output and subsequent hypoglycemia.

Insulin resistance in patients with β-islet cell tumors may thus have two components: an insulin (or proinsulin)-induced component that was reversed after tumor removal, and a more permanent defect that persisted long after tumor resection. The persistence of this defect 2 years after tumor removal raises the possibility that this defect in glucose utilization may have existed before tumor development. This defect then would have resulted in subclinical and intermittent hyperinsulinemia that could have worsened the insulin resistance. This continuous and progressive pancreatic stimulation might constitute a predisposing state for the development of an insulin-secreting tumor. An alternative but even more unlikely explanation would be that chronic hyperinsulinemia induces a permanent defect in peripheral glucose utilization. For this to have occurred would have required alterations in the genomic structures responsible for the various proteins that control glucose utilization.

Acknowledgments

We thank Dr. David C. Robbins, from the College of Medicine at the University of Vermont, for assaying plasma and tumor insulin and C-peptide content in the patient with proinsulinoma. We also thank Dr. Kenneth Sharp from Vanderbilt University Medical Center for allowing us to study and include one of his patients (#3) in this manuscript. The authors also thank Dr. Keith Carr, Laurel Brown, and Theresa Becker for their excellent technical assistance and Ellen Longworth and Shirley Hall for their outstanding secretarial assistance.

DISCUSSION

DR. DONALD S. GANN (Providence, Rhode Island): I very much enjoyed this paper, and I would like to thank Dr. McGee and Dr. Abumrad for the opportunity to read the manuscript as well.

The hypothesis that appears to have given rise to this study is an intriguing one. If I understand it correctly, it is that the increase in insulin itself is the cause of decreased insulin sensitivity. Therefore, one would expect that the removal of the insulin source would lead to a restoration of normal sensitivity, which the authors did not find.

The primary question this raises then is: what is the mechanism of this insensitivity that appears to be in part only dependent on insulin? Specifically, I would like to ask, since the authors did not find significant decrease in insulin receptors, what is the mechanism of the post-receptor insensitivity that appears to have been generated? They did find some lowering of receptors, as I understand it, and I would also like to ask what is the contribution of partial down regulation to the observations? However, the most intriguing thing to me about this manuscript seems to be the possibility that, in fact, there is a pre-existing insulin insensitivity. Contrary to the initial hypothesis, this might provide a chronic stimulus to insulin production, which in turn might lead to islet cell hyperplasia and then to the development of autonomous islets and ultimately to the formation of an islet cell tumor. I realize that this is a wild speculation, but I would very much appreciate the author's comments.

DR. WILLIAM R. DRUCKER (Rochester, New York): The study is an investigation of down-regulation. I think most of us interested in this area realize that this is an internal homeostatic mechanism by which the body will adjust to a decrease in various stimuli. In this case the insulin became elevated, by mechanisms yet to be determined, leading to a decrease in the receptors for insulin.

It is fascinating that this change seemed to persist for at least 2 years after excision of the known stimulus, namely, the islet cell tumor. In studying the phenomenon, the authors concocted a model in which they infused glucose over a 48–72-hour period. Thereby they induced an increase in endogenous output of insulin. In itself that will create a desensitization, if you will, or a loss of the receptor mechanism, at least from a functional standpoint.

Therefore, my first question would be: just how long does this iatrogenic decrease in receptor activity last?

To obtain proper control in this study, I believe it is necessary to have some idea of what the surgery itself does in terms of the receptor mechanisms. As you all know, there is much literature, to which Dr. Donald Gann and I also have contributed, about the changes in insulin response following surgery. To what extent does the surgery itself influence the early studies that were performed on these patients?

I am concerned about the influence of the glycogen content in the liver on the results they demonstrated because in the study of the patient with an insulinoma, they did their study after the blood sugar has fallen to 50 mg/dl. At that point they started their study with the glucose clamp. If the blood sugar has fallen to that level, I would expect the glycogen to be virtually depleted in the liver, whereas in their control study the blood sugar was at a normal level when they started their study with the glucose clamp. Do they think this probable difference in hepatic glycogen content may have influenced the results?

My final question is: have they done or are they planning any studies to localize this defect? Have they done any forearm studies to measure the differences in glucose uptake in these patients, and how long the changes last?

I share with Dr. Gann the fascination with the hypothesis put forward by the authors in their article that this may very well be started by an inborn or acquired defect in insulin sensitivity of the insulin receptors in the periphery, leading to a chronic stimulus of the pancreas, and thereby leading to a tumor. My only concern about that hypothesis is that there are a large number of similar clinical situations, some of which are identified by the authors, and I am not aware of the fact that those clinical situations are associated with an unusually high incidence of insulinomas. Perhaps other clinical situations would be worth looking into as one way of testing their hypothesis. Do these other situations in which there is a defect in insulin receptors become associated with insulinomas?

DR. P. BESSEY (Birmingham, Alabama): Drs. McGee, Kulaylat, and Abumrad from Vanderbilt have presented a very interesting study and given us information that again illustrates how illness and surgical treatment may affect glucose and insulin metabolism.

They have used the insulin clamp techniques, originally developed by Rubin Andrews over 25 years ago, to study patients both before and after resection of insulinomas and correction of chronic hyperinsulinemia.

Using the clamp, they have been able to reproduce, both before and after operation, identical conditions of glucose and insulin concentrations. Under those identical conditions, they have observed an apparent difference in the sensitivity to insulin in these same patients. Whole body glucose disposal was approximately doubled after resection of the tumors, indicating that the patients had been insulin-resistant before operation. They also observed that patients were less sensitive to insulin than a group of age, sex, and weight matched controls.

The equating of glucose disposal with glucose uptake should be made with caution. Glucose disposal as measured under the clamp technique may underestimate actual whole body uptake if hepatic glucose production is appreciable. Since the patients presumably had increased activity of the counter-regulatory hormones in response to periods of hyperinsulinemia and hypoglycemia, it may be that the hepatic glucose production was different or differently suppressed in the two periods. Do the authors have any information about that?

Alternatively, as Dr. Drucker suggested, is there any information regarding uptake of glucose across a specific microvascular bed such as the forearm or the leg?

The authors have attributed these observations and changes in the insulin response to alterations in the affinity or occupancy rate of the receptors. Are there other supporting data? For example, have you tried to use higher insulin concentrations so as to saturate the receptors to overcome this apparent receptor defect?

The hypothesis is supported by the experimental group receiving chronic glucose infusions in an induced state of hyperinsulinemia. However, in the patients, may there not be some other mechanisms involved?

Black and associates several years ago presented to this Association information about another group of patients with insulin resistance, namely those recovering from acute injury. They had quantitated insulin resistance, and it appeared to be a postreceptor defect.

We reported information on the effects of hormones on the interactions of glucose and insulin. When normal subjects received a "cocktail" of three stress hormones, hydrocortisone, glucagon, and epinephrine, both glucose uptake across the forearm and whole body glucose disposal were greatly reduced. This appeared to be a cortisol effect. Do the authors have any information about counterregulatory hormone activity in their patients? Were they comparable both before and after operation?

Finally, I have a bit of a concern regarding the difference between the patients after resection of the tumor and the controls. Considering this is a relatively small group, were the patients and controls comparable in terms of body composition and activity immediately before the study?

DR. JOHN F. BURKE (Boston, Massachusetts): Dr. McGee has presented a well carried out and interesting study looking at glucose metabolism in a select group of patients with insulin-producing tumors.

The evidence that there is an insulin receptor, postreceptor complex abnormality, is very persuasive, and I have two questions concerning this concept.

One, since hyperinsulinemia is regularly generated in patients receiving hyperalimentation, do the authors have any idea how long it takes to develop the abnormality they postulate, and are we producing this abnormality in some of our patients?

Second, it is intriguing to believe that perhaps there is more than just an inslulin receptor, postreceptor, problem. Are there metabolic consequences that last? What is the long-term status of the metabolic rate or amino acid metabolism, etc? Are they altered in this state? If so, do they persist?

DR. NAJI N. ABUMRAD (Closing discussion): Obviously this paper has raised many more questions than it has attempted to answer. You all know that we do not see these patients often, and over a 7-year period we took care of only nine patients, and we are currently presenting data on six such subjects.

Many questions have been raised, and I will attempt to answer them one by one:

Dr. Gann asked about the mechanism of insulin insensitivity, and whether it is related to insulin itself or it is a postreceptor defect.

It is currently well established from several *in vitro* and *in vivo* studies that insulin itself can result in both receptor and postreceptor defects, leading to insulin insensitivity. It is possible to speculate in the current study that insulin itself could have caused a permanent defect that resulted in insulin insensitivity. For this to occur, it has to affect the genomic structure of the target cells. *i.e.,* affect the cellular DNA. Currently we are not aware of any data (*in vitro* and *in vivo*) to substantiate such a claim.

The fact that the removal of the pancreatic tumors did not reverse the defect suggests the existence of an already existing genetic defect, which might explain our results. We do not have supporting data for this speculative assumption. We are currently interested in examining whether such a defect actually exists, and as a result we have started collaborative studies to examine this particular issue using specific cDNA probes. We believe that such studies are important as they will shed light on the mechanism of this disease both in a longitudinal and a cross-sectional manner. Furthermore, such studies will enable us to understand whether infants with nesidioblastosis are susceptible to this disease because of the presence of a genetic defect. If true, then we need to examine these patients over a prolonged period to determine whether they will be more susceptible to development of pancreatic adenomas in their pancreatic remnants over time.

Third, could such a defect be due to a change in the receptor number and affinity? As you are all aware, only 10% of cellular receptors are usually occupied, and 90% fit the description of "spare receptors." It is thus difficult to speculate that the defect is due to a decrease in the absolute number of receptors. There is only one known clinical condition where the number of receptors is low, and that is Leprechaunism. Even in such patients, and this will answer Dr. Bessey's question, there is a mild decrease in the total number of insulin receptors, associated with a decrement in hormone-receptor affinity.

Dr. Drucker, your comments are very well taken, and I agree with you that the issue of receptor down regulation is at the heart of the problem. Our studies and those found in the literature indicate that the defect has two components. The first component is due to prolonged exposure to insulin itself, and is responsible for partial resolution of the defect with tumor removal. The second component is most likely due to a postreceptor defect, which is due to down regulation of the receptors. Two groups of investigators have already looked at this problem and both have suggested that the decrement in insulin receptor number cannot account for more than 10% of the defect. Therefore, the majority of the defect is most likely due to down regulation of the receptor, the nature of which is still unknown. This defect could be the result of an alteration in any of the cascade pathways beyond the hormone-receptor interaction that occurs at the cell membrane. Such defects could be in the expression of the second messenger, in adenylate cyclase or in the activation of protein kinase enzymes, or even in alteration in the phosphodiesterase pathways. Currently we have no data to indicate which of these pathways is affected.

Dr. Drucker, your question regarding insulin insensitivity in the normal controls is a very interesting question. We are currently doing studies to establish the length of time it takes normal volunteers to develop insulin insensitivity while they are being exposed to prolonged glucose infusions. We hope to report on such studies in the future.

Dr. Bessey, I appreciate your comments regarding the use of various insulin infusion rates to examine whether this defect in insulin action is due to insulin sensitivity or specificity at the target tissues. Such studies will be performed in the future. With regards to the question that you and Dr. Drucker raised regarding the exact site of insulin resistance, *i.e.,* is it mainly in the liver or the peripheral tissues, we currently do not have any data to incriminate one or the other. As you are aware, the liver is sensitive to insulin's action, and as was shown by Rizza et al., the liver maintains this degree of sensitivity after prolonged exposure to insulin. Therefore, by deduction, I will assume that this defect must be mainly seen in the peripheral tissues, and most likely skeletal muscle. We are currently doing studies using the forearm as a model to examine the role of skeletal muscle in such a defect and the results are still pending. Furthermore, we do not believe that this insensitivity is due to the activation of the counter-regulatory hormones, as glucagon, epinephrine, norepinephrine, and cortisol levels in select patients were not different from those of normal controls.

Dr. Burke, your question regarding insulin insensitivity in patients receiving prolonged TPN is very interesting. We are not aware of any studies addressing this particular issue, and future studies will need to be designed to examine this problem. If I had to guess, I would presume that such a defect does indeed exist in patients receiving prolonged TPN, and I presume that this defect is due to excess carbohydrates and not to excess availability of amino acids.

Finally, Dr. Drucker asked about the differences in glycogen content between the patients and the normal controls. This is an extremely important point to consider. We like you, believe that the normal volunteers are glycogen replete, whereas the patients were most likely glycogen depleted. Therefore, if we assume that most of the glucose infused in the normal volunteers was channelled into repletion of hepatic glycogen stores, there then will be less glucose going to the peripheral tissues, thus augmenting insulin resistance in the periphery. This would result in underestimation of insulin resistance in these individuals, and thus such results would further strengthen our argment already raised, that prolonged endogenous hyperinsulinemia results in insulin resistance.

The Early Fate of Venous Repair after Civilian Vascular Trauma

A Clinical, Hemodynamic, and Venographic Assessment

Repair of major venous injuries of the extremities has been advocated to improve limb salvage rates and to prevent the early and late sequelae of venous interruption. The contribution of venous repair to the surgical outcome remains controversial, however, in part because the fate of venous reconstruction has previously not been well defined. The current study was done to determine the early patency rate of venous repair; to compare the accuracy of various methods used to assess venous patency, and to analyze the relationship between early venous patency and surgical outcome. During a recent 27-month period, 36 patients with major extremity venous injuries were treated by venous reconstruction; 34 patients (94%) had an associated major arterial injury that also required repair. Venous repair was performed in the upper extremity (22%) as well as the lower extremity (78%) using various reconstructive methods, including lateral repair (17%), end-to-end anastomosis (11%), autogenous vein patching (25%), interposition autogenous vein grafting (42%), and panelled autogenous vein grafting (6%). After operation, venous repair patency was evaluated by clinical examination, impedence plethysmography, and Doppler ultrasonography, and contrast venography. There were no perioperative deaths in these 36 patients. The limb salvage rate was 100% and all 34 major arterial repairs were patent at the time of hospital discharge. Venography performed on the seventh postoperative day demonstrated that 14 venous repairs had thrombosed (39%) and that 22 had remained patent (61%). Local venous repair had a significantly lower thrombosis rate (21%) than those requiring interposition vein grafting (59%) ($p < 0.03$). Compared with venography, the clinical evaluation was 67% accurate in the assessment of venous repair patency, and the noninvasive examination was 53% accurate. In conclusion, a substantial percentage of venous repairs will thrombose in the postoperative period, especially if interposition vein grafting is used. However, in this series limb salvage was not adversely influenced by an unexpectedly high rate of venous repair thrombosis. In addition, clinical evaluation and noninvasive testing did not provide an accurate assessment of venous patency after venous repair.

THE OPTIMAL MANAGEMENT of major venous injuries continues to be a controversial topic. Although successful venous repair was reported as early as the latter part of the 19th century, ligation of major venous trauma was the accepted method of treatment during World Wars I and II.[1,2] Hughes reported on repair of selected cases of venous injury during the Korean War,[3] but it was not until the Vietnam conflict that routine repair of venous injuries was advocated by Rich and Hughes.[4] Most reports from the civilian sector during the post-Vietnam era continued to encourage an aggressive approach towards major venous trauma,[5-9] but several recent publications have questioned the necessity of routine venous repair, citing good results in selected patients with venous injuries managed by primary ligation.[10-12]

The contribution of venous repair to the surgical outcome remains an unresolved issue, in part because the fate of venous reconstruction has previously not been well defined. This study was done to determine the early patency rate of venous repair, to compare the accuracy of various methods used to evaluate venous patency, and to assess the relationship between early venous patency and surgical outcome.

Patients and Methods

From January 1985 to March 1987, 36 patients with major venous injuries to the upper or lower extremity

---

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

Reprint requests and correspondence: Joseph P. Meyer, M.D., Department of Surgery, Section of Vascular Surgery (H-725), 1835 W. Harrison Street, Chicago, IL 60612.

Submitted for publication: April 24, 1987.

were treated by venous reconstruction on the Vascular Surgery services at Cook County Hospital and the University of Illinois Hospital in Chicago. There were two females (5%) and 34 males (95%), and the age ranged from 16 to 63 years with a mean age of 27.5 years. Thirty-four patients were evaluated immediately after injury. Two patients, both with traumatic arteriovenous fistulae, were seen at 2 months and 18 months, respectively, after injury.

The mechanism of injury included gunshot wounds in 24 patients, lacerations or stab wounds in six patients, shotgun wounds in four patients, and blunt injuries associated with motor vehicle accidents in two patients (Table 1). The diagnosis of major venous injury was made in the operating room in all cases except in those with preoperative clinical or arteriographic evidence for an arteriovenous fistula. Preoperative venography was not used in any instance. Venous injuries were seen in the upper extremity (22%) as well as the lower extremity (78%) and are listed by location in Table 2. Antecubital venous injuries were included in three patients who sustained complete neurovascular disruption at the elbow joint after severe laceration. Associated major arterial injuries were seen in 34 patients (94%) and are listed in Table 3. Associated fracture requiring concomitant stabilization was seen in seven patients (19%), and associated nerve damage of varying degree was seen in 12 patients (33%).

The methods used to reconstruct the injured veins and arteries is summarized in Table 4. Systemic heparin was used routinely during vascular reconstruction except when there was concern about excessive bleeding within the wounds or into other injured body cavities. Distal venous thrombus, if present, was extracted using catheter thrombectomy, and venous repairs were done using interrupted or running monofilament suture. Adjunctive fasciotomy was performed when clinically indicated in 11 patients, all with lower extremity injuries.

After operation, all extremities were elevated until edema, if present, was resolving. On the seventh postoperative day, all patients had Doppler ultrasound and impedence plethysmography evaluation of the extremity to assess venous patency; this was followed by contrast venography. Systemic anticoagulation was given to patients demonstrating deep venous thrombosis on venography. Symptomatic pulmonary embolus was not clinically suspected nor diagnosed in any case. Prospective data on these 36 patients was then analyzed after 27 months using Cochran-Mantel-Haenszel statistic.

pair (Table 5) and type of repair (Table 6). Local venous repair (lateral repair, end-to-end anastomosis, and vein patch repair) had a significantly lower thrombosis rate (21%) than those requiring interposition vein grafting (59%) ($p < 0.03$) (Table 7). There was no significant difference in patency rates between upper *versus* lower extremity venous repair, or between large vessel (subclavian, common femoral, and superficial femoral vein) venous repair *versus* small vessel (axillary, antecubital, and popliteal) venous repair. Four patients were discharged from the hospital with mild lower extremity edema. Review of these four patients venograms revealed venous repair patency in one patient and venous repair thrombosis in three patients. Follow-up evaluation at 3 months demonstrated resolution of edema in two patients and improvement but persistence of edema requiring elastic compression stockings in two patients. Overall, two of 14 patients with venous repair thrombosis had persistent mild lower extremity edema at 3-month follow-up compared with 0 of 22 patients whose repairs were demonstrated to be patent ($p > 0.05$).

* Accuracy = 0.666, positive predictive value = 0.60, negative predictive value = 0.69.

† Accuracy = 0.527, positive predictive value = 0.4, negative predictive value = 0.62.

Compared with contrast venography, the clinical examination was 67% accurate in the assessment of venous repair patency, with a negative predictive value of 0.692 and a positive predictive value of 0.6. Compared with venography, the noninvasive venous evaluation was 53% accurate in the assessment of venous repair patency, with a negative predictive value of 0.62 and a positive predictive value of 0.4 (Table 8).

Discussion

The surgeon's prime objective in the management of major venous trauma is to prevent exsanguination. Once hemorrhage has been controlled, an organized decision must be reached about the best management of the venous injury: whether to ligate this injury or to perform venous reconstruction. The factors that influence this decision include the underlying condition of the patient, the severity of associated injuries, and the complexity of the proposed venous repair.

Nearly everyone would agree that venous repair should be done when it can be performed quickly and safely in an otherwise stable patient. The controversy that has emerged during the past decade centers around the extent to which venous reconstruction should be attempted in less than ideal circumstances.

The arguments for an aggressive approach to even extensive venous injuries have included improvement in limb salvage and a reduction in the acute and chronic sequelae of venous interruption.[4,5,8,13,14] To attribute improvement in surgical outcome to the performance of vein repair *versus* ligation, however, presupposes that the vein repairs have remained patent. Careful review of the literature, however, demontrates that a critical evaluation of the postoperative fate of venous reconstruction has been made in only a handful of patients.[7,9,14,15] To determine whether venous repair has a beneficial effect on surgical outcome, therefore, an analysis of the fate of venous repair is essential.

Contrast venography must be considered the gold standard in evaluating the integrity of the superficial and deep venous circulation. Several previous studies have used postoperative venography to assess the patency of venous reconstruction after venous trauma. Sullivan and co-workers, reporting from the 12th evacuation hospital in Vietnam, determined that seven of 11 popliteal vein repairs were patent by venography performed between 1 and 4 days after operation.[14] Hobson et al. confirmed patency of 13 of 19 femoral venous repairs with postoperative venography.[9] Snyder et al. demonstrated that three of ten popliteal venous reconstructions were patent venographically,[15] and Agarwal and co-workers found that zero of four iliac and femoral vein repairs were patent using postoperative venography.[7] Our data support the contention that a substantial percentage of venous reconstructions will thrombose in the postoperative period (39%). When vein grafting techniques were used, the number of thrombosed repairs in our series was nearly 60%. It is unlikely that this high rate of venous repair failure is a reflection of compromised surgical technique; arterial repair patency and limb salvage rates of 100% indicate that reasonable surgical care was provided to these patients. It is more likely that these results accurately reflect the early natural history of venous reconstruction performed for trauma.

Previous investigators have reported on the inaccuracy of the physical examination in determining the status of venous repair.[10,14] This study supports the finding that clinical markers for the early fate of venous reconstruction are inaccurate, with a high rate of false-positive and false-negative impressions. Surprisingly, impedence plethysomography and Doppler ultrasonography, when compared with contrast venography, were even less accurate in determining whether the venous repair was patent or thrombosed. These results strongly support the use of routine postoperative venography in determining the status of vein repair.

A central and unresolved issue in the repair *versus* ligation controversy continues to be disagreement about the relationship between the method of venous injury management and the surgical outcome. Rich and Hughes,[4] Sullivan et al.,[14] and Phifer et al.[5] have implicated venous ligation as a contributing factor to lower extremity amputation in patients with femoral and popliteal venous trauma. In contrast, Mullins et al.[10] and Timberlake et al.[12] reported no increased risk for extremity amputation in patients with venous injuries managed by ligation. Our data support the concept that maintenance of outflow from the extremity through the main venous conduit is not essential for limb salvage. This was an unexpected finding in our series, especially at the popliteal level where five of eight popliteal vein repairs thrombosed without any case of limb loss.

The effectiveness of venous reconstruction *versus* ligation in the prevention of postoperative edema and later postphlebitic syndrome is also a contested issue. Rich and co-workers reported a 51% incidence of significant edema in patients with popliteal venous injuries managed by ligation compared with a 13% incidence if venous repair was attempted.[13,16] Mullins et al. demonstrated a 23% incidence of mild edema in patients with lower extremity venous injuries managed by ligation.[10] Timberlake and others reported that although transient edema developed in up to 32% of patients managed by venous ligation, no patient had a permanent problem with extremity swelling on long-term follow-up.[12] In the current study, no patient (0 of 22) with venous repair patency had edema at 3 month follow-up, compared with 14% (2 of 14 patients) when venous repair thrombosis had occurred; the difference between these figures was not statistically significant. Long-term follow-up to determine the incidence of delayed venous insufficiency in these groups is essential, but unfortunately is not available currently.

It has been suggested previously that even short-term patency (1–3 days) of venous repair may allow for increased venous outflow from the extremity before the development of collateral venous channels that are stimulated at the time the primary repair undergoes thrombosis.[17] This would be difficult to prove without knowing the exact time at which repair thrombosis occurs. More likely, patients with early occlusion of vein repairs have the same hemodynamic alterations and clinical outcome as those undergoing primary ligation of the injury. Experimental and clinical evidence have suggested that autogenous grafts placed in the venous system which thrombose might recanalize at a later date, possibly preventing delayed venous insufficiency that would occur if ligation had been carried out.[18,19] If segmental occlusion of the vein grafts occurs with preservation of the proximal and distal native venous valves, then graft recanalization may play a role in the maintenance of venous competence. On the other hand, more extensive thrombosis involving the native vein that results in significant valvular damage during recanalization will more likely result in the development of a postphlebitic limb.

Under what circumstances, then, should venous repair be attempted? This study has demonstrated that local repair, including lateral venorraphy, end-to-end repair, and limited vein patching have an acceptable early patency rate of nearly 80%. Local repairs can be performed relatively quickly, and in the case of lateral repair, actually may be an integral step in controlling hemorrhage. When the venous injury is limited enough to allow for local repair, it should be performed routinely, except in those patients too unstable to tolerate the modest increase in operating time.

The decision regarding extended venous repair is a more difficult one; when, if ever, should it be performed? Extended repairs are more complex and time-consuming procedures, and for patients with venous injuries so extensive as to preclude local repair, the decision to perform primary venous ligation can be made more liberally. Our data demonstrate questionable merit to venous repair using vein grafting techniques: the early thrombosis rate was high (59%), and the limb salvage was identical whether these extended repairs were shown to be patent or occluded. Although this study did not demonstrate a statistically significant difference in the incidence of dependent edema at 3 months in patients with patent venous repairs compared with patients with thrombosed repairs, 5- and even 10-year follow-up evaluation will be required to determine if there is a measurable difference in the incidence of delayed venous insufficiency between the two groups. Clearly, no perioperative morbidity can be attributed to our efforts at extended vein repair in these 17 patients, but whether any good was done remains an arguable point.

To summarize, this prospective study has demonstrated that the early thrombosis rate of venous repair is substantial (39%). Local venous repairs had a significantly lower thrombosis rate (21%) than those requiring extended repairs (59%). Limb salvage in this series was not affected by whether venous repair was patent or thrombosed. In addition, the clinical and noninvasive evaluation of venous repair patency were shown to be inaccurate, prompting a recommendation for the use of routine postoperative venography.

DISCUSSION

DR. NORMAN M. RICH (Bethesda, Maryland): This is a challenging subject that has dominated many of our clinical and research activities at Walter Reed and in military surgery in general for more than 20 years. I would like to thank the authors for sending me their manuscript to review. I have been aware of their work for some time and have encouraged them on a number of occasions.

I would like to comment on several aspects of their report recognizing there are many areas that could be selected. First, and extremely significant, I would like to emphasize the concerns that many surgeons expressed as recently as 15 years ago that the vast majority of patients with attempted venous repair would develop thrombophlebitis and/or pulmonary emboli.

We have been able to refute these concerns through a combined effort, and the authors as well as authors in other civilian series have corroborated these findings on recent years.

The authors have re-emphasized what we all know, that some extremity veins can be ligated without sequelae. Remaining questions identify the challenge: are there patients, and how many patients, where there can be a difference? We found that in lower extremity venous ligation that some amputations were required because of acute venous hypertension.

Another aspect of our long-term follow-up that prompted our interest in this subject was the increasing number of individuals with ligated lower extremity veins, and I emphasize lower extremity veins, who returned years later with all the chronic sequelae of the postphlebitic syndrome. I would offer and challenge those who have had recent reports with 3-month follow-ups and 6-month follow-ups that these follow-ups are absolutely inadequate to know the long-term manifestations of interrupting lower extremity veins.

As Harvey pointed out in the 17th century, and as those who replant extremities know, venous return is of paramount importance.

Finally, the authors are to be congratulated on their success in venous repair. I take the optimistic approach. They document a 61% patency rate. I believe their success rate is excellent, and I would like to ask the authors how many different surgeons were involved in these repairs because as Dale and DeWeese showed 35 years ago, and we corroborated in our laboratory, with a certain amount of experience (as we have been hearing all day, experience is important) dramatic increase in patency rate by an individual surgeon can be achieved.

These experiences are important for us. There are many other aspects to consider from the ideal venous conduit, to the inconsistent venous anatomy, to adjuvant therapy, to recannulization of veins, to pathophysiology as reported and championed by Hobson and Wright, and many other complex considerations. I believe the fact that there are seven people to discuss this presentation emphasizes the interest in this subject at this time. I anticipate that this will remain a significant challenge for us in the future.

Dr. Charles E. Lucas (Detroit, Michigan): Twenty years ago, we were taught that civilian venous injuries were best ligated. Primary venous repair, purportedly, thrombosed thus, increasing the risk for pulmonary embolism. During the 1970s, primary venous repair was used more frequently by most centers, including our own, when the repair could be done easily and the patient was hemodynamically stable. Richard Mullins, in 1980, reported 3 years of our data in a paper that highlighted the natural history and recommended therapy after venous ligation. Although most of our patients treated during those 3 years had primarily venous repair, we are often misquoted as recommending routine venous ligation. Needless to say, we are quite pleased by this since it is far better to be quoted incorrectly than to not be quoted at all. That is from Confucious several centuries B.C.

The 1980s controversy centers around how aggressive one should be with primary venous repair when vein graft interposition is needed and the patient has associated injury. Both sides of the controversy regale the listener with either clinical or noninvasive studies supporting each respective conclusion. The ratio of published papers to patients with postoperative venograms is about 2/1. Dr. Meyer and co-workers have added to the controversy something different, namely, hard data. Based on this hard data, I concur with their following conclusions: (1) simple primary venous repair is almost always indicated; (2) complicated venous repair is indicated only when the patient setting is not unduly compromised; (3) venous thrombosis has minimal effect on the patency of associated arterial repair; (4) the need for fasciotomy is influenced more by distal ischemia from associated arterial injury or associated soft tissue injury as evidenced by the fact that they had the same number of fasciotomies after primary venous repair as we had after primary venous ligation; and (5) long-term venograms 5–10 years later are still needed.

I disagree with one conclusion, namely, that anticoagulation is needed when deep venous thrombosis is confirmed by venography. Dr. Meyer, assuming that the rest of us have the same incidence of unsuspected venous thrombosis after primary venous repair, then dozens of such patients have been treated without anticoagulation. I have not seen such a patient develop a pulmonary embolus. Have you?

Dr. John J. Bergan (Chicago, Illinois): This paper is important because it describes the fate of modern day venous repair in a major accident hospital and does so objectively.

The three conclusions drawn from the paper are well supported, and I want to repeat them for you.

Pulmonary embolus after failed venous repair is not a threat in patients who sustain trauma and have their repair done. Second, achievement of patency in venous repair is disappointing. It is a surprising fact that interposition grafting is associated more with failure than local repair. That is contrary to some research work on this subject. Finally, extremity edema does not occur if the repair stays patient. The conclusion I take from that is that if venous repair can be done, venous repair should be done. Therefore, the questions are: why do the interposition grafts fail? Dr. Meyer, is that a question of disparity of size? Are small saphenous vein grafts being put into major larger veins? If size disparity is not the problem, is it redundancy?

If we are to increase the patency of our repairs, would paneled grafts be better? They were not in your two experiences. Would a spiral graft be better in a major vein?

Dr. R. Rhodes (Cleveland, Ohio): I want to congratulate the authors on an excellent clinical series and particularly Dr. Meyer for a well-presented paper. I do share some of Dr. Rich's concerns, however, that occlusion of the vein graft at 1 week is not necessarily the equivalent of adopting a nonrepair philosophy. I certainly would second his comments regarding the late sequelae of venous occlusion.

I would like to ask a question regarding the relatively high false-negative rate that was seen with the noninvasive venous studies. This suggests that possibly the thrombosis of the venous repair was not a major restrictive factor in venous outflow from the limb. If it is not such a restrictive factor, then perhaps the excellent results with the arterial repair can be explained on the basis of the excellent collateral circulation.

If the authors are proposing an alternative approach to repair, would they suggest a selective approach and would this selective approach be based on preoperative noninvasive venous testing to identify those patients in whom the venous injury is providing venous occlusion and, thus, subsequent restriction of arterial inflow?

Dr. Robert W. Hobson, II (Boston, Massachusetts): I wish to compliment the authors on bringing to our attention the potential value of universal venous reconstruction for major venous injuries of the upper and lower extremity, and yet the data may not be definitive when venous patency is related to limb salvage or amputation rates. My initial comments relate to combining upper and lower extremity venous injuries. Amputations are reported rarely in cases of upper extremity venous injury treated by ligation, which therefore tends to skew your data toward limb survival regardless of venous patency. I recommend an emphasis on lower extremity venous injuries, particularly popliteal and common femoral injuries, which are of greatest clinical significance.

I do not regard universal venous repair as necessary. Based on our investigative and clinical studies, the most important subset of patients would appear to be those with major venous injuries and evidence of peripheral venous hypertension. I ask Dr. Meyers whether peripheral venous pressure measurements were performed or clinical notes recorded on presence or absence of venous distension on his patients in an effort to identify the subset of patients who might benefit most from venous repair?

Second, since the noninvasive vascular laboratory was inaccurate in the analysis of postoperative patency, I question of timing of venography on the seventh postoperative day. Adverse hemodynamics associated with venous occlusion that might influence limb survival occur within the first 48–72 hours after ligation or failed venous repair. Do you have any venographic data on immediate postoperative venous patency? Patency of a major venous repair at that time may ensure survival of the extremity, even though the repair may have occluded by the seventh postoperative day.

Dr. Watts R. Webb (New Orleans, Louisiana): Our experience at Tulane and at Charity Hospital Service, monitored primarily by Dr. Morris Kerstein and published in the *Journal of Vascular Surgery*, recently looked at 156 vascular injuries in 223 patients since 1979. Of this group, there were 83 patients who had venous injuries. Twenty-three of these patients had isolated venous injuries and the rest were associated with arterial injuries. Seventeen patients had venous injuries of the major veins of the arm, not of the trunk, but just of the arm. All were ligated and subsequently there have been no sequelae evidenced at all; therefore, we do not believe that these need to be repaired.

In the leg, about half the injuries were repaired and about half were simply ligated except for the popliteal, which we always repaired, usually with vein grafts. We ligated the veins if the condition of the patient, because of other injuries or because of shock, indicated that it would be better not to spend the time in a detailed repair.

There has been no limb loss in this group. The arteries have stayed open. One thing we have done that perhaps has been slightly more aggressive is utilization of early fasciotomy, in anyone who has the slightest sign or symptom of a compartment syndrome. About 80% of those with combined arterial and venous injuries, and all of those with popliteal combined injuries, and about 70% of those with only venous injuries of the leg have had fasciotomies.

The long-term follow-up after nearly 8 years has demonstrated that about 25 or 30% of those with ligation of the leg veins are going to have some minor disability. The major disabilities occur only in those with nerve injury. In those who have had veins ligated, about one fourth have some minor swelling, which has been controlled easily with elastic stockings.

We would like to say that this experience does not negate or deny the beautiful documentation and experience of military injuries of Dr. Hughes and Dr. Rich, but we do believe that there is a tremendous difference in the populations that we see. In military casualties the injuries have usually disrupted more than one vein, multiple veins, including all the collaterals, and in these patients there is no doubt that it is extremely important that every attempt be made to repair the vein or veins.

We similarly agree that at this time if it is at all feasible and the condition of the patient allows, then one should repair lower extremity veins; but if this is not feasible because of the condition of the patient, then fortunately the long-term consequences probably are not going to be disastrous.

DR. JAMES W. MAY JR. (Boston, Massachusetts): I enjoyed the paper very much.

Virchow has taught us that stasis is related to freshly repaired anastomosis thrombosis. I would like to ask Dr. Meyer if there was a correlation in those repairs that thrombosed with patency of other collateral veins within that extremity. In other words, did the repairs stay patent that needed to stay patent and those thrombose that did not need to stay patent?

DR. JOSEPH MEYER (Closing discussion): I want to thank everyone for their thoughtful comments. I will do my best to answer your questions.

We believe this study has helped to define the early fate of venous repair and the relationship between venous patency and limb salvage. The unexpectedly high rate of venous repair thrombosis has demonstrated to our satisfaction that maintenance of venous patency in the acute setting after a major venous injury is not necessarily required to achieve limb salvage.

Another central issue, which several of our discussants have identified, centers around the long-term sequelae of venous interruption. The 3-month follow-up obtained in our group of 36 patients is clearly insufficient to offer much useful clinical information. Large civilian series reported from Detroit and New Orleans have demonstrated a remarkably low rate of chronic venous insufficiency in patients whose major venous repairs were managed by primary ligation. In contrast, data reported from Viet Nam suggest that late morbidity (at 5- and 10-year follow-up) related to postphlebitic syndrome was substantially higher in patients undergoing venous ligation compared with those with attempted venous repair. These divergent conclusions indicate that the issue remains largely unresolved and will likely remain so until long-term follow-up data, which include venography and hemodynamic testing are available for analysis.

Dr. Rich, most of these patients were treated at Cook County Hospital and had their procedures performed under my supervision. All 36 of our patients were staffed by fellowship-trained vascular surgeons who personally scrubbed in and supervised on each operation to ensure the best possible result.

Dr. Lucas, the natural history of venous repair thrombosis has not been well documented, but we have no reason to believe it should be much different from that of garden variety deep vein thrombosis. Our concern has been that these patients may be at an increased risk for pulmonary embolus (although we have no scientific basis for this) and thus they have been given 3 months of oral anticoagulation.

Dr. Bergan, we were initially surprised at our rather poor results with venous reconstruction, especially when extended vein repairs were performed. As time went on, however, we realized that a substantial number of our repairs were failing, without affecting our overall surgical results. These were particularly unexpected findings at the popliteal level, where five of eight of our venous repairs thrombosed without a case of limb loss. This did not appear to be a function of size discrepancy between the native vein and vein graft, as the results were worse at the popliteal level (where there is less size discrepancy) than at the superficial femoral level.

Why are these vein grafts occluding at higher rates than the local venous repairs? The answer probably lies at the cellular level. The amount of interface between the blood and that portion of the repair that is not native vein may alter thomboxane production and platelet aggregation to stimulate the clotting of blood. This is a question that we will have to refer to the laboratory.

Regarding the technical performance of these procedures, we did use the same meticulous care in repairing the veins as we did the arteries. My impression from reviewing our intraoperative photographs was that they were satisfactory from a technical standpoint. Intraoperative completion angiography was used routinely in these cases, but completion venography was not; this may have helped to detect any intraluminal defects and might have improved our overall results.

Dr. Rhodes, if either the IPG or Doppler ultrasound was incorrect compared with venography, that patient was considered to have an incorrect noninvasive examination. The large number of false-negative noninvasive examinations probably is a reflection of the excellent potential collateral venous circulation in these young patients. We have not used the noninvasive evaluation selectively to determine which vein injury should be repaired and which should be ligated, but I believe it is an interesting idea.

Dr. Hobson, your point about our results being skewed toward the favorable side because of the number of upper extremity venous injuries we included is a good one. Upper extremity venous ligation has been shown to be well tolerated by a number of investigators. It is probably related to the superior venous collateral bed in the upper extremity compared with the lower, and also with the lower hydrostatic pressure in the arm than in the leg in the upright patient. Nonetheless, 80% of our venous injuries were in the lower extremity, and the surgical results were uniformly satisfactory regardless of the anatomic location of the injury.

Peripheral venous pressure measurements were not performed, but venous pressure was clinically elevated in many patients after restoration of arterial flow to the extremity. It is dramatic to remove your distal venous clamp and see a jet of venous blood squirt across the operating table.

Postoperative venography was not performed on the first day after surgery primarily for practical reasons. Many of these patients remained intubated, or had chest tubes or fresh thoracotomies or craniotomies. We believed that a trip down to the x-ray suite under these conditions would be hazardous, and we arbitrarily chose the seventh postoperative day because most patients were stable by then. This approach, unfortunately, did not tell us when our repairs were thrombosing, only what their status was at day seven.

I would like to conclude by offering our recommendations on the management of major venous injuries. The surgeon's primary objective in the management of venous trauma is to prevent exsanguination. Once this has been accomplished, a decision must be reached about the most appropriate management of the venous injury, to ligate or repair. The factors that will influence this decision include the underlying condition of the patient, the severity of associated injuries, and the complexity of the proposed venous repair. Our data indicate that local venous repair has an acceptable early patency rate of 80%, is generally a rapid procedure, and in the case of lateral venorraphy actually may play an integral rôle in controlling hemorrhage. We believe, therefore, that local venous repair can be recommended in nearly every instance.

Extended venous repairs are clearly more complex and time-consuming procedures, and for patients too unstable to tolerate the increase in operating room time the decision to perform primary venous ligation can be made more liberally. Our data have shown that these repairs have a substantial thrombosis rate (59%) and that limb salvage was not affected by the status of vein repair patency.

Well-documented long-term follow-up will be required before a definitive conclusion can be drawn about the delayed effects of venous interruption. Until these data are available, our group will probably continue to perform even extended venous repair so long as the safety of the patient is not jeopardized.

Computerized Axial Manometry of the Esophagus

A New Method for the Assessment of Antireflux Operations

C. THOMAS BOMBECK, M.D., F.A.C.S.,* OCTAVIO VAZ, M.D.,† JOHN DESALVO, B.S.,‡
P. E. DONAHUE, M.D., F.A.C.S., § and LLOYD M. NYHUS, M.D., F.A.C.S.||

This is a presentation of a new manometric parameter of the mechanical competence of the lower esophageal sphincter (LES), the lower esophageal sphincter vector volume (LESVV). It is determined by computer analysis of continuous-pressure measurements during constant speed pullback of a radially oriented 4- 6- or 8-channel manometry catheter across the LES. Patients were studied with this method both before aggressive medical therapy for esophagitis and before and after Nissen fundoplication. LESVV accurately predicted failure of medical therapy and success of the fundoplication. In patients with successful fundoplication, LESVV demonstrated a 100-fold increase in mechanical competence of the LES, even in the absence of increased LES pressure or length, increasing from 113 ± 63 mm^3 to 11357 ± 3733 mm^3.

From the Division of Surgical Gastroenterology, Department of Surgery, the University of Illinois College of Medicine at Chicago, Chicago, Illinois

SINCE THE FIRST DESCRIPTION of the pressure differential and pressure barrier between the esophagus and stomach by Fyke and co-workers,[1] multiple investigators have attempted to ascribe the normal competence of the lower esophagus and its resistance to reflux from the stomach to this "physiologic lower esophageal sphincter."[2] More recently, it has become obvious that simple measurements of maximal pressures generated in the area of the lower esophagus are insufficient to distinguish between patients who have reflux and those who do not.[3] This discrepancy has relegated esophageal manometry as a surgical investigative tool to an adjunctive position only, in which it was reserved to rule out motility disorders of the esophageal body that might cause symptomatic failures after otherwise perfectly satisfactory antireflux operations.[4] On the other hand, Joelsson et al.[5] have repeatedly emphasized that gastroesophageal reflux is a multifactorial disease and that manometry of the "cardia" or lower esophageal sphincter (LES) is essential to distinguish mechanical failure of that structure from either gastric or esophageal mechanisms that might also cause reflux. Both that group and our own[6,7] have emphasized also that not only is the maximal pressure that the LES can generate important in LES competence, but also that the length over which the LES generates such pressure is of equal importance. These two factors alone, length and pressure, are still insufficient to describe LES mechanical failure, although when taken together, they are much more successful than either one alone.[6]

We postulate that the LES mechanism is not a single "all or none" mechanical structure at the lower end of the esophagus. Rather, it is an aggregation of contractile units, probably corresponding to the muscle fibers of the LES. Any method that describes the LES must take into account not only the length over which those fibers are distributed and the maximum pressure that the strongest of them must generate, but also the symmetry of unit contraction around the circumference of the LES and the distribution of contractile pressures along the entire length of the LES. In a preliminary report we have described a new method, computerized axial manometry

(CAM), which accomplishes all these interactive measurements.[8] This is a report of the first application of the method to the selection of patients for operation for gastroesophageal reflux.

Methods

CAM was developed in conjunction with the Sensormedics Corporation (formerly Beckman Instruments, Inc.) of Anaheim, California, which markets the hardware and software as the "Esophaplot System." The system consists of a standard four or six lumen motility catheter, composed of 1.0-mm I.D. polyvinyl tubing, with concentric openings either all at the tip or staggered at 3.0 cm proximal from the tip. The individual catheters are perfused at 0.764 mL/min from a custom-made pneumohydraulic pump and connected *via* "T" tubes to standard Statham pressure transducers (Statham Instruments, Oxnard, CA). The transducers are connected to a Sensormedics R-611 8-channel Dynograph (Sensormedics Corp., Anaheim, CA) equipped with a voltage equalizing amplifier to provide linear output to a Texas Instruments Professional Model microcomputer (Sensormedics, Corp.), equipped with 512 KB of RAM and a Winchester 20-MB hard disk. Recorder output is digitized by a Data Translation model 2801 A-D converter in the computer (Sensormedics, Corp.). For LES measurements, the catheter is mechanically pulled back across the LES by a custom-made linear pullback device, powered with a high torque hysteresis synchronous motor, to provide a constant 1.0-cm/sec pullback speed over a wide range of loads. Pressure readings are sampled during pullback from each catheter opening with a 0.4-msec interval between individual catheter readings and a 100-msec interval between sets of readings. Pressure values are therefore concentrically recorded at each millimeter of catheter pullback. Pressure values are recorded in RAM during the examination as 2-byte integer values, and simultaneously displayed graphically on the computer CRT. Seventy seconds of recording is possible, although the maximum required for each pullback rarely approaches 20 seconds.

Subsequently, the RAM recorded values are transferred to disk and converted, by reference to a predetermined standardization curve, to mmHg for final calculations. The Sensormedics system uses a set of programs, written in compiled Microsoft Basic (Stat Systems Inc., Philadelphia, PA), to print out maximum LES pressure relative to intragastric pressure, measured by each catheter tube during a pullback, the length of the LES pressure "hump," and the rate of pressure increase *versus* LES length. The area circumscribed by the LES pressure curve is also calculated as the sum of pressures measured by an individual catheter channel at each millimeter over the length of the LES. A minimum of three pullback measurements is made of the LES for each patient for each examination.

The program also is capable of providing a three-dimensional graphic representation of the LES pressure profile, using the recorded pressures as the individual radii of a three-dimensional figure in which the pressures are plotted at either 90 degrees to each other for a 4-channel catheter, or at 60 degrees to each other for a 6-channel catheter. Individual sets of measurements are spaced 1.0 mm apart in the graphic representation, yielding a three-dimensional figure in which the radius is proportional to the pressure of the LES, oriented around the circumference of the LES. The figure may be rotated around three axes on the computer screen for inspection, especially of LES symmetry.

A final measurement consists of calculation of the volume of the three-dimensional figure, which is a direct representation of the individual force of the LES contractile units, integrated over the length of the LES. This program, written in our laboratories, uses the beginning and end points of the LES as determined above to locate the LES pressure curve in the spectrum of measured values. It then normalizes the values to intragastric pressure as 0 and converts the mv values to mmHg according to the predetermined standardization curve. The area of the individual LES "slices" is then calculated using the LES pressures as radii of the slice. The general formula for the area of an irregular polygon is used:

$$A = 0.5 \times \sin(360/n) \times (P_1P_2 + P_2P_3 + \cdots P_1P_n)$$

where n is the number of catheter channels spaced equidistantly around the circumference of the catheter and P_1 to P_n are the individual pressures measured in the catheter channels. For four pressures, the area of the slice is given by the formula:

$$A = 0.5\,[(P_1 + P_3)(P_2 + P_4)]$$

and for six pressures, by the formula:

$$A = 0.433\,(P_1P_2 + P_2P_3 + P_3P_4 + P_4P_5 + P_5P_6 + P_6P_1),$$

The volume of each "slice" is then calculated by multiplying its area by its thickness, 1.0 mm, and the volume of all the "slices" added to give the volume of the entire LES, the LES vector volume (LESVV). Calculation of this parameter requires approximately 4 seconds of microcomputer time, whereas hand calculation, even if the values were available, would require hours, making it prohibitively expensive for routine clinical use.

Patients

This study has been approved by the Institutional Review Boards of the University of Illinois College of Med-

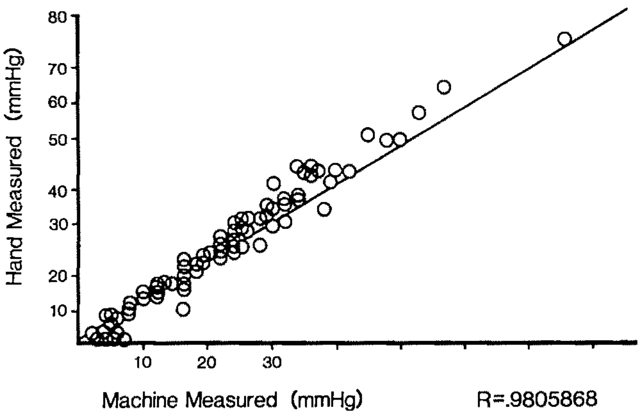

FIG. 1. Scatterplot of hand-measured maximum LES pressures determined by standard manometric means, and the same pressures determined by the on-line microcomputer (r = 0.98).

icine at Chicago, and of Cook County Hospital, Chicago.

Thirty patients were studied. Six patients were normal volunteer controls, and seven patients were studied before they began an eventually unsuccessful course of nonoperative therapy and then again 6 weeks to 3 months after Nissen fundoplication carried out in the "floppy" fashion that we have described.[9] Eight patients were studied before successful nonoperative therapy, and the remaining nine patients were studied after either successful Nissen fundoplication or in the course of investigations for other nonreflux symptoms. In all patients, reflux and/or esophagitis was either confirmed or ruled out by 24-hour pH measurements and esophagoscopy. Patients were unselected and were studied as they were referred to the special Esophageal Disease Clinic of the Division of Surgical Gastroenterology for evaluation and treatment. When matched pair grouping was possible, as in the pre- and postoperative fundoplication group, results were analyzed using the Student's t-test, but, in most cases, only simple variances were calculated since, to be of clinical use, tests must exclude abnormal measurements beyond two standard deviations from the mean.

Results

Initial verification of the measurement method and apparatus is shown in Figure 1. LES pressures measured by standard manual measurement were correlated with those measured by the apparatus in 115 separate determinations. Values correlated with r = 0.98 and significance level of 0.0001. Similar values were obtained for measurement of LES length.

The ability to measure LES maximum pressure, LES length, the area circumscribed by the LES pressure curce, and LESVV to distinguish between patients with proven reflux and those without reflux is shown in Figure 2. When either pressure or length of the LES alone was used, there was a large overlap between the two groups of patients The separation between groups was somewhat better with LES area, and was complete with LESVV.

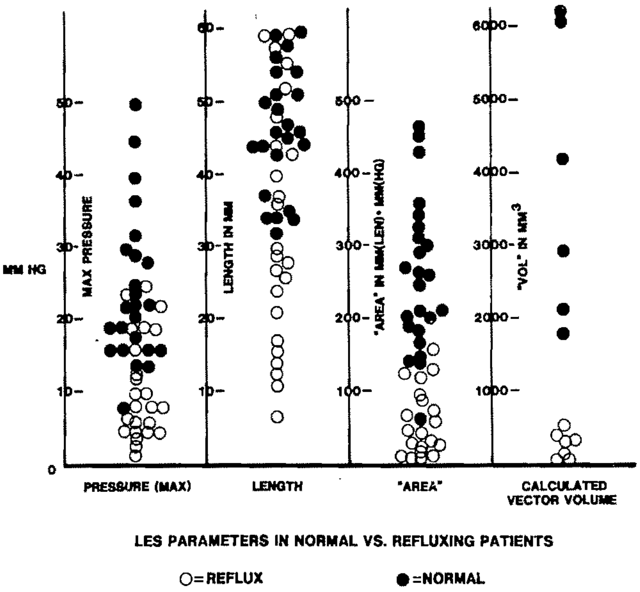

FIG. 2. Distribution of LES maximum pressures (column 1), LES length (column 2), LES area (column 3), and LES volume (column 4) in patients with and without gastroesophageal reflux. Open circles indicate patients with reflux. Filled circles indicate patients without reflux.

Nissen fundoplication had an unpredictable effect on LES maximal pressure (Fig. 3), LES average pressure (Fig. 4), or LES average length (Fig. 5). The effect of LES

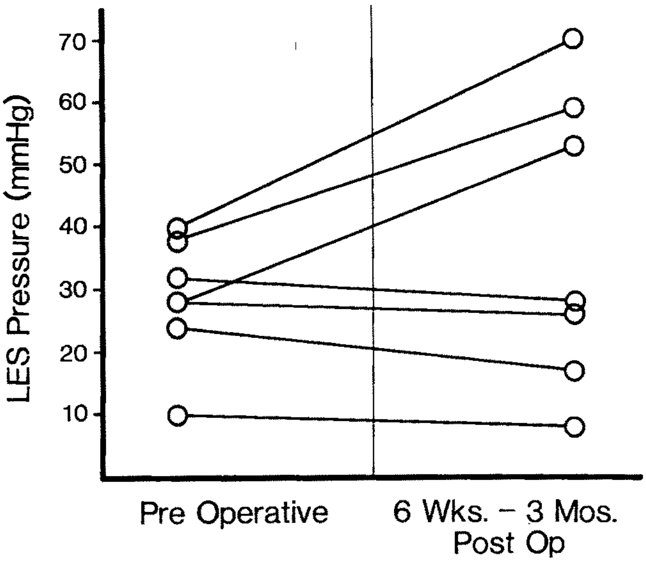

FIG. 3. Maximum LES pressure before and after Nissen fundoplication. Paired measurements in seven patients.

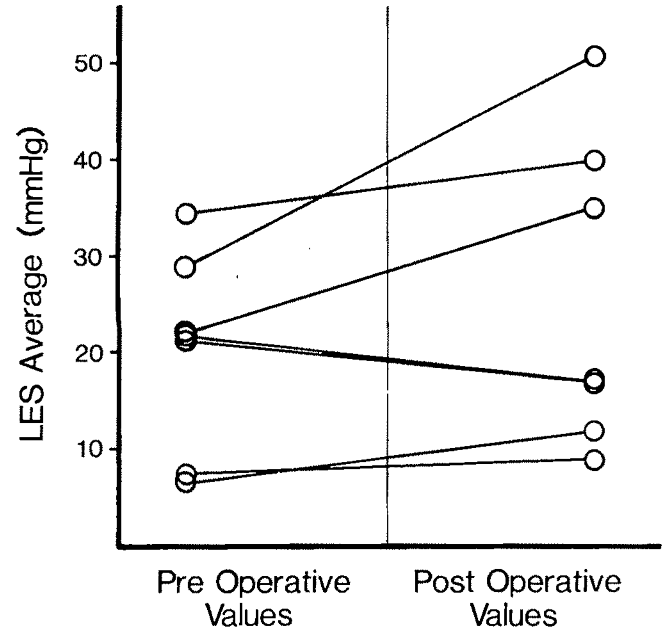

FIG. 4. Averaged LES pressures from a 4-channel manometric catheter before and after Nissen fundoplication. Paired measurements in seven patients.

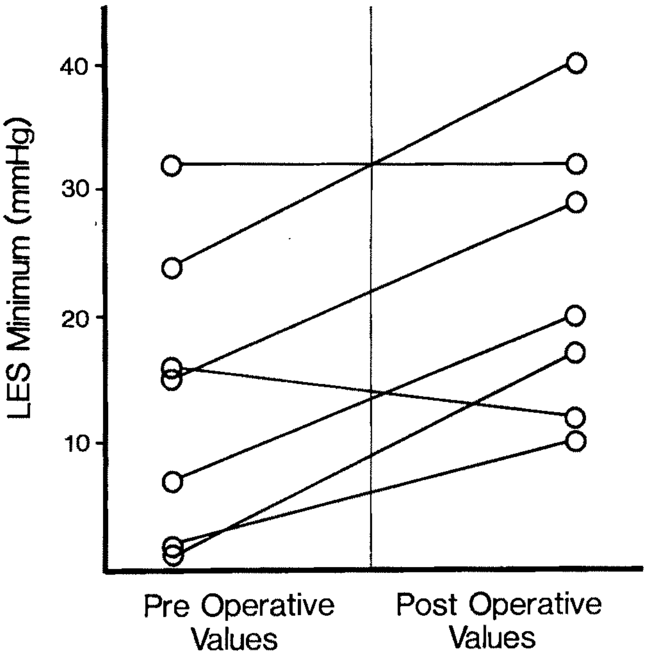

FIG. 6. LES minimum (lowest maximum) pressure before and after Nissen fundoplication. Paired measurements in seven patients.

minimum pressure, the lowest maximum pressure of the four measured in the four-channel catheter on pullback, was more predictable (Fig. 6). In five patients, the pressure was increased by fundoplication, in one patient it was unchanged, and in one patient it decreased. The preoperative value in all patients was 13.9 ± 4.3 mm, and the postoperative value was 22.9 ± 4.2. In the patient with the decrease in minimum pressure, reflux persisted after operation for reasons that are unclear. $LESP_{min}$ for only the patients who were cured of reflux changed from 15.83 ± 4.5 to 25.0 ± 4.27 ($p < 0.05$).

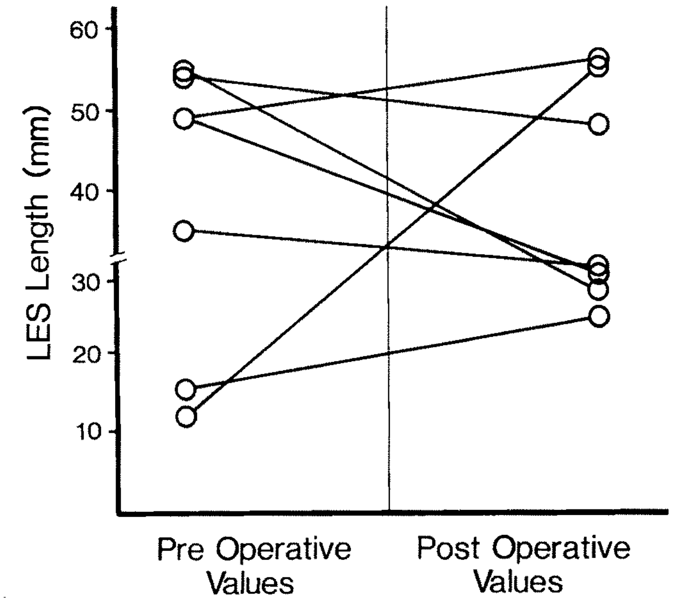

FIG. 5. LES length before and after Nissen fundoplication. Paired measurements in seven patients.

LESVV (Fig. 7) increased greatly after fundoplication in all patients except one, from 119 ± 42 mm^3 to 9994 ± 3508 mm^3 ($p < 0.001$). In the patient with no LESVV increase, the same patient who had the minimum pressure decrease, reflux persisted after fundoplication. All patients except one had very low LESVV values before fundoplication. The patient with the initially high value of 4500 mm^3, had been noncompliant with nonoperative therapy and had only mild esophagitis. He was operated on because he also had severe pulmonary obstructive disease and had nocturnal aspiration.

Figure 8 contains representative printouts of the graphic representations of LESVV from eight different patients, seen in profile. Gastric pressures are on the left end of each figure and esophageal pressures on the right end. As the measuring catheter is drawn from the stomach to the esophagus, from left to right, the pressures measured at millimeter intervals are plotted, in this case as vertical lines, one line per millimeter. That portion of the line extending vertically above the central axis of each figure is proportional to the pressure directed down toward the central axis, and that portion of the line extending vertically down from the central axis represents the pressure directed up toward the central axis. A and B are tracings from control patients. C, D, and E are from patients with reflux, before Nissen fundoplication. In these tracings, the LES is more narrow than controls,

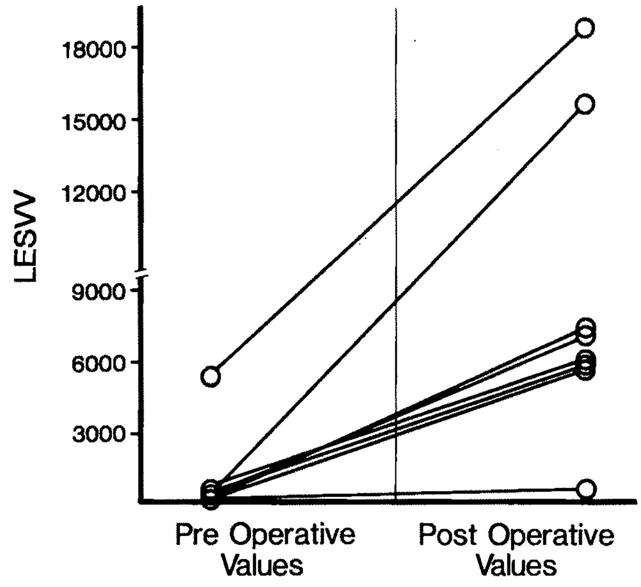

FIG. 7. LES vector volume before and after Nissen fundoplication. Paired measurements in seven patients.

greatly asymmetrical, and in both D and E show absence of one component of the LES profile. F is from the same patient as C, and G is from the same patient as E, after fundoplication. The re-establishment of a more normal LES configuration is obvious. The complete graphic representations plotted on three-dimensional axes show the same changes but are difficult to transpose to the printed page. It can nonetheless be easily appreciated that the volumes of the figures shown in F and G are considerably greater than those in the corresponding preoperative figures in C and E.

The ability of LESVV measurement to predict nonoperative therapy failure and the eventual need for fundoplication is shown in Figure 9. Three groups of patients are plotted: those without reflux for comparison with those with reflux who were successfully treated medically and those who failed medical therapy either because it was ineffective or because they could not tolerate the rigorous treatment necessary to control their reflux. There are 11 patients in the group who eventually required operation, which includes four patients who have not yet been studied after operation. All of those patients had LESVV values below 1000 mm^3 with a mean of 161 ± 72 mm^3, and a 95% confidence range of 0–639 mm^3. The patient who was unable to comply with nonoperative management is excluded from this group because he was never adequately treated with medical measures. There are seven patients in the group who succeeded with nonoperative therapy and who could decrease or cease treatment entirely after resolution of esophagitis. Mean LESVV in that group was 1582 ± 159 mm^3 with a 95% confidence range of 740–2424 mm^3. Some minimal overlap was noted between that group and the control group, which was included for comparison.

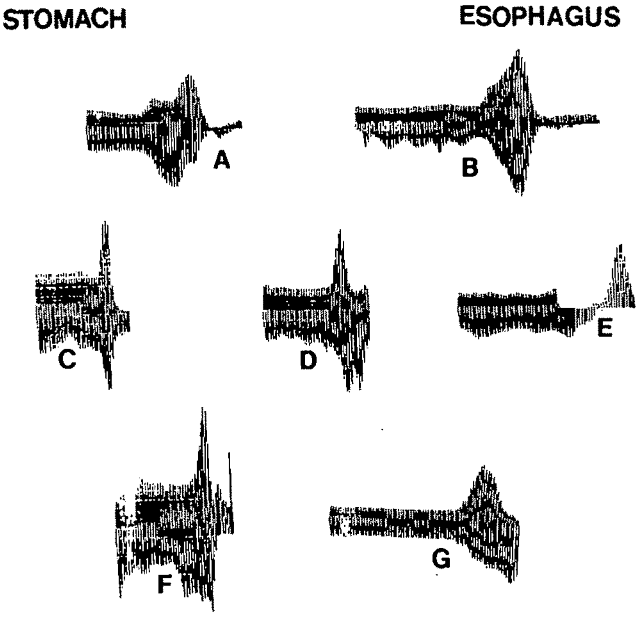

FIG. 8. Manometric pressure profile graphs, in two dimensions of LES pressures measured at 1-mm intervals across the LES from the stomach to the esophagus. A, B: normal controls. C, D, E: patients with reflux. F, G: patients after fundoplication.

Dose LESVV reflect the severity of gastroesophageal reflux as determined by 24-hour pH measurements, or the severity of the patient's peptic esophagitis graded endoscopically? LESVV was correlated with 24-hour pH measurements in patients with endoscopically demonstrated esophagitis. The percentage of the 24-hour

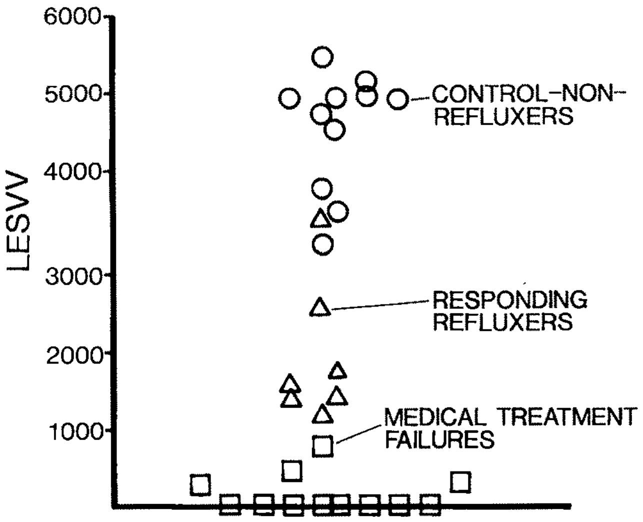

FIG. 9. Distribution of control patients (circles), patients with reflux who were cured by nonoperative treatment (triangles), and patients who eventually required operation (medical failures) (squares), according to pretreatment LESVV values.

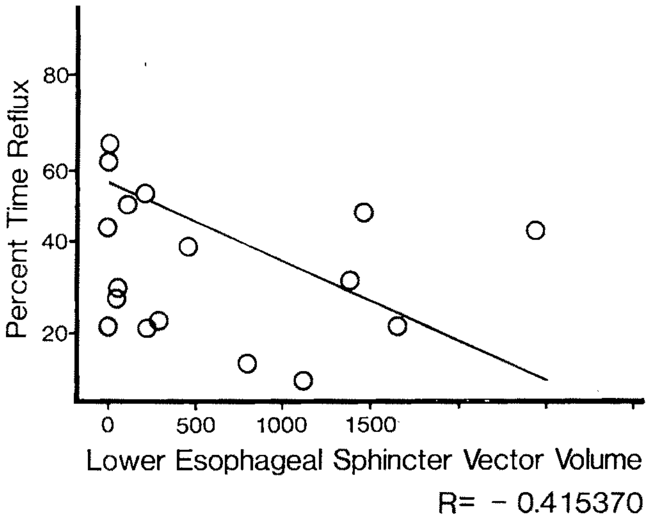

FIG. 10. Scatterplot LESVV *versus* the total percentage of a 24-hour period that the patient's intraesophageal pH 5.0 cm above the LES was les than 4.0.

measurement period that the patient's intraesophageal pH was below 4.0 *versus* LESVV in that patient is shown in Figure 10. Approximately the same results were obtained when the percentage of upright reflux time was used instead of total time. As demonstrated, there was insignificant correlation (r = −0.40) between the measured volume of reflux and LESVV. As might be expected from this finding, there was also insignificant correlation between this measure of the severity of reflux and whether the patient would eventually require operation.

There was similar lack of correlation between LESVV and the endoscopic severity of the patient's esophagitis.

Discussion

Computerized esophageal motility data are not new. Castell and others[10–12] have used large mini- or mainframe computers for both collection and interpretation of motility data in the body of the esophagus and for prolonged measurement of reflux. The significant new method proposed here is the application of the microcomputer to real-time, on-line data collection and analysis and the introduction of a new parameter for measurement of LES mechanical integrity, the LESVV. A preliminary report of the method has been presented.[8] Castell and Castell have recently presented a similar method with a different but equally reliable microcomputer system, for determination of all parameters discussed here except for LESVV.[13]

Physiologic mechanisms that prevent gastroesophageal reflux remain incompletely understood although currently it is recognized that the central barrier to reflux prevention is the lower esophageal sphincter mechanism. Much confusion has been generated by the erroneous assumption that reflux necessarily causes esophagitis and that the absence of esophagitis, regardless of other symptoms, rules out reflux. In this study, we have avoided that problem simply by excluding patients with reflux but without esophagitis.

A current theory that is widely held is that all reflux, normal as well as pathologic, occurs as a result of transient LES relaxation.[14] On the other hand, it is well known also that, on balance, maximal LES pressure is decreased, especially in patients with reflux so intransigent as to require surgical therapy. DeMeester and coworkers have called such a condition "mechanical LES failure"[15] and used it as an indication for an LES protective operation such as a Nissen fundoplication. The purpose of this study was to further refine the definition of mechanical LES failure, beyond simple LES shortening, simple LES pressure decreases, or combinations of the two.

Any measure of the static, mechanical LES pressure barrier must provide some measure of the functional capacity of the entire LES msucle mass. It is a matter of common intuition that the resistance of the LES to backflow must be the sum of the resistances provided by all the circular muscle fibers that make up the LES. This is analogous to the concept of series electrical resistance to current flow, in which the total resistance of the electrical circuit, made up of resistors connected end to end (in series), is the sum of the individual resistor resistance values. The LES may be thought of as such a "series resistance circuit." Although the single highest resistance in the circuit is provided by the point at which the LES exerts its highest or maximal pressure, total resistance to backflow is also made up of the remaining points along LES length at which lesser pressures are generated. A major advance in the application of this hypothesis to the LES was made by the addition of LES total length to simple maximum pressure.[6] This introduced the concept that LES backflow resistance is generated over the length of the LES and not at a single point at which the maximum pressure is measured. That the concept is valid is demonstrated in the first series of patient measurements in this study. Neither simple pressure measurements nor simple length measurements adequately separate patients with reflux from those without reflux. LES area measurements in which pressure is continuously measured over the length of the LES provide much better separation. Nonetheless, LES area measurement has the major drawback in that it is made in one plane only, ignoring the fact that the LES must exert its pressure not only over its length but also around its circumference. Winans[16] has shown that the LES does not contract symmetrically around its circumference; therefore, the assumption that measured pressures at any given LES level are equally exerted from all points around the LES is invalid. The difference in pressures registered by multiple concentrically oriented catheters at any single level in the LES is caused by this asymmetry.

It is easily demonstrated by simple calculus that pressure exerted toward the center of a cylinder from around its circumference is the sum of the centrally directed pressure vectors measured at infinitely small intervals around the circumference of the cylinder. If the radius of the cylinder is directly proportional to those pressure vectors, then the centrally directed pressure, which generates cylinder "closure" at that point, will be directly proportional to the area of the cylinder at that point. The detailed mathematical demonstration of this phenomenon is not appropriate to this discussion. Total resistance to flow through the cylinder will then be directly proportional to the sum of the cross-sectional areas, measured at infinitely small intervals along the length of the cylinder.

Physical limitations of the size of the pressure measurement device that can be passed through the LES without unduly distending it limit the number of radially oriented pressure measurements that can be made at a single point to six or eight at the most. In this study, we used four pressure channels but have subsequently begun to use six for the greater definition afforded. It was likewise impossible to measure pressures at infinitely small intervals along LES length, but it is a common observation that pressure changes from millimeter to millimeter are very small compared with the absolute magnitude of radially measured pressure. Accordingly, areas were measured at each millimeter, both because more frequent measurements would detect minimal change and because of the finite sampling rate of which the A-D interface was capable. Because pressure measurements are taken axially and then both recorded and calculated by computer, we have called the method computerized axial manometry or CAM. Since the sum of cross-sectional areas of a cylinder taken along its length equals the volume of the cylinder, we have called the resultant "volume" of the LES the LES vector volume, or LESVV.

Using this new manometric parameter, we have studied two groups of patients, one with reflux before and after Nissen fundoplication, and a larger one with reflux, at first treated by standard nonoperative methods, and then with treatment failures submitted to Nissen fundoplication.

In the first group, "floppy" Nissen fundoplication did not change either LES maximum pressure, LES average pressure, or LES length, despite stopping reflux in all patients but one. The failure of this variant of the Nissen fundoplication to augment LES maximum pressure has been reported elsewhere and is suggested as the reason that the "floppy Nissen" avoids the gas bloat syndrome.[17]

LES minimum pressure, the lowest of the four radially oriented pressures, was increased in five patients, unchanged in one patient, and decreased in one patient. The patient with the decreased value had persistent reflux. This suggests that one action of the Nissen fundoplication was to make the LES more symmetrical around its circumference, and also that the procedure had corrected the "weak link in the chain."

An approximate 80-fold increase was produced in LESVV by fundoplication, demonstrating that the operation, even without dramatic increases in single maximum pressure measurements or LES length, greatly increased the total antireflux barrier. All patients except one had abrupt cessation of reflux and reflux symptoms. If that patient is excluded, then LESVV increased 100-fold in those patients who were cured of reflux. It is evident that for LESVV to increase by these magnitudes, pressure, length, or symmetry must be increased. Individual patients had such increases in one or more of these parameters, but no single parameter, with the possible exception of $LESP_{min}$, changed in the same direction for all patients. In addition, the "shape" of the LESVV graphic representation of the LES changed. Pressures along the length of the LES were increased without exceeding LES maximum pressure, but still greatly contributing to the new pressure barrier.

In the second group of patients, pretreatment LESVV determinations provided clear separation between those patients who succeeded with nonoperative therapy and those who eventually required operation despite adequate treatment. Although it has been suggested that LES maximum pressures less than 6.0 mmHg or very severe grades of reflux esophagitis are indications for immediate operation,[18] LESVV seems to provide the most clear definition to date. It is a direct measure of the mechanical competence of the LES, and it is this alone that is corrected by operations for reflux. That LESVV correlated neither with the duration of reflux as measured by 24-hour pH studies nor with the grade of esophagitis determined endoscopically is not surprising. Reflux duration depends on the availability of material to be refluxed, which is, in turn, dependent on diet, exercise, and other factors. The degree of esophagitis depends on the composition of the material that is refluxed, how long it remains in contact with the esophagus, and whether the esophagus is sensitive to it.

The ability of LESVV to distinguish reflux patients who will require operation from those who will not is of importance both for the comfort of the patient, who no longer will have to persevere through a trial of ultimately unsuccessful therapy, and as a cost saving measure in the treatment of this common disease. A few patients will also have more severe complications of reflux develop during impotent nonoperative treatment, and these can be avoided by earlier operation.

It is now appropriate to change the recommendation for the place of manometry in the evaluation and treatment of gastroesophageal reflux disease. CAM should be used in the evaluation of the 10% of patients who have failed simple mechanical measures for reflux prevention and who are considered for more vigorous and aggressive medical treatment. In these patients, it will allow the identification of those patients in whom such treatment will prove fruitless and bring them to an early and effective operation.

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

ANNALS OF SURGERY
c/o J.B. Lippincott Company
Attn: Dorothy Glover
East Washington Square
Philadelphia, Pa. 19105
(215) 238-4215

Deadline: Copy received by the 15th of month will run in the second following month's issue, e.g. November 15th for January issue. Ads received after the 15th will run in the next available issue.

ASSISTANT PROFESSOR— REGULAR, FULL-TIME—ANNUAL SALARY - 70K—**REQUIREMENT:** M.D., Board Certified in General Surgery. Completion of 2 year Fellowship in Surgical Oncology. Current Texas Medical License required. At least two years experience in Oncology Research or Practice. Ability to participate in the multidisciplinary approach to the treatment of malignant neoplasms, both primary and metastatic. **DESCRIPTION OF DUTIES:** To provide the atmosphere for education in Surgical Oncology, both through patient care and through scholarly activity involving basic and clinical research. Send Curriculum Vitae, letter of introduction and three references to: **William J. Fry, M.D., Department of Surgery, University of Texas Health Science Center at Dallas, Southwestern Medical School, 5323 Harry Hines Blvd., Dallas, Texas 75235.** An Equal Opportunity Employer.

BC/BE general surgeon to join expanding department in multispecialty group practice serving FFS and prepaid patients in Central Massachusetts. Practice in university-affiliated hospitals with opportunities for clinical research. Send CV to **Medical Director, Fallon Clinic, 630 Plantation Street, Worcestor, Massachusetts 01605.**

COLORADO PERMANENTE MEDICAL GROUP is an expanding multispecialty prepaid group practice caring for members of the Kaiser Foundation Health Plan. Position available immediately for BE/BC general surgeon to join existing eight man department. Competitive salary and benefits. Contact: **Toby Cole, M.D., Executive Medical Director, Colorado Permanente Medical Group, P.C., 2045 Franklin Street, Denver, CO 80205.** EOE, m/f/handicapped/veterans.

DIRECTOR OF TRAUMA and SURGICAL CRITICAL CARE— Selected applicant will be Director of Trauma and Surgical Critical Care, responsible for developing clinical and laboratory projects pertaining to these areas. Additionally, the director will be heavily involved with both clinical responsibilities and graduate surgical education of surgical residents in our fully approved residency program. **QUALIFICATIONS:** Graduate of an A.A.M.C. approved medical school, board eligibility/certification in surgery, fellowship in trauma with extensive critical care experience. Documented experience in clinical and laboratory research. Salary guarantee and extensive benefits. **REPLY TO: Helmut Schreiber, M.D., Chairman, Department of Surgery, Huron Hospital, 13951 Terrace Road, Cleveland, OH 44112.**

EXPERIENCED GENERAL SURGEON needed to step into busy established practice with multi-specialty group. Successful candidate must be Board Certified/Eligible and have some training or expertise in Vascular Surgery. Package includes $80,000 first year salary, plus productivity and complete benefits. Full partnership after one year. Located in lovely northern Illinois community. Contact: **James Russell, Inc., P.O. Box 427, Bloomington, IL 61702, phone (309) 663-9467.**

GENERAL SURGEON— BC/BE, with broad-based training (especially in areas of trauma, burns, pediatric and non-cardiac thoracic surgery) to join a 38-doctor multi-specialty clinic with three well-established general surgeons. Modern forward looking hospital with excellent staff and superb equipment. Located in a southern Wisconsin college town of 50,000 near Chicago, Milwaukee and Madison. Guaranteed salary initially but optional transition to compensation based on production. Position available for June, 1988 or sooner. Contact: **James F. Ruethling, Administrator, Beloit Clinic, S.C., 1905 Huebbe Parkway, Beloit, WI 53511, Ph. (608) 364-2200.**

GENERAL SURGEON: To join busy private practice in Capital District/Upstate New York. Excellent benefits and salary leading to partnership. **Box ANN10C, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

GENERAL SURGEONS— Newly established prepaid group practice desires to begin offering general surgery services. Looking for general surgeons interested in establishing and building a department. Physicians must be from high quality residency programs. Positions available immediately. CV's to: **Larry A. Oates, M.D., Regional Medical Director, Carolina Permanente Medical Group, P.A., 2900 Highwoods Blvd., Raleigh, N.C. 27604 (919) 878-9870.**

HAMAD GENERAL HOSPITAL DOHA—STATE OF QATAR—ARABIAN GULF— HGH 660 bed referral facility, and is the main health establishment in the country with its modernly equipped facilities, invites qualified candidates for the post of Consultant in:—**1.** Pediatric Surgery **2.** Plastic Surgery **3.** Ophthalmology **REQUIRED QUALIFICATIONS AND EXPERIENCE**—3 Years of Experience after Board certification or equivalent. **BENEFITS**— Attractive tax free salaries based on qualification and Experience. Free furnished accommodation. Monthly transport allowance. Round trip air ticket. 50 days paid leave annually. Contracts for 3 years renewable upon mutual agreement. **HOW TO APPLY**—Qualified applicants should send complete C.V. with contact telephone number to **Medical Director, Hamad General Hospital, P.O. Box 3050, Doha—State of Qatar, Arabian Gulf.**

NAUSEA
AND
VOMITING
CAN RUIN
YOUR
BEST WORK.

SURGICAL PERFECTION DEMANDS A POSTOPERATIVE ANALGESIC WITH FEW IMPERFECTIONS

STADOL® (butorphanol tartrate) lets you be as demanding about pain management as you are about surgical technique. Because STADOL provides the same relief as morphine and meperidine, but usually without the nausea and vomiting that requires an antiemetic… or a return to the OR.

You can dose STADOL based on patient need — rather than narcotic shortcomings — because it has a ceiling effect on respiratory depression and a low addiction potential. And even the sedation that may occur is different: the patient remains cooperative and responsive. Do not use STADOL when there's evidence of narcotic abuse or addiction as it may cause withdrawal. But for most cases STADOL can help smooth the patient's full recovery. Which, after all, is every surgeon's best work.

Please see next page for brief summary of prescribing information.

Stadol® IM IV
(butorphanol tartrate)

NO PAIN. FEWER PROBLEMS.

BRISTOL®

Stadol® (butorphanol tartrate)
Brief Summary of Prescribing Information

For complete information, consult Official Package Circular.

INDICATIONS AND USAGE–Stadol is recommended for the relief of moderate to severe pain. Stadol can also be used for preoperative or preanesthetic medication, as a supplement to balanced anesthesia, and for the relief of prepartum pain.

CONTRAINDICATIONS–Stadol should not be administered to patients who have been shown to be hypersensitive to it.

WARNINGS–Patients Physically Dependent on Narcotics: Because of its antagonist properties, Stadol is not recommended for patients physically dependent on narcotics. Detoxification in such patients is required prior to use.

Due to the difficulty in assessing addiction in patients who have recently received substantial amounts of narcotic medication, caution should be used in the administration of Stadol. Detoxification of such patients prior to usage should be carefully considered.

Use During Balanced Anesthesia: Since the combined respiratory depressant effect of all intravenous medication used during conduct of general anesthesia may lead to underventilation or apnea, butorphanol should be administered during balanced anesthesia only by persons specifically trained in the use of intravenous anesthetics and adjuncts, the maintenance of a patent airway and management of respiratory effects of all intravenous medication administered. An opioid antagonist, resuscitative and intubation equipment and oxygen should be readily available.

Drug Dependence: Special care should be exercised in administering Stadol to emotionally unstable patients and to those with a history of drug misuse. When long term therapy is contemplated, such patients should be closely supervised. Even though Stadol has a low physical dependence liability, care should be taken that individuals who may be prone to drug abuse are closely supervised. It is important to avoid increases in dose and frequency of injections by the patient and to prevent the use of the drug in anticipation of pain rather than for the relief of pain.

Head Injury and Increased Intracranial Pressure: Although there is no clinical experience in patients with head injury, it can be assumed that Stadol, like other potent analgesics, elevates cerebrospinal fluid pressure. Therefore the use of Stadol in cases of head injury can produce effects (e.g., miosis) which may obscure the clinical course of patients with head injuries. In such patients Stadol must be used with extreme caution and only if its use is deemed essential.

Cardiovascular Effects: Because Stadol increases the work of the heart, especially the pulmonary circuit, (see Clinical Pharmacology), the use of this drug in acute myocardial infarction or in cardiac patients with ventricular dysfunction or coronary insufficiency should be limited to those who are hypersensitive to morphine sulfate or meperidine.

PRECAUTIONS–Certain Respiratory Conditions: Because Stadol causes some respiratory depression, it should be administered only with caution and low dosage to patients with respiratory depression (e.g., from other medication, uremia, or severe infection), severely limited respiratory reserve, bronchial asthma, obstructive respiratory conditions, or cyanosis.

Impaired Renal or Hepatic Function: Although laboratory tests have not indicated that Stadol causes or increases renal or hepatic impairment, the drug should be administered with caution to patients with such impairment. Extensive liver disease may predispose to greater side effects and greater activity from the usual clinical dose, possibly the result of decreased metabolism of the drug by the liver.

Biliary Surgery: Clinical studies have not been done to establish the safety of Stadol administration to patients about to undergo surgery of the biliary tract.

Usage as a Pre-operative or Pre-anesthetic Medication: Slight increases in systolic blood pressure may occur, therefore caution should be employed when Stadol is used in the hypertensive patient.

Usage in Pregnancy: The safety of Stadol for use in pregnancy prior to the labor period has not been established; therefore, this drug should be used in pregnant patients only when in the judgment of the physician its use is deemed essential to the welfare of the patient.

Reproduction studies have been performed in rats, mice, and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to Stadol at about 2.5 to 5 times the human dose.

Usage in Labor and Delivery: Safety to the mother and fetus following the administration of Stadol during labor has been established. Patients receiving Stadol during labor have experienced no adverse effects other than those observed with commonly used analgesics. Stadol should be used with caution in women delivering premature infants.

Usage in Nursing Mothers: The use of Stadol in lactating mothers who are nursing their infants is not recommended, since it is not known whether this drug is excreted in milk. Stadol has been used safely for labor pain in mothers who subsequently nursed their infants.

Usage in Children: Safety and efficacy in children below age 18 years have not been established at present.

ADVERSE REACTIONS–The most frequent adverse reactions in 1250 patients treated with Stadol are: sedation (503, 40%), nausea (82, 6%), clammy/sweating (76, 6%).

Less frequent reactions are: headache (35, 3%), vertigo (33, 3%), floating feeling (33, 3%), dizziness (23, 2%), lethargy (19, 2%), confusion (15, 1%), lightheadedness (12, 1%).

Other adverse reactions which may occur (reported incidence of less than 1%) are:

CNS: nervousness, unusual dreams, agitation, euphoria, hallucinations, seizures
Autonomic: flushing and warmth, dry mouth, sensitivity to cold
Cardiovascular: palpitation, increase or decrease of blood pressure
Gastrointestinal: vomiting
Respiratory: slowing of respiration, shallow breathing
Dermatological: rash or hives
Eye: diplopia or blurred vision

OVERDOSAGE–Manifestations: Although there have been no experiences of overdosage with Stadol during clinical trials, this may occur due to accidental or intentional misuse as well as therapeutic use. Based on the pharmacology of Stadol, overdosage could produce some degree of respiratory depression and variable cardiovascular and central nervous system effects.

Treatment: The immediate treatment of suspected Stadol overdosage is intravenous naloxone. The respiratory and cardiac status of the patient should be evaluated constantly and appropriate supportive measures instituted, such as oxygen, intravenous fluids, vasopressors and assisted or controlled respiration.

SUPPLY–Stadol (butorphanol tartrate) Injection for I.M. or I.V. use is available as follows:

NDC 0015-5644-20–2 mg per ml, 2-ml vial
NDC 0015-5645-20–1 mg per ml, 1-ml vial
NDC 0015-5646-20–2 mg per ml, 1-ml vial
NDC 0015-5648-20–2 mg per ml, 10-ml multi-dose vial

For information on package sizes available, refer to the current price schedule.

Long-established 47 physician multispecialty clinic in the Puget Sound area seeking BE/BC General, Vascular and Non-Cardiac Thoracic Surgeon. Guaranteed salary leading to stockholdership. Excellent fringe benefits. Send CV and letter to: **Box ANN 10B, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

SOUTHEASTERN NEW MEXICO: We are seeking a board certified/board eligible general surgeon interested in a lucrative career move with a first year guaranteed salary of $90,000+. This up-to-date private practice has a service area population of approximately 30,000. For additional information, please send current CV to **Linda Smith, Occupational Health Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri, 64111; or call 800-821-5147 or 816-561-2105.**

Surgeon for Oncology Clinic and Hospital: BC/BE General Surgeon, Salary negotiable. Send CV to: **P.O. Box 35161, Dallas, Texas 75235.**

THORACIC/GENERAL SURGEON— Thoracic/General Surgeon with experience in pulmonary surgery and thoracic trauma to join 34 physician multi-specialty clinic. Potential vascular work. Two established Pulmonologists on staff. Must be Board Certified or eligible. 100 miles southeast of St. Louis. Population 28,000 plus 25,000 Southern Illinois University students. Drawing area near 100,000. Flexible compensation package with generous fringe benefits including health and disability insurance, vacation, CME leave, and profit sharing retirement plan. Fee-for-service plus prepaid. Contact: **Bill Harris, Administrator; Carbondale Clinic, S.C.; 2601 West Main Street, Carbondale, IL 62901 or call (618) 549-5361.**

THORACIC SURGERY— Well established Group in suburban New York area is seeking a Board Certified/Board Eligible university trained associate to provide quality General/Thoracic/PV Surgery (no open heart). Excellent salary and benefits leading to partnership. Malpractice paid. Send CV to **Box ANN10A, J. B. Lippincott Company, Philadelphia, PA 19105.**

The Center for Clinical Medical Ethics (CCME) at the University of Chicago is pleased to announce **The National Leadership Training Program for Physicians in Clinical Medical Ethics.** This new training opportunity will prepare mid-career physicians as leaders of programs in clinical medical ethics. Training will include one year at the CCME with stipend of $52,000, followed by three years at the trainee's sponsoring institution with program support of $15,000/year. The Center seeks nominations from deans of medical schools and from directors of major health organizations and ethics institutes. CEOs of major health systems may also nominate an individual but the health system must support the entire cost of training. Sponsoring institution must be committed to the development of a clinical ethics program. The University of Chicago is an Affirmative Action/Equal Opportunity Employer. Please direct requests for applications and inquiries to **Dr. Mark Siegler, CCME, Box 72, 5841 S. Maryland Ave., Chicago, IL 60637, (312) 702-1453.**

Manufactured for Glaxo Inc.,
Research Triangle Park, NC 27709
by Abbott Laboratories, North Chicago, IL

Convenient

☐ Ready to use–no mixing needed

☐ Premixed 100-ml bag, containing 50 mg ranitidine (as the hydrochloride)

☐ No need to refrigerate

☐ Stores for up to 18 months

Cost effective

☐ Saves pharmacy and nursing time

Raises gastric pH in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses

☐ No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin

Zantac® Injection Premixed
ranitidine HCl/Glaxo

New premixed 100-ml bag containing 50 mg ranitidine HCl

*Some patients may require q6h dosing.

See next page for brief summary of Product Information.

ZANTAC® Injection
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC® Headache, sometimes severe, seems to be related to ZANTAC administration. Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain have been reported. There have been rare reports of malaise, dizziness, somnolence, insomnia, vertigo, tachycardia, bradycardia, premature ventricular beats, and arthralgias. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.

Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.

Although controlled studies have shown no antiandrogenic activity, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Incidents of rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia, have been reported, as well as rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
(NDC 0173-0362-38) 2-ml single-dose vials (Tray of 10)
(NDC 0173-0363-39) 10-ml multidose vials (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

The community of **ARTESIA, NEW MEXICO** is seeking a Board Certified or Eligible GENERAL SURGEON to establish a private practice. Fully-equipped office with established referral patterns available for purchase. Community-based financial assistance may be available to the right individual. Artesia is a community of 14,000 located in Southeast New Mexico. A great place to raise a family—peaceful community with year-round recreation and excellent weather. Fully equipped, 38-bed new hospital. Please submit CV to: **Bill Norris, Southwest Community Health Services, P.O. Box 26666, Albuquerque, NM 87125-6666; or, call 1-800-545-4030, Ext. 8300.**

VASCULAR SURGEON: Full time academic position. Excellent opportunity with large clinical volume and funds for research. Candidate should be eligible for appointment as Assistant Professor of Surgery, SUNY Stony Brook. Attractive area on North Shore of Long Island. Must be board certified or eligible for vascular certificate. Excellent salary/benefits. Send curriculum vitae to: **Leslie Wise, MD, Chairman-Department of Surgery. Long Island Jewish Medical Center, 270-05 76th Avenue, New Hyde Park, NY 11042.** An Equal Opportunity Employer.

VASCULAR SURGEON— The Department of Surgery, Medical College of Pennsylvania is recruiting a board certified/eligible vascular surgeon for a full-time academic position. Responsibilities include patient care, research, medical student and resident instruction. Benefits and insurance included. **Apply to Division of Vascular Surgery, Medical College of Pennsylvania, Philadelphia, PA 19129.**

PHYSICIANS

TRAUMA SURGEONS

Two excellent opportunities to join thriving private practices in Allentown, Pennsylvania.

A trauma surgeon is being sought by a six-man group to participate in the group's trauma and general surgical case load with emphasis on surgical critical care and resident teaching.

A trauma surgeon is needed to become a second member of a hospital trauma practice to participate in the trauma case load, surgical critical care, teaching and to assist in administration of the trauma program.

Both positions would practice primarily at the Lehigh Valley Hospital Center, Pennsylvania's first Level I designated Trauma Center. Over 1800 trauma patients are seen by the Trauma Center including 600 patients with an ISS greater than 15. The Trauma Center includes a 12-bed dedicated shock/trauma unit, an 8-bed central nervous system unit, a 6-bed burn center and a special resuscitation area including a 24-hour fully equipped trauma operating room. The Trauma Center is supported by a six year old on-site helicopter program. The Trauma service supports a trauma fellow and five shock/trauma residents dedicated only to the trauma service. The trauma/general surgeon will also have a significant practice at The Allentown Hospital, with regional infant, children, women's, renal and psychiatric services.

Qualified candidates must be board eligible or certified in general surgery and eligible/certified in surgical critical care. Training and experience in the care of trauma and critical care patients a must. Interested applicants send resumes to:

Gastroplasty and Fundoplication for Complex Reflux Problems

Long-term Results

F. GRIFFITH PEARSON, M.D., F.R.C.S.(C.), JOEL D. COOPER, M.D., F.R.C.S.(C.),
G. ALEXANDER PATTERSON, M.D., F.R.C.S.(C.), JUAN RAMIREZ, M.D., and THOMAS R. TODD, M.D., F.R.C.S.(C.)

Between 1964 and 1984, 430 patients with complex reflux problems were managed by a modified Collis gastroplasty and partial fundoplication. The indications for selecting the addition of gastroplasty were as follows: (1) obvious acquired shortening due to peptic esophagitis and stricture, and (2) subtler degrees of acquired shortening frequently encountered in cases that required reoperation and in patients with massive sliding hiatal hernia. The addition of gastroplasty in this second group obviates the risk of even minimal tension on the repair. Follow-up is complete in 382 patients (90%), and extends 1–20 years. Two hundred fifty patients have been followed up for 5 or more years and 101 patients for more than 10 years. Results were classified as follows: good: asymptomatic, or inconsequential symptoms requiring no therapy; fair: improved, but with symptoms and/or endoscopic findings requiring intermittent therapy; poor: unimproved or worse. Patients are divided into four categories, and the results are tabulated below (see Table 2). The best results are obtained in patients with acquired shortening due to esophagitis with and without stricture who have had no prior antireflux surgery and have no associated primary motor disorder. The proportion of unsatisfactory results is almost tripled (20% fair or poor) after reoperation after one or more failed antireflux procedures. When reflux esophagitis and stricture are associated with a primary motor disorder, onl half of the patients have a good result sustained throughout long-term follow-up.

THE CURRENT REPORT reviews the experience with a group of patients with complex reflux problems managed by a modified Collis gastroplasty[1] combined with a Belsey-type partial fundoplication. We first reported our early experience with this procedure in 1971.[2] A meaningful evaluation of results requires a long follow-up and is particularly important for the assessment of surgery for benign disease in which a majority of patients survive for long periods.

From the Division of Thoracic Surgery, University of Toronto, and Toronto General Hospital, Toronto, Ontario, Canada

This procedure was initially designed for the management of patients with sequelae of grades of peptic esophagitis resulting in acquired shortening. During the first few years, the operation was restricted to patients with peptic strictures associated with obvious acquired shortening. A Belsey Mark IV repair was our procedure of choice in the absence of obvious acquired shortening. With experience, however, it became apparent that subtle degrees of shortening occurred in many cases of gross ulcerative esophagitis, even without a peptic stricture. On occasion, this resulted in tension on a standard Belsey repair that was evident only after the operation had been completed. Similar difficulty is unpredictably encountered in patients who have repeat antireflux operations. Since the distal esophagus is already scarred from previous surgery we have chosen to add a gastroplasty to the fundoplication in almost all such reoperations to obviate any possibility of tension on the antireflux reconstruction. Similar subtle degrees of acquired shortening are commonly encountered in patients with the most advanced stages of sliding hiatus hernia in which most of the stomach lies in the posterior mediastinum and has usually undergone organoaxial volvulus. Many patients have little or no symptomatic reflux at the time of presentation with an intrathoracic stomach. A careful history, however, will reveal that most of these patients have had significant symptomatic reflux during the years preceding this late stage,[3] and a degree of tension is commonly encountered when a standard Belsey repair is used. Like Belsey,[4] we observed a higher than expected recurrence rate when these cases of intrathoracic stomach were assessed over a longer follow-up period. As a result of these observations, we have been adding a gas-

Submitted for publication: April 24, 1987.

troplasty to the fundoplication during the past 15 years. Patients with a true paraesophageal hernia are excluded from this approach.

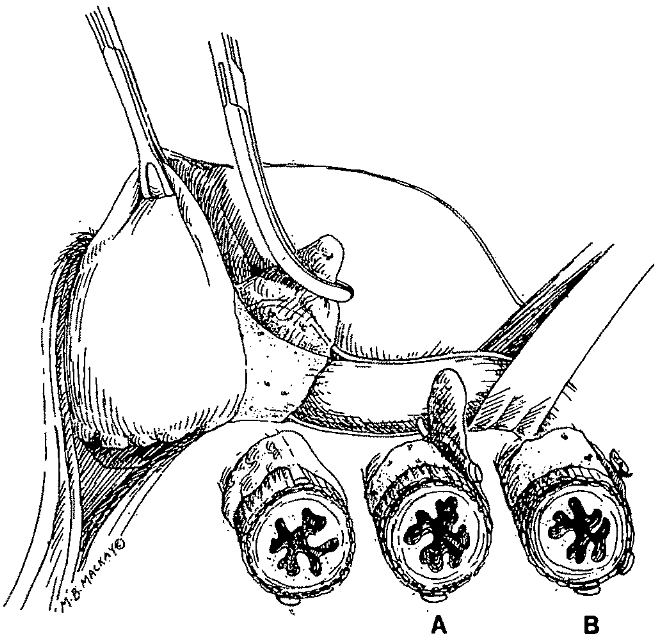

FIG. 1. The esophagogastric fat pad is always present and envelops the esophagogastric junction (A). This fat pad is meticulously dissected from most of the circumference of the junction. With this dissection, the left vagus nerve is lifted free from the muscular wall of the esophagus and is carried with the fat pad (B). The fatty tissue is cleared away from the entire anterior surface of the esophagogastric junction and adjacent upper part of the lesser curvature. This dissection is tedious and requires coagulation or ligation of many small penetrating vessels similar to the technique for highly selective vagotomy. The gastroplasty tube can then be constructed through an area of stomach that is free of any fatty covering. This dissection results in displacement of the left vagus nerve to a more posterior location where it lies close to the right vagus nerve (C).

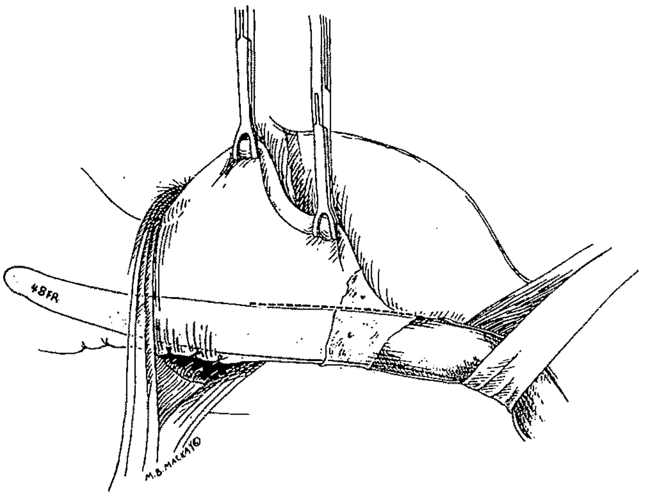

FIG. 2. A No. 48 French Maloney bougie is passed *via* the mouth through the esophagus and well into the stomach beyond. The dotted line indicates the site of division of the gastric wall in order to create a gastric tube in continuity with the distal esophagus.

Material and Methods

Between 1964 and 1984, 430 patients had modified gastroplasty and partial fundoplication for the management of complex reflux problems. Ages ranges between 19 and 79 years with a mean age of 56 years.

Operative Technique

A double lumen orotracheal tube or bronchus blocker is used in each case to permit collapse of the left lung during the procedure. Exposure is obtained through the sixth, left intercostal space. The esophagus is mobilized circumferentially from the hiatal attachments below to the back of the pulmonary hilum above. The greater and lesser peritoneal sacs are opened through the hiatus and the upper part of the gastrohepatic omentum is divided to allow the cardia to be freely elevated into the left hemithorax. In patients who have repeat antireflux surgery, this part of the operation may require additional abdominal exposure obtained through a marginal incision in the anterior aspect of the left diaphragm, in its muscular part near the costal margin. The esophagogastric fat pad is meticulously dissected free (see Fig. 1). Up to this point, the operation is identical to that described by Belsey for his Mark IV repair. The addition of gastroplasty requires a more extensive clearance of the esophagogastric fat pad from the anterior and lesser curvature aspects of the cadia (see Fig. 2). The gastric tube is created on the lesser curvature side of the stomach, in continuity with the distal esophagus for a length of 4–5 cm. This is usually accomplished with a single application of the GIA stapler. Traction is exerted on the greater curvature side of the gastric fundus before closing the jaws of the stapler to ensure that the gastric tube closely approximates the diameter of an indwelling No. 48 French Maloney bougie. The gastric tube should be of uniform diameter throughout its length (see Figs. 3 and 4). The subsequent 270-degree fundoplication is created with three tiers of sutures placed between the esophagus and stomach, and each tier is placed 1.5–2 cm above the other (see Fig. 5). The hiatus is closed posteriorly. A detailed description of the operative technique is reported in a recent publication.[4]

In patients with a peptic stricture, the techniques of esophageal dilatation are essential to achieving optimal results. Most strictures can be dilated before operation, and dilatation up to a size 50 French bougie is desirable. The most severe grades of fibrous stricture may require a more forceful, intraoperative dilatation using Hegar dilators passed in retrograde fashion through a small gastrotomy in the upper gastric fundus. The need for postoperative dilatation is variable and depends on the severity of the stricture. Short, mild strictures are easily

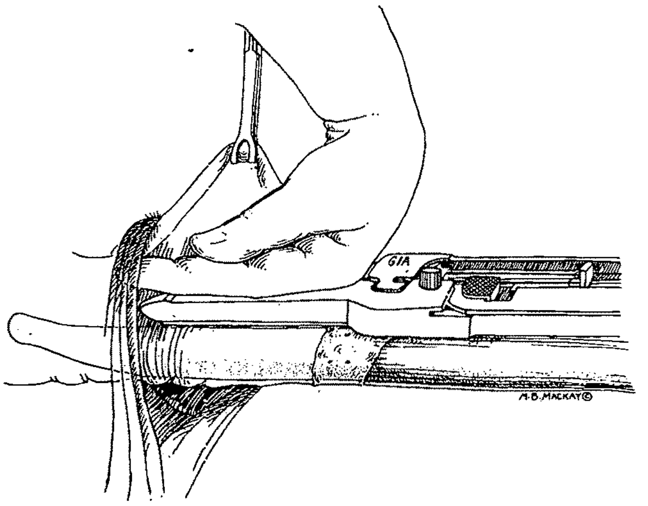

FIG. 3. The stomach is then divided with the GIA stapler, although division between two obtuse angled clamps may be used as an alternative technique. The length of gastric tube created depends on the degree of acquired shortening. A 5-cm gastric tube is sufficient in the majority of cases and can be accomplished with a single application of the stapler. Traction is exerted on the greater curvature side of the fundus before closing the jaws of the stapler. This ensures that the gastric tube closely approximates the diameter of an indwelling No. 48 French bougie throughout its length. The length and diameter of the gastric tube are an important component of the antireflux properties of the repair.

dilated by the single passage of a 50 French Maloney bougie before operation, and rarely require further treatment after repair. Postoperative dilatation will be beneficial in many patients with moderate degrees of stenosis, and in all cases of severe, long stricture. These dilatations are done by indirect bouginage in the out-patient clinic using topical anesthesia that may be supplemented by intravenous diazepam. Intermittent dilatation is continued until the healing process in the esophageal wall is complete and scar contracture has ceased. In the most severe cases, this process of resolution may last for as long as 12–18 months, and during this time, intermittent dilatation may be necessary to maintain normal swallowing.

Follow-up

Follow-up examination was conducted by personal interview on an annual basis during the first 5 years, and at 2-year intervals thereafter. A standard questionnaire was completed at the time of each follow-up examination. Endoscopy, esophageal manometry, and pH studies were not used routinely and were only done in symptomatic patients. Follow-up is complete in 382 patients (90%) and extends from 1 to 20 years. Two hundred fifty patients have been followed up for 5 or more years and 101 patients for more than 10 years.

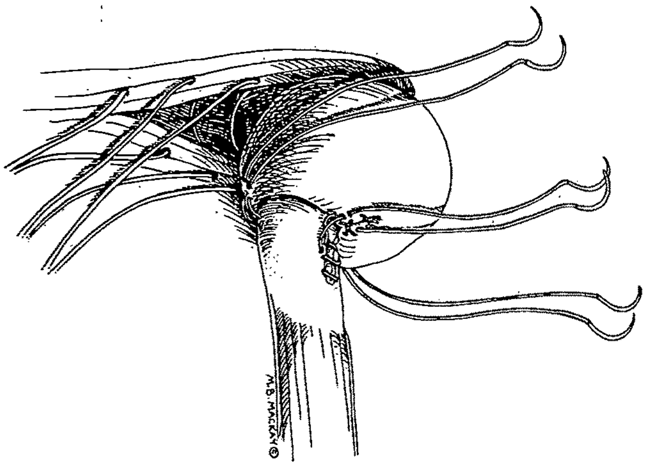

FIG. 4. A partial, Belsey-type fundoplication envelops a 4–5-cm length of the gastroplasty tube. The fundoplication encircles at least 270 degrees of the circumference, and is created with three tiers of double-ended No. 000 silk sutures. The tiers are spaced at 1.5-cm intervals beginning 1.5 cm above the esophagogastric junction and extending proximally. Three sutures are used to secure each tier. In this diagram, the first two tiers have been tied and the third and final tier of three sutures has been placed.

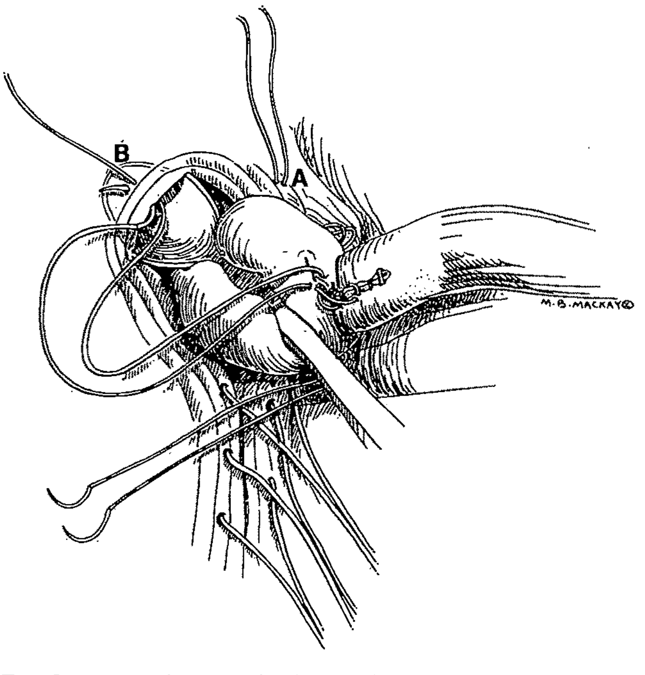

FIG. 5. A spoon is placed in the anterior opening of the hiatus to facilitate passage of the last tier of fundoplicating sutures. These sutures are directed through the hiatus and then brought back up through the diaphragmatic margin from the abdominal to the thoracic side. In this diagram, both ends of the fundoplicating suture on the right side have been passed in this fashion, but not tied, and are situated in the diaphragmatic margin just to the right side of the anterior "apex" of the hiatus (A). The middle suture is in the process of placement just to the left of the "apex" of the hiatus (B). These three sutures are spaced apart in the diaphragmatic margin by the same distances that separate them on the circumference of the gastric tube or esophageal wall.

TABLE 1. *Complications in 424 Patients*

	No. of Patients
Atelectasis, pneumonia	18
Wound infection	12
Esophageal fistula	6
Prolonged incisional pain	17
Other	30

Results

Two patients died within 30 days of operation: one died of a myocardial infarction during operation, and the other died of pneumonia with respiratory failure.

Complications are listed in Table 1. The complications observed in this series are similar in severity and frequency to those anticipated after any of the standard hiatus hernia repairs. There were six esophageal fistulas: none were fatal, and three of the six occurred in patients who had reoperation. Prolonged incisional pain was identified as a significant complaint in 17 patients at more than 1 year after operation.

Functional results were classified as follows: good: asymptomatic, or with inconsequential symptoms requiring no therapy; fair: improved, but with symptoms and/or endoscopic findings requiring intemittent therapy (antireflux medication or dilatation); poor: unimproved or worse. Table 2 is a tabulation of results that have been subdivided into four categories for purposes of this review.

Group 1

There were two hundred fifteen patients with acquired short esophagus due to peptic stricture (138 cases), or severe ulcerative esophagitis without significant stricture (77 cases), who had never had prior antireflux surgery and had no associated primary motor disorder. One hundred twelve patients in this group were followed up for more than 5 years, and 46 of these patients were followed up for more than 10 years. One hundred ninety-eight patients (93%) had good to excellent results sustained over this long follow-up period. Eleven results were categorized as fair because of dysphagia in eight cases, reflux in one case, and both reflux and dysphagia in 1 case. All of the six poor results were due to dysphagia. Two of the six patients with poor results were submitted to further antireflux surgery for the management of persistent ulcerative esophagitis and restenosis. In each case, the partial fundoplication was taken down and then reconstructed using a 360-degree Nissen-type wrap. Two additional patients with good reflux control required reoperation for complications of subsequent duodenal ulcer: one required an antrectomy for pyloric stenosis, and the other required an emergency omental patch for a perforated duodenal ulcer.

TABLE 2. *Results by Category*

	No. of Cases	Results		
		Good	Fair	Poor
Short esophagus due to stricture (138), esophagitis (77) (excluding reoperations and motor disorders)	215	93% (199)	4% (10)	3% (6)
Reoperations: 1 or more previous unsuccessful antireflux operations	118	80% (93)	12% (15)	8% (10)
Peptic stricture (25), or esophagitis (12), associated with a primary motor disorder	37	54% (19)	24% (9)	22% (8)
Intrathoracic stomach	54	91% (40)	9% (5)	0% (0)

Group 2

There were one hundred eighteen patients who had had one or more prior, unsuccessful antireflux operations. There were 149 prior operations in 118 cases. Twenty-two patients had had two or more previous procedures. The types of previous repairs were as follows: transabdominal Nissen fundoplication (65), transthoracic Belsey Mark IV repair (31), transabdominal Hill repair (9), transthoracic Thal operation (3), gastroplasty and fundoplication (1), and unidentifiable repair (9). Follow-up was complete in 101 of 118 patients. Fifty-eight patients were followed up for longer than 5 years, and 23 patients were followed up for more than 10 years. Thirty-eight of 118 patients had a peptic stricture, and an additional eight patients had severe ulcerative esophagitis without significant stenosis.

Good to excellent results were obtained in 93 (80%) of 118 patients. In 15 patients (12%), the result was classified as fair because of both symptomatic reflux and dysphagia in 10 cases, and dysphagia alone in five cases. A poor result observed in 10 patients (8%) was due to reflux and dysphagia in six cases, dysphagia alone in three cases, and reflux alone in one case. Thee of the 10 patients with poor results were reoperated on and all were managed by revision with a complete fundoplication.

Group 3

There were 37 patients with an underlying primary motor disorder: scleroderma (16 cases), achalasia (14 cases), and diffuse spasm (7 cases). All 37 patients in this group had gross endoscopic ulcerative peptic esophagitis, and there was some degree of peptic stricture in 25 of the 37 patients. In patients with achalasia, reflux esophagitis is only seen as a complication that may follow esophagomyotomy. All 14 patients with achalasia had had a previous myotomy, and six of the 14 patients had had an additional antireflux operation in an attempt to control the subsequent complication of reflux. One of 16 patients with scleroderma had had previous antireflux surgery, and one of the seven patients with diffuse spasm had had a long myotomy. Follow-up is complete in 34 of these 37 patients and extends for longer than 5 years in 25 patients, and for more than 10 years in 13 patients.

Long-term results were much less favorable in this group of patients. Furthermore, the quality of result continued to deteriorate with time in a significant number of patients, particularly in cases of achalasia. This trend to continued deterioration was much less apparent in the other groups without an associated motor disorder. The results are tabulated in Table 3. Good results were obtained in only 54% of the 37 patients. The worst results were observed in patients with achalasia, and unmanageable, progressive dysphagia developed in three of these eight patients and they were submitted to thoracic esophagectomy and cervical esophagogastrostomy.

Group 4

There were 54 patients with a massive, sliding hiatal hernia or intrathoracic stomach. It is emphasized that patients with true paraesophageal hernia have a normal esophagus, do not require a gastroplasty, and have been managed by a standard Belsey repair. They are excluded from this group of 54 patients. Thirty-eight of the 54 patients have been followed up between 5 and 10 years, and 11 patients were followed up for more than 10 years. Follow-up is incomplete in five patients. Good to excellent results were obtained in 49 (91%) patients. No patient has required further operation.

Subsequent Adenocarcinoma

An adenocarcinoma that appeared to originate in the distal esophagus was subsequently diagnosed in five patients. All five patients had some degree of acquired columnar-lined esophagus, and four of the five had associated peptic strictures. A diagnosis of carcinoma was established between 3 months and 7 years after gastroplasty and fundoplication. In two patients, the adenocarcinoma was diagnosed at 3 months and 9 months after repair, and may well have been present as an occult tumor at the time of repair. In the remaining three patients, the tumor was identified after 2.5, 3, and 7 years and was probably not present at the time of the repair. Only one of these three patients was known to have poor reflux control after gastroplasty and fundoplication, a patient with scleroderma and a peptic stricture whose cancer was identified 7 years after antireflux surgery.

TABLE 3. *Primary Motor Disorders*

	No. of Cases	Results		
		Good	Fair	Poor
Scleroderma	16	9 (57%)	4	3
Achalasia	14	6 (43%)	4	4
Diffuse spasm	7	5 (71%)	1	1

Discussion

Throughout the study we have used gastroplasty and fundoplication in all patients with dilatable peptic strictures selected for operation. During this same period, we have operated on 15 patients with undilatable strictures, and these patients were managed by distal esophagectomy and short colon interposition. In an additional patient, instrumental perforation of a severe stricture was managed by a Thal esophagogastroplasty. Various authors continue to recommend differing options for the management of patients with peptic esophagitis, stricture, and acquired short esophagus. Preferences range from a standard repair (Nissen, Belsey, Hill) to resection and replacement. Among the standard repairs, Hill's procedure is the only one that reports a high proportion of good results obtained in large numbers of patients with long-term follow-up.[5,6] Intrathoracic antireflux reconstructions such as the Thal procedure[7] or the intrathoracic Nissen fundoplication[8,9] may provide good reflux control with resolution of esophagitis and stenosis. The quality of result after intrathoracic reconstructions may be impaired, however, by an unexpectedly high incidence of gastric ulceration in the intrathoracic stomach or progressive, massive herniation on long-term follow-up. The addition of gastroplasty to an antireflux repair assures a tension-free reconstruction and an anatomic recurrence of the hernia is rare after this operation. In our series of patients with acquired short esophagus due to esophagitis and dilatable peptic stricture, good results were obtained in more than 90% of patients who did not have an underlying primary motor disorder or a history of previous antireflux surgery. This high proportion of good results was sustained over long periods of follow-up and was achieved with a low operative mortality and a morbidity that was no greater than that anticipated after any standard hiatal repair. We again emphasize the important need for postoperative dilatation in patients with severe strictures that may undergo a very slow resolution of the inflammatory changes responsible for continuing scar formation and contracture after good reflux control has been achieved.

Reoperation after unsuccessful previous antireflux surgery yields significantly fewer good results. There are relatively few publications to date that report the results of reoperation in large numbers of patients with failed, antireflux surgery.[10-15] It is apparent from these reports that these reoperations are often technically difficult, and expertise with the operative management is only achieved after significant experience. The optimal procedure in any given patient can be unpredictable and may be determined only at the time of exploration and mobilization. Preoperative preparation should include consideration of a resection, which is necessary in some cases and may only be determined at the time of surgery.[14,15] The potential for good results diminishes with the number of reoperations. Little et al.[14] advise serious consideration of resection in patients who have had more than two previous repairs. The results of gastroplasty and fundoplication in patients who were reoperated on have been reported by Henderson and Marryatt[13] and Orringer.[15] These authors favor a complete Nissen-type fundoplication, and both reports indicate that the results of reoperation for reflux problems are less satisfactory. In our own series, the number of unsatisfactory results (20%) was more than double that observed in patients with acquired short esophagus and stricture undergoing a first operation (7%). Nevertheless, 80% of these patients had good results that were sustained through long follow-up periods, and this was achieved without any operative mortality and an acceptably low morbidity in 118 cases.

By far the most difficult group of patients are those with ulcerative reflux esophagitis and peptic strictures that are associated with an underlying primary motor disorder. Among these motor disorders, achalasia presents the most difficult problems in management. When ulcerative reflux esophagitis and stenosis develops after esophagomyotomy for achalasia, there appears to be no conservative operation that will control both reflux and dysphagia in these patients with an aperistaltic esophagus and absent distal sphincter. Good results were obtained in only six of our 14 patients with achalasia, and three of the four patients with poor results have ultimately required resection and replacement of the thoracic esophagus. As a result of this experience, we currently recommend serious consideration of resection in any patient with achalasia who has endoscopic confirmation of gross ulcerative peptic exophagitis or peptic stricture. Gastroplasty and fundoplication may still be the best option for patients with intractable reflux symptoms in the absence of ulcerative esophagitis or stricture. We continue to recommend this conservative operation in patients with esophagitis and stricture associated with scleroderma. Of 16 patients with scleroderma, 13 have had sustained improvement (9 good, 4 fair) in our series. Our experience with cases of diffuse spasm associated with significant reflux esophagitis is too small to warrant further comment.

In conclusion, gastroplasty and fundoplication provides a high proportion of good results in patients with acquired, short esophagus due to peptic esophagitis. The addition of gastroplasty assures a tension-free repair in patients with obvious acquired shortening and is also recommended in cases of reoperation for failed antireflux surgery and for massive sliding hernias since subtle degrees of shortening are commonly encountered. The presence of a primary motor disorder in association with peptic esophagitis and stricture has a severely adverse effect on results, which continue to deteriorate throughout long follow-up periods. The poorest results occur in patients with achalasia, and in such patients, serious consideration should be given to esophageal resection rather than a more conservative repair.

Acknowledgments

We thank Mrs. N. Blair and Mrs. J. Basiuk for their help in organizing and conducting the long-term follow-up of these patients.

DISCUSSION

DR. DAVID B. SKINNER (Chicago, Illinois): I greatly enjoyed both of these papers that raised several important issues.

In regard to Dr. Bombeck's paper, he has introduced a sophisticated new method for manometry that raises the possibility as to the application of this for the selection of patients for antireflux surgery. To put this into perspective, manometry was first proposed for this purpose over 30 years ago by Code et al. and about 20 years ago it was found not to be very effective in selecting patients with an incompetent cardia based on the technology at that time. Therefore, pH testing was introduced with the standard acid reflux test, and then a little over 10 years ago the 24-hour pH study was introduced as the gold standard for assessing this problem.

Dr. Bombeck is suggesting that going back to pressure measurements rather than direct measurements of reflux by pH testing may be applied to the selection of patients for surgery. I believe considerably more experience will have to be obtained with this new technique before we can say whether his thesis can be supported or not, but I do believe it is an important technological breakthrough in our ability to evaluate and study the distal esophageal sphincter mechanism. As a research tool, this should prove highly valuable in understanding some of the complex mechanisms that go into the normal control of gastroesophageal reflux.

I have a few specific questions for Dr. Bombeck. On his slide where he compared the pressure in the area with the LESVV, he had considerable fewer points on the LESVV bar than he did on the other ones, and I wondered how he selected those cases that showed such a nice clear discrepancy on that far right-hand bar compared with the other charts that he showed.

He also told us that he knew the LESVV before starting patients on therapy and then told us that those with the lowest LESVV were selected for subsequent surgery, but he did not tell us why they were selected for surgery.

Is this a self-fulfilling prophecy since he knew ahead of time what the values were in his study? I believe we are still selecting patients for antireflux surgery based on documentation of reflux (pH testing remains the standard for that) and based on the complications of reflux. I do not believe we should be selecting patients for surgery based simply on a manometric measurement since the disease is not a hypoactive LESVV but is reflux esophagitis, which can be assessed more directly by pH testing and by endoscopy. However, I do believe we have heard a very elegant new technique that would be of interest in the future as we refine our knowledge of this.

Dr. Pearson, of course, is the world leader in the evaluation of the gastroplasty operation. We have all admired his experience for many years. I disagree with him about some of the indications that he has used it for. We have had this disagreement over many years, and I will not repeat it here.

I do have two specific questions for him, however. The incidence of five cases of adenocarcinoma in this disease brings to mind the incidence of cancer in Barrett's esophagus, and in fact, the gastroplasty is an iatrogenic form of Barrett's esophagus. If I did my math correctly, his incidence of cancer is approximately 1 in 450 to 1 in 500 patient years of follow-up, which is not significantly different from the 1 in 400 patient years of follow-up incidence of cancer that Cameron reported in Barrett's esophagus cases from the Mayo Clinic. This does raise one question: is this gastroplasty operation a form of Barrett's esophagus biologically as well as technically? I would like to ask him in the patients that he has endoscoped in follow-up, has there been metaplastic epithelium, the type that we see in Barrett's as a harbinger of the potential malignant degeneration?

Second, when he does the gastroplasty he leaves a 5 cm or more segment of nonperistalsing tubular digestive swallowing tube, and I wonder what proportion of his patients continue to have some degree of dysphagia because of the interposition of a nonperistalsing tube below their esophagus.

DR. MARTIN ALLGÖWER (Basel, Switzerland): Ever since my secretary fell in love with Dr. Bombeck I knew that he was up for very sophisticated techniques (Laughter).

Now, if I am getting up as a discussant for the third time today, I apologize, but being the successor of Professor Nissen, I believe this gives a certain legitimisation, and Dr. Bombeck kindly asked me to comment on his paper.

It is obvious that my former chief invented the right operation for probably the wrong reason (but that is a much better thing than the other way around!).

I believe one fact that we could contribute in recent years and with which Dr. Bombeck agrees is the work of Dr. Liebermann. She could prove that there is an anatomic corollary to the lower esophageal sphincter, a fact contested by certain anatomists. Dr. Liebermann, working on cats, correlated her morphologic findings to the function of the LES, evaluated in these animals by pullback manometry. In light of these facts, Dr. Bombeck's findings are a most important adjunct to our diagnostic armamentarium in the patient.

Two questions to Dr. Bombeck: I wonder how much his CAM will replace what we formerly got in information from radiology, endoscopy, and pH monitoring. Furthermore, in a recent meeting in Switzerland there was some agreement that beyond all objective data, the amount of suffering may influence indications although you cannot really get data on this element.

My second question: what about other pathophysiologic mechanisms that have been accused of being instrumental: the length of the abdominal segment and the gastric secretion? Is this now all out?

DR. TOM R. DEMEESTER (Omaha, Nebraska): I am appreciative to both Drs. Bombeck and Pearson for having the opportunity to review their manuscript. The definition of gastroesophageal reflux disease is not precise. Some define it as the presence of the symptoms of heartburn and regurgitation. This definition is too selective that many patients with the disease are dismissed as not having the disease because their symptoms do not conform to the definition. Some define the disease as the presence of esophagitis, but esophagitis is a complication of reflux, which only 40–50% of the patients manifest. We would define the disease on the basis of what it is, an increased esophageal exposure to gastric juice. This can be measured objectively by 24-hour esophageal pH monitoring. The problem becomes more complex in that there are a number of causes for increased esophageal acid exposure. This is where Dr. Bombeck's work comes into perspective because his use of computer technology has allowed him to identify when a mechanically defective cardia is the cause for increased esophageal exposure to gastric juice; a subject in which we have a great deal of interest. He has integrated sphincter pressure and length together into a single measurement for determining competency of the cardia.

One aspect of the sphincter that his approach does not measure was pointed out by Dr. Allgower, that is, the position of the sphincter and whether it is exposed to abdominal or thoracic pressure. I would ask Dr. Bombeck if he believes the position of the sphincter is important and how would he integrate this into his measurement.

The fact that he was able to separate patients into those with a good and bad sphincter early in the course of the disease might be an indication for early operation instead of waiting until complications of the disease occur. Could he tell us how his measurement compares with standard motility measurements for pressure and length. Are patients with abnormal values on standard motility for pressure, overall length, and abdominal length likely to be abnormal on his computer analysis? If so, then do we need such a sophisticated computer technique to make this differential? I suspect that the computer analysis program described by Dr. Bombeck will be shown to be superior to standard motility and represents a step in the development of diagnostic criteria based on recording and analysing large amounts of data using the office computer.

I shift my comments to Dr. Pearson's presentation. I congratulate him on his 93% success rate for uncomplicated patients with gastroesophageal reflux. We found exactly the same success rate based on a 10-year follow-up evaluation of 100 consecutive abdominal Nissen fundoplications done for uncomplicated reflux disease. Consequently I do not appreciate the need for the addition of a gastroplasty, particularly when in Dr. Pearon's experience it led to six fistulas.

Motility studies in patients with a gastroplasty tube have shown that the tubes are adynamic. It appears that this adynamic tube causes no difficulty in esophageal clearance who have good esophageal contractions, but as soon as that esophagus contractility deteriorates, as in the presence of a motility disorder, the adynamic tube may function as a retard to esophageal clearance. Dr. Pearson, have you seen these problems?

I am also concerned about the passage of medication through these gastric tubes. Do oral tablets clear or are they prone to become trapped in the tube and cause mucosal injury? Are the patients instructed on any specific precautions regarding taking the medication after they had a gastroplasty?

Lastly, I am concerned about the incidence of cancer in these patients. If the gastric tube secretes acid, which fails to clear adequately, then a Barrett's esophagus may develop due to the constant acid environment. The use of the gastroplasty may set up the potential for malignancy. This is a very important factor. The incidence of malignancy in 100,000 patients with Barrett's esophagus is about 500 at the lowest estimate. That is almost 1.5 times the incidence of lung cancer in 100,000 patients who smoke.

DR. JOHN R. BENFIELD (Los Angeles, California): We are indebted to Dr. Pearson and the Toronto group for the long-term follow-up regarding their use of the Collis gastroplasty. The routine use of gastroplasty has been associated with more than 90% good results in patients operated on for the first time. This fact in itself represents a significant improvement as compared with the more usual reports of about 85% good results from first time treatment of reflux esophagitis.

The main potential disadvantage of gastroplasty, other than that pointed out by Dr. Skinner and Dr. DeMeester, is the risk of fistula. Since this complication occurred in less than 2% of the patients who had gastroplasty without death as a result of the use of this approach, Dr. Pearson's argument becomes significantly convincing.

Having had the occasion to work with Dr. Pearson in Toronto during the early days of their use of gastroplasty, I became convinced that the meticulous removal of the fat pad at the cardioesophageal function is, indeed, a main feature in making this operation a success, and I would like to stress that.

With Dr. Pearson I have had the frustrating problems of achalasia in association with reflux esophagitis and hiatus hernia, culminating in the need for cervical esophagogastrostomy.

I agree that the combination of a primary motor disorder with esophagitis is a difficult problem, fortunately rare in my experience, and perhaps is best managed with primary resection.

I am frankly a bit bored with the discussion as to the relative merits of total fundoplication as compared with the Belsey approach in the treatment of reflux esophagitis. Nevertheless, the fact that the Toronto group treats failures from dysphagia after Belsey procedures with the use of complete fundoplication is noteworthy. Indeed, one of the main causes for failure of Nissen procedures is dysphagia.

Dr. Pearson, since you rely on complete fundoplication for the management of treatment failure, why do you not use the Nissen procedure for the initial form of fundoplication?

DR. C. THOMAS BOMBECK (Closing discussion): I would especially like to thank Drs. Skinner and DeMeester for their comments. I am not sure whether I want to thank Professor Allgower or not.

Dr. Skinner is quite correct. This is a new method. This is a refinement of an old method that has been made possible by the addition of the microcomputer and the high-speed A to D interface, and we could not have done this before.

A great deal more experience is needed with it before we can actually say what it is going to be good for. It certainly does have a good theoretical background in that it is supported by just simple standard high school physics as to why it works, and indeed, in the initial test it does seem to work.

He asked why do this, why not use standard pH testing and so on because those demonstrate reflux adequately. Indeed they do, and the benefit of this particular method is not that it demonstrates the patients who will reflux, that separates the refluxer from the nonrefluxer, because pH testing does that better. What it does do, however, is look at why the patient is refluxing and measure the competence and the residual competence of the lower esophageal sphincter. It will pick out the patients who have enough residual competence that they can benefit from medical therapy *versus* the patients who do not.

You asked about the separation between patients who eventually came to operation and those who did not. Those were patients who were studied before they began medical treatment. They went through a course of 6 weeks of medical treatment. Some flunked it, and they had operations. Others had their reflux esophagitis greatly improved, and they were continued for another six weeks, and if they did, they were withdrawn.

Those who failed the treatment were the ones who eventually had operation and those who did not were the ones who were counted as medical successes, and this method clearly distinguished those patients.

You asked about the discrepancy between the number of patients on that one slide, and I do apologize for that. That was early in the series. The slide that shows the separation much better is the last one, which shows the nonrefluxers at the top, the medical successes in the middle, and the Nissens at the bottom, and that includes the whole series that shows the same degree of refluxers and nonrefluxers.

Both Dr. DeMeester and Professor Allgower asked about the length of the abdominal segment and where does this come in. The length of the abdominal segment is a relative thing. All lower esophageal sphincter lengths are relative things. These are not actual anatomic lengths. These are simply the length over which one measures an increased pressure, and what it has to do with the actual length of the sphincter is not clear. For that reason, if the sphincter is moved into the thorax, the relative length may actually go down simply because of negative intrathoracic pressure.

Regarding length of the abdominal segment, we do not believe that that is terribly important simply because of the mechanism by which the Nissen works. Whether it is important in the patient who refluxes or not is very difficult to say because this moves all the time.

What about gastric secretion? Gastric secretion has no role in worrying about gastroesophageal reflux except that one has to have some acid if one is going to have acid esophagitis, but it is not a disease of gastric hypersection and should not be treated that way.

Finally, Dr. DeMeester asked about what is new about this. We have had very low, lower esophageal sphincter pressures. The patient who has a very low lower esophageal pressure is going to have a very low or nonexistent LESVV as well. The patients we are concerned about are those who are somewhat higher. We are concerned about that large amorphous group of patients between medical failures, true medical failures, and medical successes. That group right in the middle that we cannot predict, that we do not know what is happening to them because we have no way of fully quantifying their LES, this will do that. We do not need it for the patient whose LES pressure is zero.

DR. F. G. PEARSON (Closing discussion): I would like to thank my colleagues for their comments and questions.

There were several questions. Dr. Skinner and Dr. DeMeester raised the issue of adenoma developing in these patients, and it is certainly a serious concern. The majority of the patients in the series have the latest, the most advanced stages of peptic esophagitis, and my judgment would be that well over 200 patients in this series have some degree of acquired columnar line esophagus. Many of these patients were operated on in the 1960s in the days before we were documenting that clearly, and the first three cancers occurred during that time.

I can only say, Dr. Skinner, that my assumption has been that these are cases of carcinoma that are developing in the columnar line segment, and two of them developed within 3 months and 9 months of operation. I believe they were almost certainly there when we did the initial surgery.

The last case that we have encountered is the patient seen at 7 years. This patient had scleroderma, inadequately controlled after operation as far as reflux was concerned, and he had a definite, long columnar line segment. In that patient, cancer in the columnar line segment, not in the gastric tube, developed 7 years later. I had not even considered that prospect until you raised the question.

The gastric tube both Dr. Skinner and Dr. DeMeester have noted would appear to be an inert tube. Is it related to dysphagia? As long as the tube is not created at too small a diameter, and that is why we leave in that bougie when it is constructed, I do not believe it is ever responsible for dysphagia by itself. It is, in fact, functional and not inert, and we did many intraoperative studies using a system with a terminal transducer, and clearly identified that that gastric tube functions similar to the distal esophageal sphincter in two areas. First, it does relax in response to swallowing, and it will respond to drugs such as atropine, and will drop the pressure. Gastrin will elevate the pressure, and a colleague of Dr. Allgower's in Switzerland, Dr. Leibermann, has done some elegant anatomic studies on the anatomic disposition and function of this lesser curvature part of the stomach from which the tube is created. I believe there is good evidence from that study and other studies that lesser curvature is almost a part of the lower esophageal sphincter mechanism. Therefore, it is certainly not an inert tube.

Dr. DeMeester, I remind you that when I have used the word "uncomplicated cases," I mean uncomplicated by reoperation or a motor disorder. These still represent a group of patients with the most advanced degrees of esophagitis, and I do not believe that a sequential group of Nissen fundoplications will result in a consecutive series of long-term results of this quality, if you wish, because some of those patients simply have too short an esophagus for any of the standard repairs other than possibly a Hill repair to be effective.

Dr. Benfield emphasized the importance of technique, and I would think one of the disadvantages of this operation, and it is a significant one, is that it is technically difficult. It is not an easy operation to pass on to the resident. The Belsey operation is in the same category, but this is even more so.

Dr. Benfield, you also asked about using a complete fundoplication for the reoperations. We did not use it right off the bat because we were reoperating for patients with dysphagia. The dysphagia in our failures is due to recurrent stenosis and stricture, which is due to a failure to control reflux. I do not have any doubt that a complete fundoplication provides better reflux control. Our concern has been that used routinely with this particular reconstruction we would have a higher incidence of mechanical dysphagia using a complete fundoplication than the partial operation.

Prolongation of Pig-to-Dog Renal Xenograft Survival by Modification of the Inflammatory Mediator Response

LEONARD MAKOWKA, M.D., PH.D., CHARLES MILLER, M.D., PAULO CHAPCHAP, M.D., LUIS PODESTA, M.D., CHEN PAN, M.D., DEBRA PRESSLEY, M.D., VINCENZO MAZZAFERRO, M.D., CARLOS O. ESQUIVEL, M.D., PH.D., SATORU TODO, M.D., BARBARA BANNER, M.D.,* RONALD JAFFE, M.D.,* ROBERT SAUNDERS, PH.D., and THOMAS E. STARZL, M.D., PH.D.

The pathogenesis of hyperacute renal rejection consists of a nonspecific effector cascade that invokes most of the components of a typical acute inflammatory response. Platelet-activating factor (PAF) represents the most recent and perhaps the most significant mediator and promoting agent of this phenomenon. These studies evaluated SRI 63-441, a novel, synthetic, and the most potent PAF receptor antagonist available, alone and in combination with other prostanoids, for their ability to influence this response and to prolong renal xenograft survival and function in a model of pig-to-dog heterotransplantation. Inhibition of PAF by SRI 63-441 alone, at the dosage and schedule used in these experiments, did not significantly prolong xenograft survival or function. However, the combination of SRI 63-441 with either prostacyclin (PGI_2) or prostaglandin E_1 (PGE_1) infusion demonstrated significant synergism, and resulted in a 6–9-fold increase in kidney survival and a 3–20-fold increase in urine output. Neither PGI_2 nor PGE_1 infusions alone significantly influenced this xenograft model. Electromagnetic flow studies demonstrated significantly delayed diminution in renal artery blood flow in the combination-treated animals. Serial and end-stage histologic examination of kidneys receiving combination therapy demonstrated a delayed onset of the pathologic deterioration and an overall amelioration of the entire process. These studies demonstrate that significant abrogation of a rapid and violent form of hyperacute rejection can be achieved solely by the pharmacologic manipulation of the inflammatory mediator response.

From the Departments of Surgery and Pathology, University Health Center of Pittsburgh, University of Pittsburgh, and the Veterans Administration Medical Center, Pittsburgh, Pennsylvania*

THE PATHOPHYSIOLOGIC EVENTS leading to hyperacute allograft rejection have been relatively well characterized and differ little today from the process originally described almost 20 years ago.[1-3] The initiating event is clearly a specific immunologic reaction consisting of antibody-mediated injury directed against antigens on the vascular endothelium of the transplanted organ.[4-6] This immunologic phenomenon leads to the accumulation of platelet-polymorphonuclear leukocyte-erythrocyte plugs in small arteries and capillaries, followed by intravascular coagulation and ischemic necrosis.[1,4,5,7]

The sequence of events leading from the initial specific immunologic reaction to the final characteristic pathologic result of hyperacute rejection of a kidney, which can best be described as a failure or breakdown of the microvasculature, represents a nonspecific, intense, and complex inflammatory response. This effector cascade invokes most, if not all, of the classical mediator systems of the acute inflammatory process (*i.e.*, complement, coagulation, fibrinolytic, and kallikrein-kinin systems).[8,9] During this process, a large number of biologically active molecules are generated that are responsible for the increased vascular permeability, arteriolar vasoconstriction, damage to the cytoskeleton, fibrin deposition, generation of oxygen-free radicals, and the recruitment, activation, and release of various inflammatory cells, which all contribute to the entire pathogenesis of hyperacute kidney rejection.[8,9]

Many of these chemical mediators of inflammation, including kinins, various chemotactic factors, anaphylatoxins, serotonin, and arachidonic acid metabolites

(prostaglandins, leukotrienes, thromboxanes) have been proposed as central candidates in the overall process of hyperacute rejection, and have served as the targets in attempts to develop therapeutic interventions to regulate organ function. The newest and perhaps most important inflammatory mediator to be nominated as a central candidate in the overall evolution of hyperacute rejection is acetyl glyceryl ether phosphorylcholine (AGEPC).[10] Also known as platelet-activating factor (PAF), as it will be referred to here, because it was initially discovered by its ability to cause potent platelet aggregation and release, it represents the most recently described and novel class of potent lipid autocoids.[8,11,12]

The implication that PAF plays a central role in the induction of tissue injury is attributed to a spectrum of biological activities that may manifest all of the cardinal signs of acute inflammation.[8,10-12] PAF is produced by a variety of inflammatory cells including platelets and neutrophils. It is also produced by endothelial cells, which supports its importance as a key regulator of the microvasculature, and more importantly, its disruption under pathophysiologic circumstances. Specific biological activities of PAF that are germane to its role in hyperacute rejection include: platelet and neutrophil release and aggregation, release of thromboxane A_2 and other eicosanoids, increase of vascular permeability, vasoconstriction, increase in hematocrit, systemic hypotension, and generation of oxygen-free radicals.

With the availability of specific receptor antagonists of PAF, further insight into the role of PAF in the pathogenesis of hyperacute rejection is now possible. The potential for a new method of controlling the effector cascade of hyperacute rejection by pharmacologic intervention can now be exploited also. Pig-to-dog renal heterotransplantation results in a rapid and violent form of cortical necrosis and ischemic destruction of the organ, which mimics the situation in humans and is due to preformed humoral antibodies in the recipient.[4,5,13] It represents an appropriate severe model in which to evaluate new methods of therapeutic intervention. The studies reported evaluated the effect of a novel and potent synthetic PAF receptor antagonist, alone and in combination with other prostanoids, on this renal xenograft model.

Materials and Methods

Animals

Female, white outbred SPF pigs that weighed 15–20 kg were purchased from Shadyside Farms, Ohio and served as donors. Male beagles that were bred for research and weighed 13–16 kg were purchased from Laboratory Research Enterprise, Kalamazoo, Michigan and served as recipients. All animals were housed in a central animal facility and were allowed to acclimatize for at least 1 week before experimentation. They received standard animal chow and water *ad libitum* and were fasted for 24 hours before surgery.

Surgical Procedures

All animals for both the donor and recipient procedures were anesthetized with intravenous sodium pentobarbital (30 mg/kg). Recipient dogs were maintained with 30% oxygen through an endotracheal tube. During the experimental procedure, dogs were monitored for depth of anesthesia by EKG and arterial pressure. Additional anesthetic (pentobarbital, 3 mg/kg IV) was given as required.

Donor pigs received intravenous Ringer's lactate (1000 mL), mannitol (12.5 g), and Thorazine® (50 mg). After systemic heparinization (5000 units) and *in situ* cooling with cold (4 C) Ringer's lactate through an aortic cannula, the kidneys were removed *en bloc.* The kidneys were then separated and transplanted simultaneously into two recipient dogs, always with less than 1 hour of cold ischemia time. A paired design was therefore performed for each experiment, by assigning one kidney as the control and the other as the test (treated) kidney.

All pig-to-dog kidney heterotransplantations were performed by a standard technique. The porcine renal artery was anastomosed end to end to the recipient right common iliac artery, and the renal vein was anastomosed end to side to the right common iliac vein. The anastomosis time was always less than 30 minutes. The dogs were kept anesthetized and the kidney was left external to the dog for observation. The ureter was cannulated with polyethylene tubing and urine was collected throughout the transplant period. For intra-arterial administration of prostaglandins, an 18-gauge polyethylene catheter was inserted through the middle sacral artery and threaded towards the orifice of the right common iliac artery. To ensure that solution infused into the terminal aorta would exclusively run into the graft renal artery, the left common iliac, middle sacral, and other smaller arteries originating at or near the aortic bifurcation were ligated near their origin. For those experiments where renal vein and artery platelet counts were measured, 18-gauge polyethylene catheters were introduced into the right femoral vein and its tip positioned at the venous anastomosis, and into the left common iliac artery and its tip positioned at the orifice of the right common iliac artery.

Each dog underwent native nephrectomy after the porcine kidney had been revascularized. A change in color or motling of the transplanted pig kidney was considered evidence of the onset of rejection. However, the end point of the experiment was signaled by a cessation of urine flow or by the onset of frank hematuria.

Drug Administration

Prostaglandins. Naturally occurring prostacyclin (PGI_2) and prostaglandin E_1 (PGE_1) or Prostin-VR were supplied by the Upjohn Company, Kalamazoo, Michigan (M. J. Ruwart). PGI_2 was reconstituted and infused in a 0.1M glycine buffer, adjusted to a pH of 10.5 with 2M Tris solution to enhance its stability. PGE_1 was reconstituted in a stock solution of 1 mg in 100 μL of ethanol. This solution was then diluted to the appropriate concentration in 0.9% sodium chloride for infusion.

All prostaglandins, freshly reconstituted for each experiment, were administered by constant infusion through the catheters placed into the aorta, and the dosage was titrated according to blood pressure tolerance. Control animals for the prostaglandin experiments received infusions of the particular prostaglandin vehicles.

PAF antagonist. SRI 63-441 was provided by the Sandoz Research Institute, Sandoz, Inc. (East Hanover, NJ). This synthetic compound represents the most potent receptor antagonist of PAF responses known to date. SRI 63-441 (molecular weight 662) is a substituted [tetrahydrofuranyl-(methoxyphosphinyloxy)ethyl] quinolinium compound[14] and is structurally similar to PAF. Structural analyses and purity (greater than 98%) were determined by NMR spectroscopy and thin-layer chromatography.[14] SRI 63-441 is readily soluble in water or sodium acetate buffer at concentrations as high as 5% and can only be given parenterally. In four species tested (rats, guinea pigs, dogs, and primates), SRI 63-441 exhibited dose-dependent inhibition of all major physiologic responses to PAF (*i.e.*, hypotension, hemoconcentration, bronchoconstriction, and increased vascular permeability).[14] For all studies reported here SRI 63-441 was reconstituted as a 10 mg/mL solution in 0.68% sodium acetate and 0.9% sodium chloride (pH 5.3). Before its administration, this solution was placed in a warm water bath (24–25 C) for 5 minutes and then administered as a bolus intravenous injection. Control dogs received the sodium acetate buffer intravenously.

Experimental Design

Four experimental groups are reported: Group I: the administration of SRI 63-441 alone was compared with controls; Group II: the combination of SRI 63-441 and PGI_2 was compared with controls; Group III: the combination of SRI 63-441 and PGE_1 was compared with controls; Group IV: the combination of SRI 63-441 and PGE_1 was compared with PGE_1 alone.

Both prostaglandins (PGI_2, PGE_1) were administered at a dose of 0.5–1.0 μg/kg/min (depending on systemic blood pressure) by continuous intra-arterial infusion commencing at 30 minutes before revascularization. SRI 63-441 was administered at 5 mg/kg/dose by intravenous bolus beginning at 5 minutes before and then 5 minutes after, and then every 15 minutes after revascularization. For each study, experiments were performed on control and test animals simultaneously.

Kidney survival was assessed for each experiment as described above. Urine was collected for the entire transplant period, and the total volume was used as an indicator of renal function. For six experiments in Group II and for three experiments in Group IV, platelet counts in the renal artery, renal vein, and peripherally were determined serially (every 10 minutes for the first hour and then every 30 minutes for up to 4 hours in the treated groups). Renal arterial blood flow in the transplanted kidneys was monitored electromagnetically using a Cliniflow II, Model FM701D Electromagnetic Flowmeter (Carolina Medical Electronics Inc., NC). Flows (in milliliters per minute) were determined every 10–15 minutes in six separate experiments in Group IV (controls received PGE_1 infusion). Serial kidney biopsies (every 15 minutes) were performed in an extra group of animals that are not included in survival statistics. Biopsies were also done at the end point of the experiment, (using the criteria outlined above) in all groups studied.

Pathologic Studies

Tissue preparation. Histologic evaluation of serial biopsies from one experiment and of sections of kidneys taken at the end stage of additional experiments are presented. In the serial studies, wedge biopsies were obtained at baseline (back table), and at 5, 15, 30, 45, 60, 75, and 90 minutes after revascularization. Tissues were formalin-fixed, paraffin-embedded, cut at 3 μm, and stained with hematoxylin and eosin.

Histologic parameters. One microscopic section from each biopsy was selected. The slides were randomized and evaluated in blind fashion. The percentage of glomeruli with segmental or global thrombosis was determined. The glomeruli with necrosis or PMNs were also counted. Acute tubular necrosis (ATN), characterized by disintegration and sloughing of epithelial cells, was graded as mild (rare foci), moderate (numerous foci), or severe (confluent). Blood in the tubular lumens and mitoses were noted. The interstitium was rated as normal, congested, or hemorrhagic; the latter was graded as mild (few foci), moderate (numerous foci), or severe (confluent). Arteries and arterioles containing thrombi were noted.

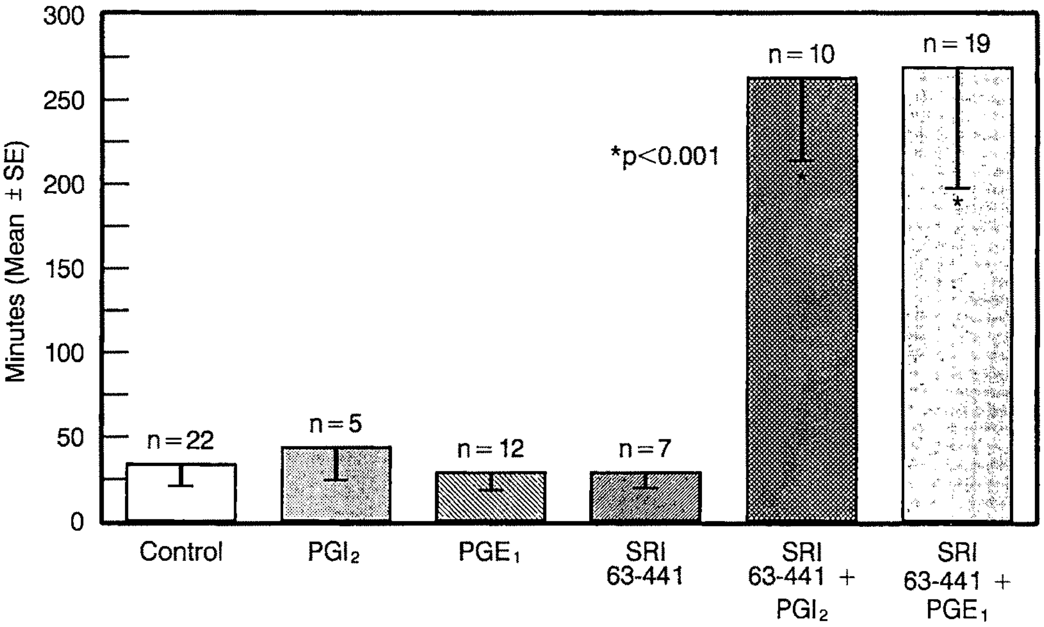

FIG. 1. Survival of renal xenografts after pig-to-dog kidney transplantation assessing the effect of single and combination treatment with a PAF receptor antagonist (SRI 63-441) and two prostanoids (PGI_2 and PGE_1). Results are expressed as total survival time (mean minutes ± SE).

Statistical Evaluation

All statistical evaluations were performed on an IBM PC-AT microcomputer using statistical analysis software (SPSS/PC+, SPSS Inc., Chicago, IL and BMDP/PC, BMDP Statistical Software, Los Angeles, CA). The mean and standard errors for urine volume and kidney survival for control and treated groups were compared using a nonparametric statistical test (McNemar) for the comparison of mean differences between two groups. The mean and standard errors for platelet counts were compared using a repeated measure design analysis. For all tests, a p value of less than 0.05 was considered statistically significant.

Results

Renal Xenograft Survival

Figure 1 depicts the survival for transplanted porcine kidneys in the four groups studied. The control dogs in all experiments consistently demonstrated violent rejection of the pig kidney within a mean time of approximately 30 minutes. The administration of SRI 63-441 as a single agent at the dosage and schedule described here did not result in a significant increase in graft survival. The addition of either prostanoid (PGI_2 or PGE_1) to SRI 63-441 treatment resulted in a marked synergism and a significant increase in kidney survival. SRI 63-441 and PGI_2 resulted in a greater than sixfold (217.1 ± 39.4 *vs.* 37.4 ± 11.1 minutes, $p < 0.001$) and SRI 63-441 and PGE_1 in a greater than sevenfold (268.6 ± 27.7 *vs.* 37.2 ± 5.6 minutes, $p < 0.001$) increase in renal xenograft survival when compared with their respective controls. PGI_2 or PGE_1 infused as single agents had no significant effect on kidney survival. In fact, in Group IV, the combination of SRI 63-441 and PGE_1 resulted in a greater than ninefold increase in kidney survival when compared with PGE_1 infusion alone (280.4 ± 31.8 *vs.* 31.0 ± 11.1 minutes, $p < 0.001$). PGE_1 in this experiment behaved no differently than the control vehicles in the other experiments.

Renal Xenograft Function

Renal function as determined by total urine output for each transplant is depicted in Figure 2. The results parallel those observed for kidney survival already presented above. SRI 63-441 alone did not significantly improve renal function. The combination of SRI 63-441 and PGI_2 resulted in a greater than threefold (99.5 ± 30.4 *vs.* 29.5 ± 13.7 mL, $p < 0.05$) and of SRI 63-441 and PGE_1 in a greater than 20-fold (436.2 ± 134.8 *vs.* 21.2 ± 7.3 mL, $p < 0.02$) increase in total urine output. Neither prostanoid alone resulted in a significant increase in urine output. The combination of SRI 63-441 and PGE_1 resulted in a 12-fold increase in total urine output (370.9 ± 78.9 *vs.* 32.7 ± 6.4 mL, $p < 0.003$) when compared with PGE_1 alone, which did not differ significantly from vehicle controls.

Platelet and Flow Studies

The serial platelet counts for six experiments in Group II (SRI 63-441 + PGI_2 *vs.* controls) and three experiments in Group IV (SRI 63-441 + PGE_1 *vs.* PGE_1) are depicted in Figures 3 and 4, respectively. There was a significant difference between the renal artery and renal vein platelet counts in Group II for both

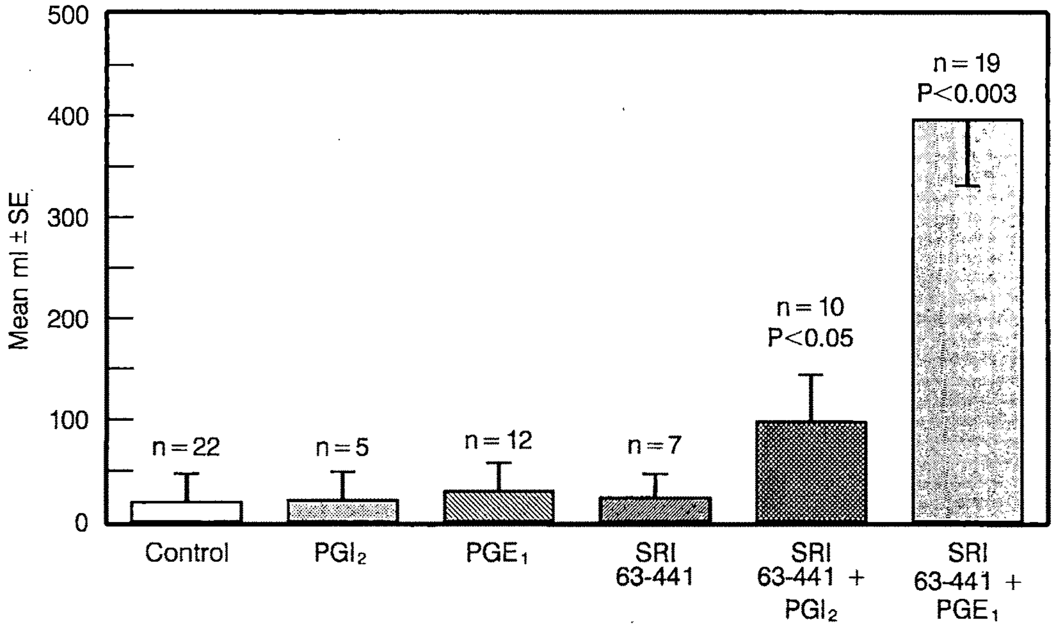

FIG. 2. Function of renal xenografts after pig-to-dog kidney transplantation from experiments described in Figure 1. Results are expressed as total urine output for the entire transplant period (mean milliliters ± SE).

control and treated animals, with a more pronounced gradient evident in the control group. No significant gradient in platelet count between renal artery and vein was observed in Group IV dogs.

The flow studies from six experiments in Group IV (SRI 63-441 + PGE_1 *vs.* PGE_1) are depicted in Figure 5. With the drug combination treatment group, as already evident in renal xenograft survival and function, blood flow to the xenografted kidneys was consistently maintained at significantly higher levels than in the control group (in this case already receiving a vasoactive agent, PGE_1). This is depicted up to 100 minutes after revascularization in Figure 5, since before that time, the PGE_1 alone group had already demonstrated severe diminution of graft flow. However, the combination treatment group maintained a degree of significant flow for most of the duration of the experiment.

Pathologic Evaluation

Microscopically, in the serial experiment, baseline biopsies from both control and treated animals contained normal glomeruli, with normal cellularity, and patent, empty capillary loops (Fig. 6). After reperfusion, both kidneys exhibited progressive obliteration of capillary loops by eosinophilic granular material mixed with red blood cells (Fig. 7). Similar thrombi were found in arteries and arterioles as early as 15 minutes. Tubules

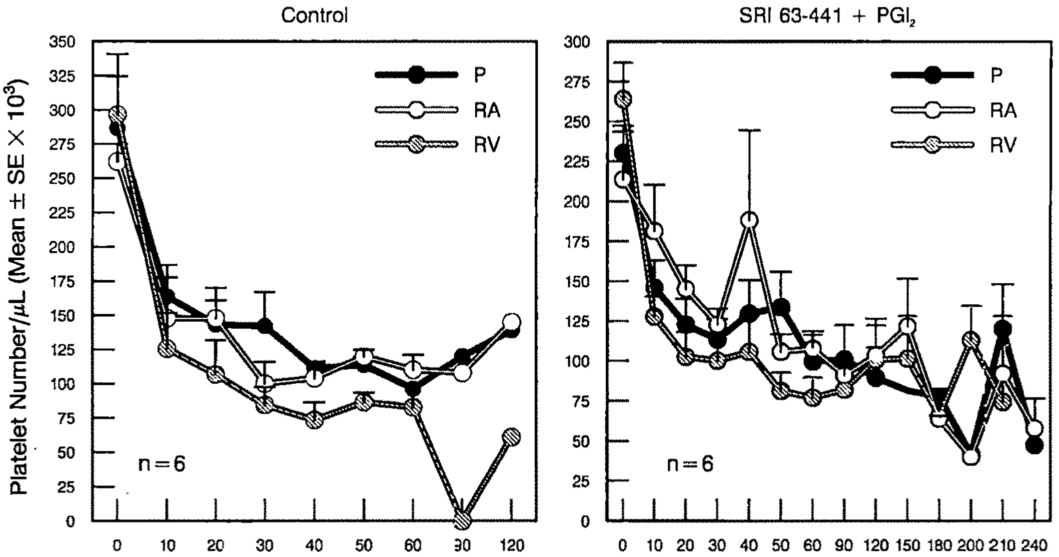

FIG. 3. Platelet counts (mean ± SE) determined for the renal artery (RA), renal vein (RV), and peripherally (P) for six sets of experiments in Group II (SRI 63-441 + PGI_2 *vs.* control).

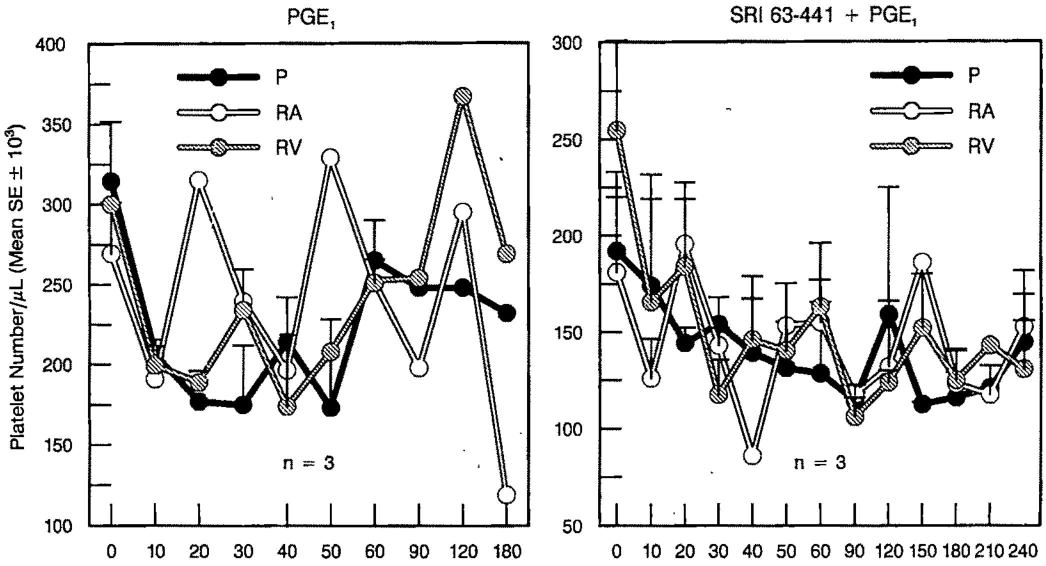

FIG. 4. Platelet counts (mean ± SE) determined for the renal artery (RA), renal vein (RV), and peripherally (P) for three sets of experiments in Group IV (SRI 63-441 + PGE$_1$ *vs.* PGE$_1$).

remained well preserved until 1 hour. There was progressive edema, then congestion, then hemorrhage in the interstitium. At the end stage, when renal function ceased, all specimens showed diffuse thrombosis of glomeruli, arteries, and vasa rectae. There were interstitial hemorrhages and early changes of ATN.

Sequential biopsies. Biopsy specimens at 5, 45, and 90 minutes are shown in Figures 8–10. Qualitatively, the glomerular changes were similar in the control and treated groups. However, the development of glomerular thrombosis proceeded at a slower rate in the treated kidneys. Table 1 shows the results from one epxeriment. The control animal reached end stage with thrombosis in 94% of the glomeruli at 45 minutes, whereas the process reached completion in the treated kidney at 90 minutes. At end stage, red blood cell thrombi were more prominent in the treated kidney (Fig. 10).

Necrosis of tubular epithelial cells was noted in the control kidney with blood in the lumens at 60 minutes. These changes persisted until the end of the experiment.

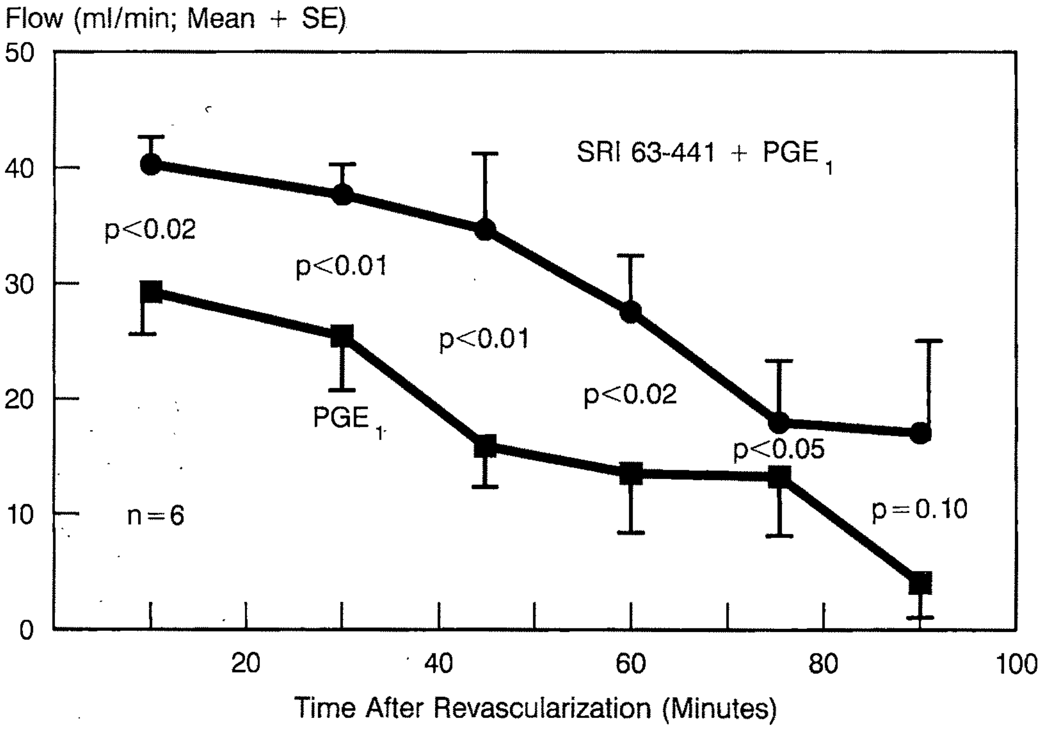

FIG. 5. Electromagnetic flow studies (mean mL/min ± SE) for six sets of experiments in Group IV (SRI 63-441 + PGE$_1$ *vs.* PGE$_1$).

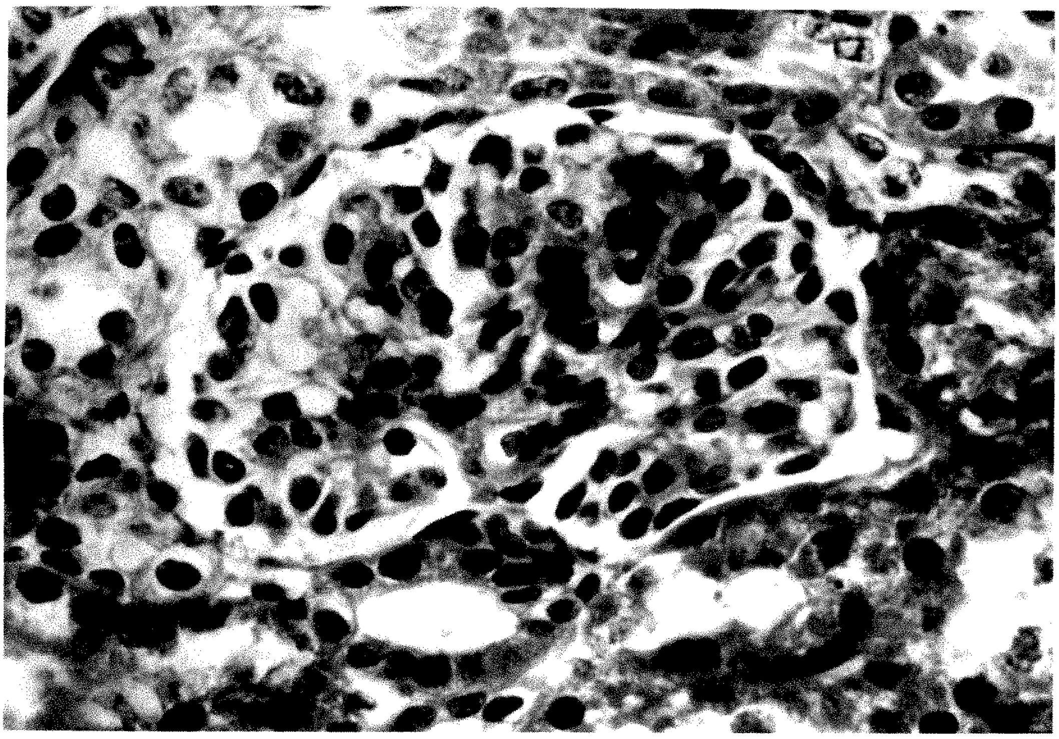

FIG. 6. Baseline biopsy specimen showing normal, empty glomerulus (hematoxylin and eosin, original magnification ×960).

It is important to note that significant necrosis was not noted in the treated kidney.

There was a difference between the two kidneys in the amount and onset of interstitial hemorrhage. Focal hemorrhages were noted in the control kidney at 15 minutes; this progressed to diffuse hemorrhage by 45 minutes and persisted (Fig. 9). In contrast, the treated kidney showed only focal hemorrhages at 30 minutes, and again at 90 minutes. There were no significant differences between the control and treated kidneys with

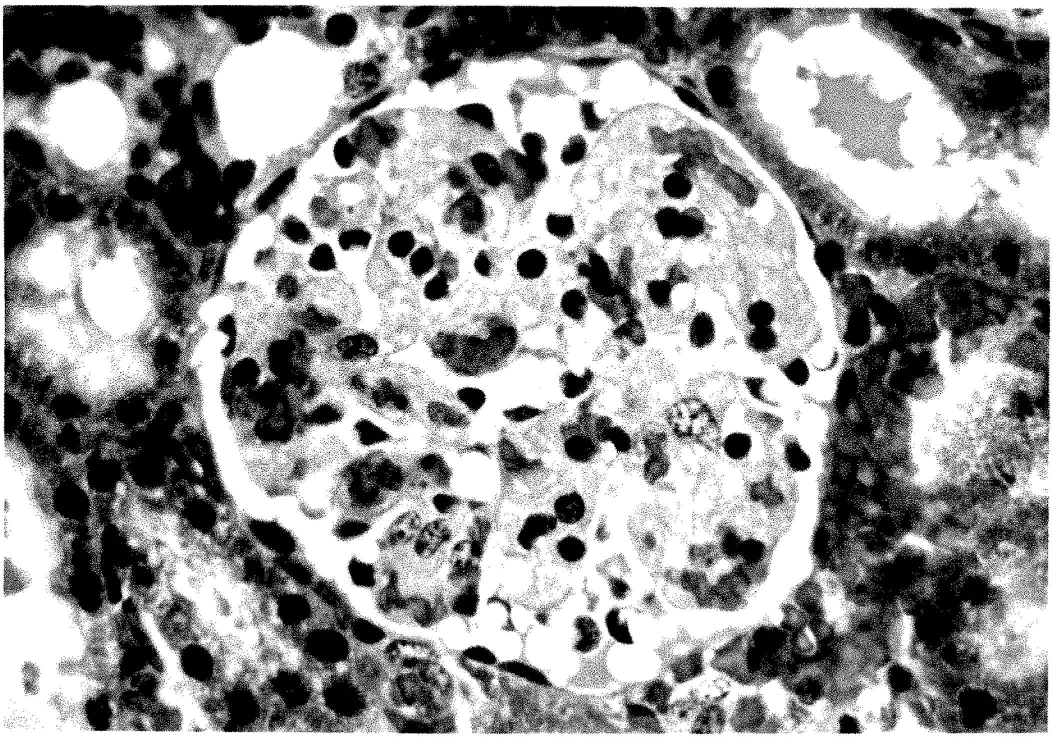

FIG. 7. Glomerulus filled with thrombi composed of RBCs in a pale granular matrix (hematoxylin and eosin, original magnification ×960).

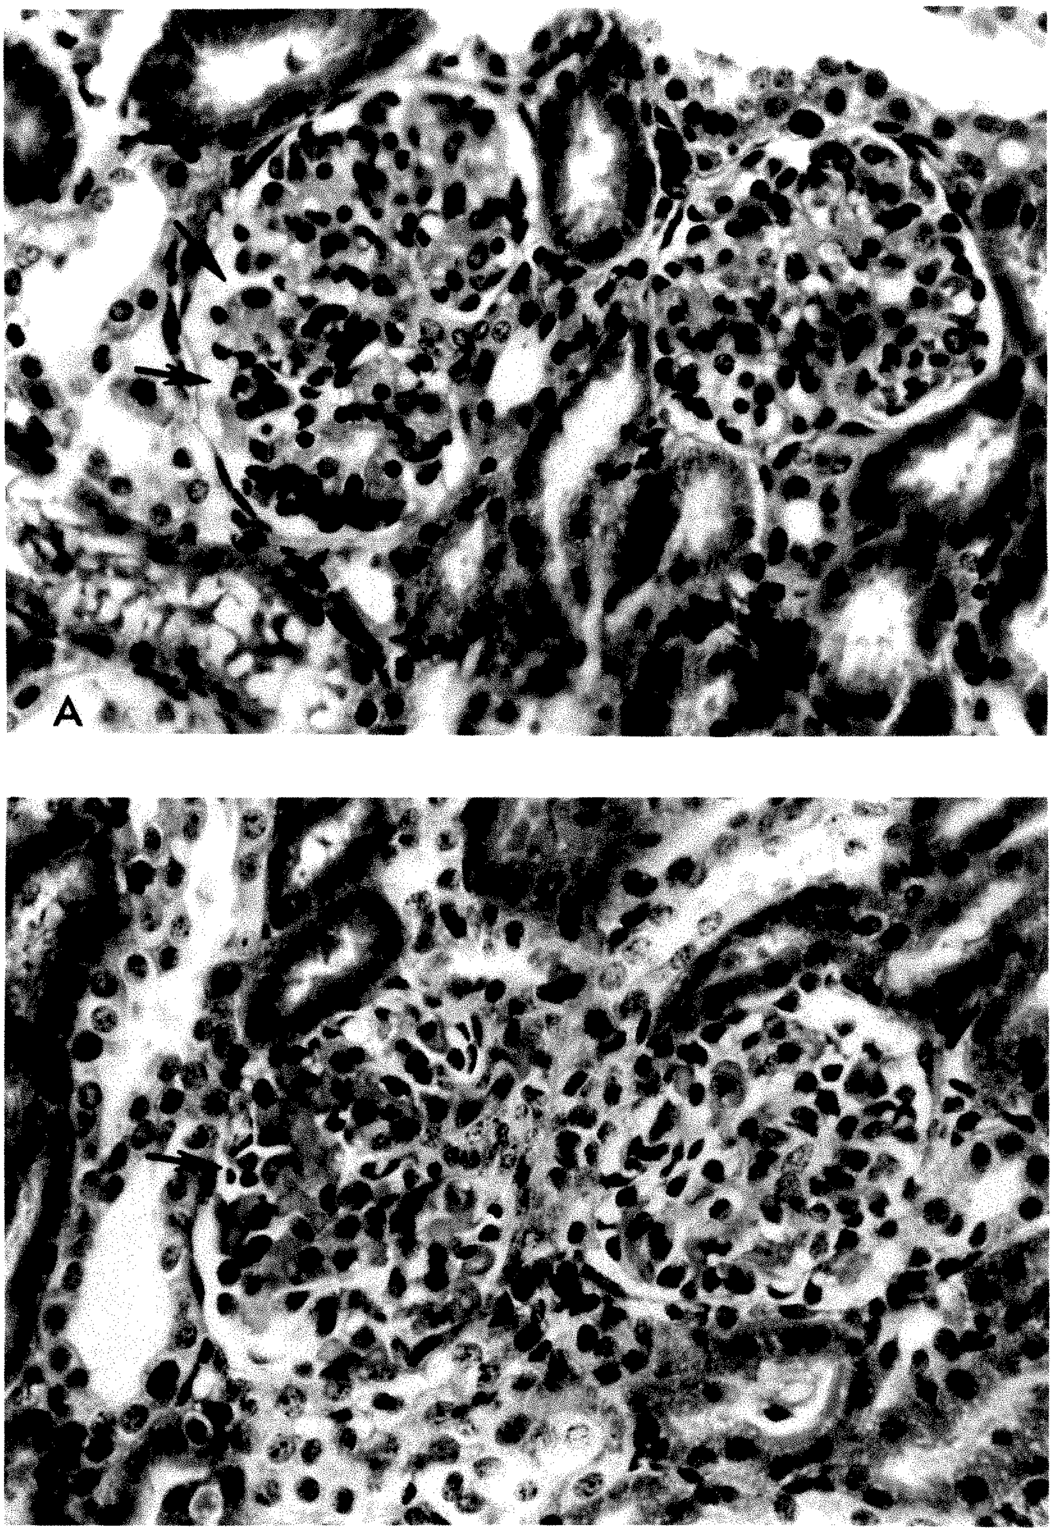
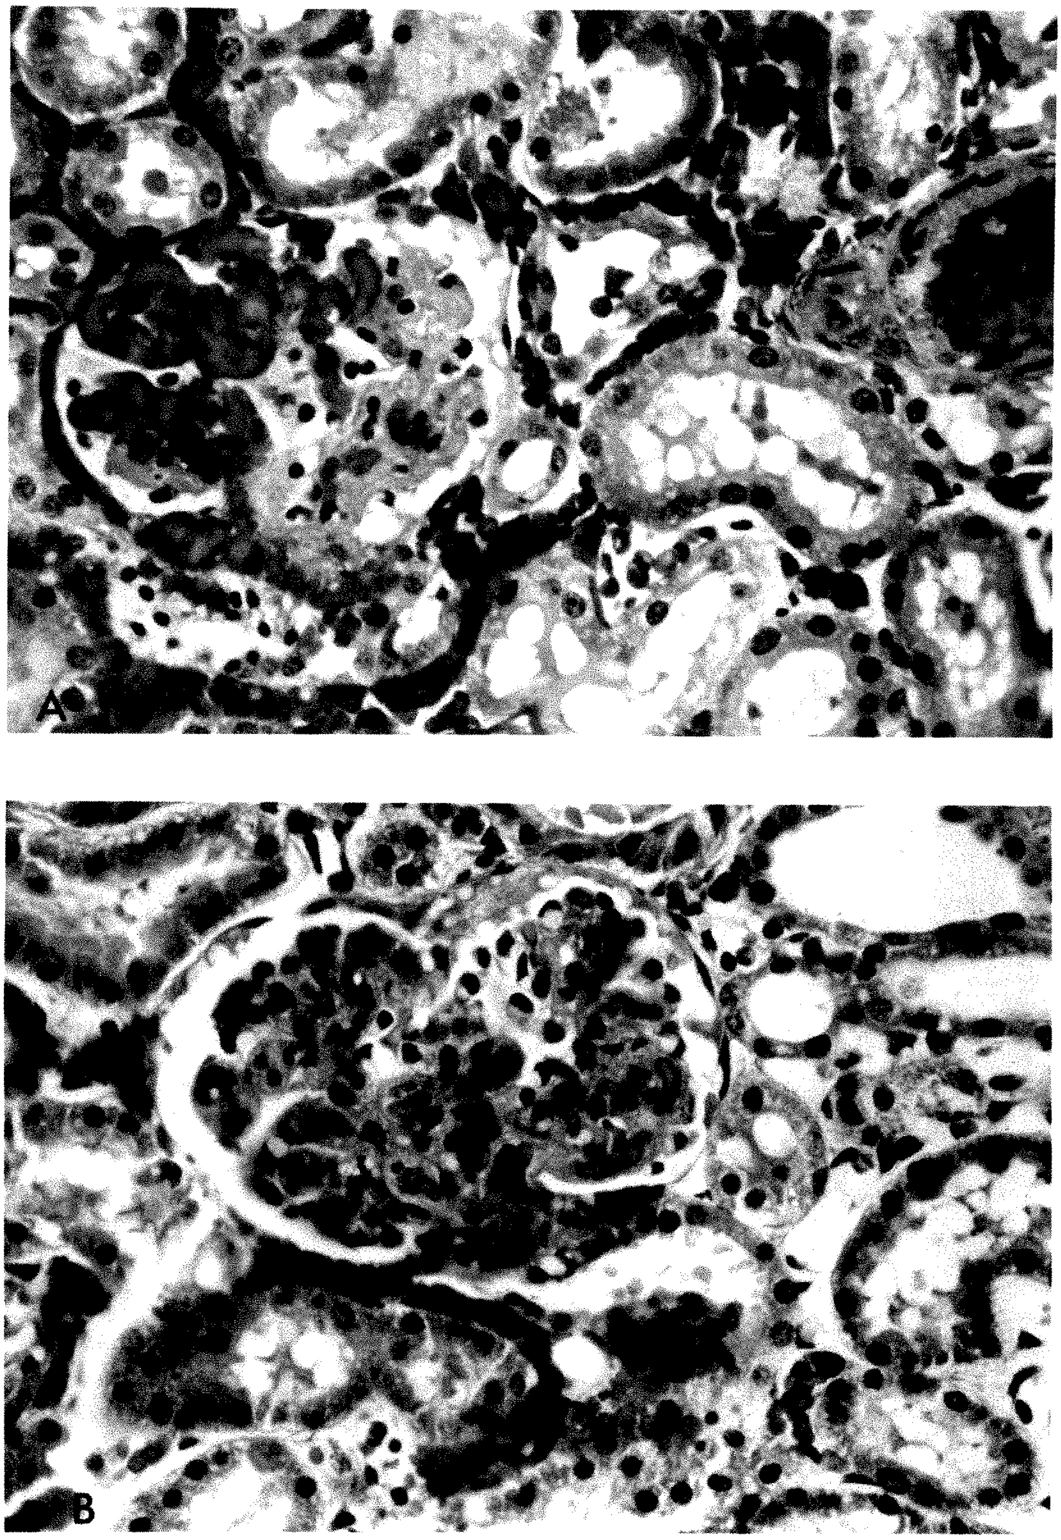


FIGS. 8A and B. Serial study, biopsy specimens at 5 minutes: *A*, control; *B*, treated. Note thrombi in some glomerular capillaries (arrows), and relatively normal tubules and interstitium (hematoxylin and eosin, original magnification ×625).

regard to the presence of thrombi in arteries and arterioles.

End-stage biopsies. The end-stage biopsies obtained after implantation represented a later stage than the sequential biopsies. In these sections, RBCs were a prominent component of the glomerular thrombi in the treated kidneys, whereas in the control groups the thrombi were composed of mostly granular eosinophilic material consistent with platelet-fibrin thrombi, similar to the changes noted in the sequential biopsies. There

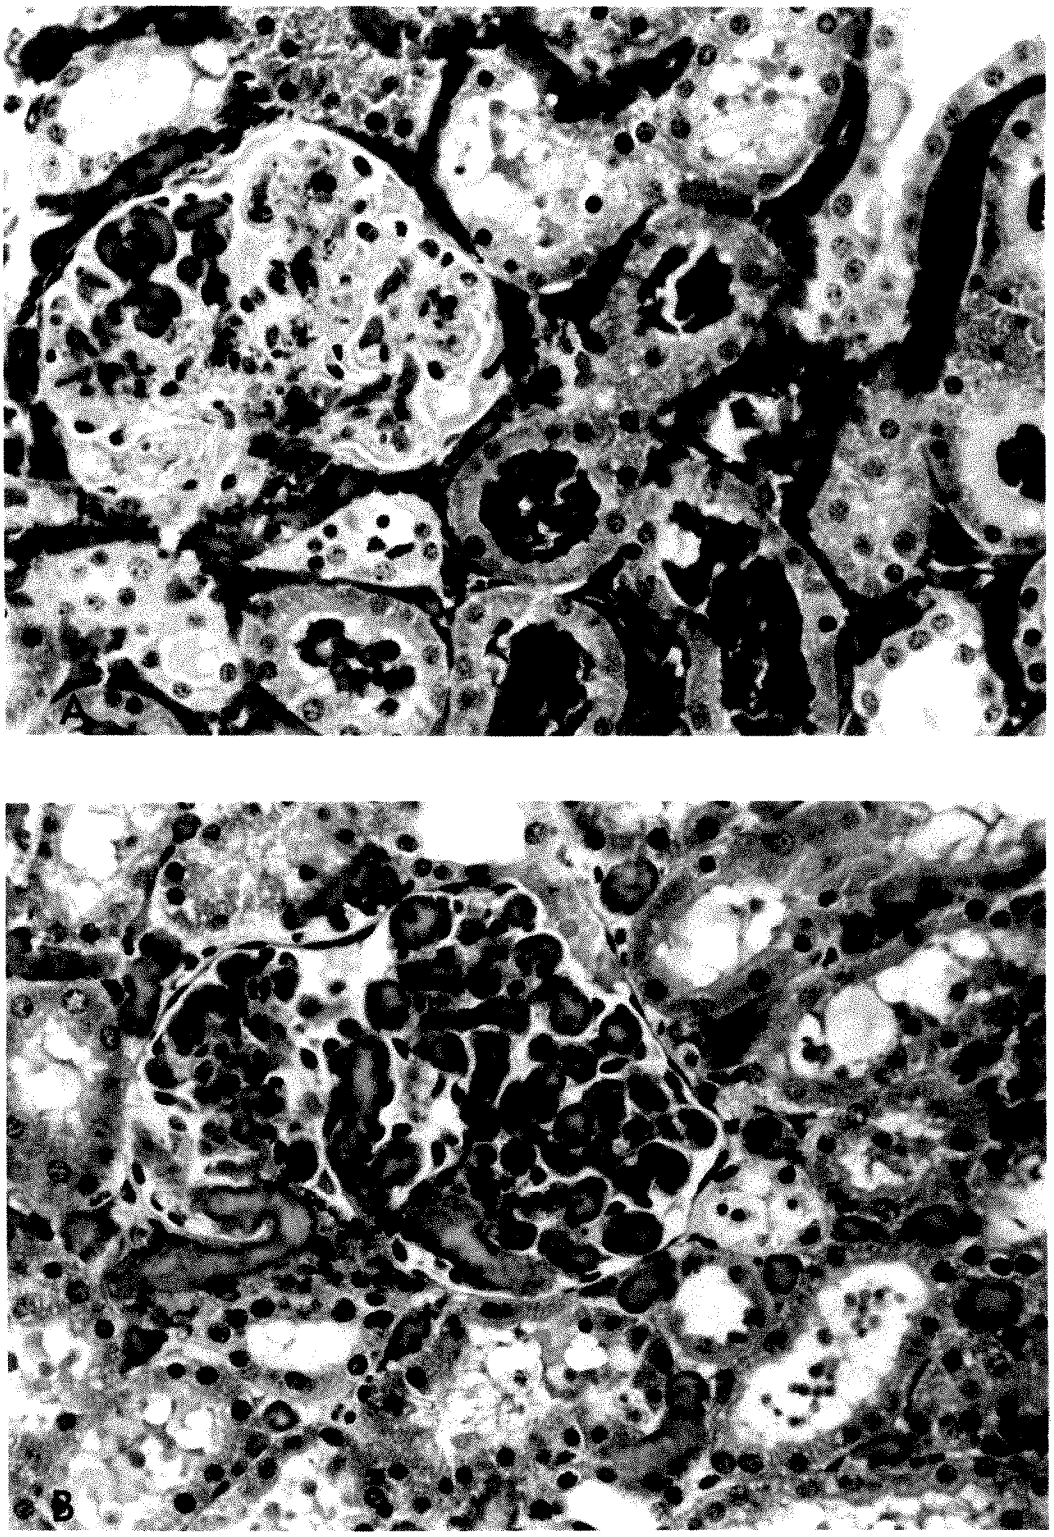


FIGS. 9A and B. Serial study, biopsy specimens at 45 minutes: *A*. control; *B*. treated. Note hemorrhages in the interstitium in the control kidney. Both glomeruli contain thrombi (hematoxylin and eosin, original magnification ×625).

was more interstitial hemorrhage in the treated dogs than in the controls in five cases, and less hemorrhage in four cases. Three of the treated kidneys and none of the control kidneys exhibited up to 20% glomeruli free of thrombi.

Discussion

The candidacy of platelet-activating factor (PAF) as a pivotal biologic mediator in the pathogenesis of antibody-mediated hyperacute allograft rejection has been



FIGS. 10A and B. Serial study, biopsy specimens at 90 minutes: *A*. control; *B*. treated. Note interstitial hemorrhages and blood in the tubules in the control kidney (hematoxylin and eosin, original magnification ×625).

clearly established. *In vitro* studies have demonstrated that PAF is released when endothelial cells are incubated with antibody to cell surface angiotensin converting enzyme.[15] This has important implications for hyperacute rejection, in which the specific initiating event is a transplantation antigen-antibody interaction on the endothelial surface. In a model of hyperacute renal allograft rejection in sensitized rabbits, PAF was identified in the blood effluent from the transplanted kidney, following antibody and complement fixation to the endo-

TABLE 1. *Progression of Histologic Findings in Sequential Biopsies of Control and Treated Kidneys*

	Control			Treated		
Time (Min)	Glomerular Thrombosis (%)	ATN	Interstitial Hemorrhage	Glomerular Thrombosis (%)	ATN	Interstitial Hemorrhage
5	26	0	0	13	0	0
15	69	0	Focal	46	0	0
30	83	0	Focal	60	0	Focal
45	94	0	Severe	73	0	0
60	91	Focal	Severe	80	0	0
75	88	Focal	Moderate	77	0	0
90	78	Focal	Severe	97	Focal	Moderate

thelium of glomerular and peritubular capillaries.[10] No PAF could be detected in rabbits without clinical or histologic signs of rejection. The PAF release was followed by the recruitment of platelets, endothelial sticking, and obliteration of capillaries by platelet-PMN plugs and evidence of cellular degranulation.[10]

The importance of PAF, even in the absence of inflammatory cells, was demonstrated in a model of *ex vivo* perfusion of the rabbit heart with transplantation alloantibodies.[16] The release of PAF followed bradycardia, conduction arrhythmias, decreased coronary flow, and cessation of heart action. These alterations in cardiac function and, moreover, the release of PAF, were prevented by complement inactivation. PAF itself induced a negative inotropic effect and reduction of coronary flow in isolated guinea pig heart muscle by a direct action on the Ca^{++} slow channel. Moreover, the injection of synthetic, purified PAF into the renal artery of rabbits reproduced a pathologic picture identical to that seen in a Shwartzman reaction of the kidney.[17] The pathophysiology of hyperacute renal rejection in humans was originally described as a Shwartzman reaction.[1]

The nonspecific effector inflammatory cascade that ensues once an antigen-antibody reaction has initiated hyperacute rejection has served as the target for therapeutic intervention by many different approaches. Classically, the platelet-coagulation system has been considered to be the most important and has received the greatest attention. These therapeutic modalities have included heparin, aspirin, dextran, citrate, defibrinating agents, cobra venom factor, induction of thrombocytopenia by antibodies etc., and various prostaglandins.[18-21] All these approaches have been either too toxic or the results too inconclusive to be accepted for generalized use.

The difficulty in overcoming the inflammatory process in hyperacute rejection and in explaining the discrepancies in therapeutic results rest not only in the complexity of the biologic reactions, but also in their resiliency and redundancy. That is, there are numerous alternative mediator pathways that can backup the same set of functions. Thus, the inhibition of one arm of an inflammatory reaction can easily be replaced by the release of other inflammatory autocoids with complete mediation of a disease process. PAF may represent somewhat of an exception to this hypothesis, because of its potency and its unique potential for mediating almost every aspect of acute inflammatory reactions. Nonetheless, the argument for polypharmaceutical therapy of hyperacute rejection is clear.

The current study represents the first known report describing the therapeutic efficacy of a receptor antagonist of PAF in any *in vivo* model of hyperacute rejection. These studies not only lend further support to the prominent role of PAF in the regulation of the inflammatory response leading to hyperacute rejection, but also introduce a new and potentially significant therapeutic approach to this entity. The agent used in these studies, SRI 63-441, is currently the most potent and specific PAF receptor antagonist available. It represents a family of compounds that can be synthesized and modified to meet desired specifications, *i.e.,* an oral compound recently has been produced.

At the single dosage and schedule of SRI 63-441 evaluated in these studies, inhibition of PAF alone was not sufficient to improve renal xenograft survival or function, although a trend did exist. From studies in rats and other recent studies in dogs, we have determined that the critical consideration for the efficacy of SRI 63-441 is to administer it at a much higher dose and before revascularization (unpublished data). However, the addition of either one of two prostanoids, PGI_2 or PGE_1, resulted in a synergistic response and a manyfold increase in renal xenograft survival and function. Although a higher dosage and more appropriate scheduling of SRI 63-441 may improve the effectiveness of single drug therapy, the need for multiple drug treatment eluded to above may be necessary to adequately modulate this violent inflammatory process.

There are many reasons for choosing PGI_2 and PGE_1 as complimentary agents to SRI 63-441. They both inhibit platelet function by stimulation of receptor-coupled adenylate cyclase and increase intracellular cAMP, a receptor mechanism different from that required for SRI 63-441 inhibition.[22] To varying degrees, they both exhibit other properties that establish them as excellent therapeutic candidates for such inflammatory processes. These biological activities include vasodilatation, fibrinolytic action, inhibition of the generation of certain deleterious metabolites of the arachidonic acid cascade, inhibition of oxygen-free radical generation, and the property known as cytoprotection.[22] Moreover, both these prostaglandins have been evaluated in other models of hyperacute rejection. Treatment with PGE_1 prolonged hamster-to-rat cardiac xenograft survival.[23] PGI_2 administration significantly prolonged kidney survival in both a model of hyperacute renal allograft rejection in presensitized dogs and in cat-to-dog xenografts,[21,23] but had no effect on guinea pig-to-rat cardiac xenograft survival.[23] Neither PGI_2 nor PGE_1, when administered alone as a constant infusion without combination SRI 63-441 treatment, had a significant effect on pig-to-dog renal xenograft survival or function as described in our studies. Furthermore, the therapeutic effectiveness of these prostaglandins in combination with SRI 63-441 was evident only when they were infused intra-arterially; peripheral administration of prostaglandins did not exhibit synergism with SRI 63-441 (unpublished results). This is most likely due to inactivation of prostaglandins as they pass through the lungs.[22]

The pig-to-dog renal xenograft model evaluated in these studies probably represents the most severe animal model of hyperacute rejection known. Rapid and violent kidney rejection is the rule and there have been only a few reports of successful abrogation of this process. Shons and Najarian reported a significant increase in pig renal xenograft survival from a mean of 5 minutes in controls up to a mean of 45 minutes in dogs treated with a variety of antiplatelet agents.[19] Merkel et al. reported renal xenograft survival times of 120, 90, and 180 minutes in three dogs that had preoperative plasmapheresis.[24] Kux et al. reported a mean rejection time of 85 minutes in 15 kidneys treated with intra-arterial citrate infusion; these experiments were limited by significant toxicity.[20] The control xenografts for the latter two sets of experiments rejected in less than 10 minutes.[20,24]

Consistent and reproducible results were achieved in the same model in the current studies by combining SRI 63-441 with either PGI_2 or PGE_1. Pig kidneys surviving for 3–4 hours were consistently achieved with maintenance of good urine output in all combination treatment groups. There were three kidneys in this series of experiments that functioned satisfactorily for 6–9 hours. These results compare most favorably with any previous reports of this particular model.

Although the differences in the pathologic evaluation of treated and control animals were subtle, there is no doubt that on serial histologic examination, treated animals demonstrated a delay in the evolution of the final morphologic deterioration. Futhermore, the end-stage histologic examination in treated kidneys demonstrated an overall amelioration, albeit minor, of the entire pathologic process. The histologic findings correlated with the clinical course. The significant improvements in renal xenograft survival and function were also paralleled by a significantly delayed diminution in renal artery blood flow and a significantly improved gradient of the plätelet count between renal artery and vein in combination treated animals.

Emphasis on platelet counts and gradients may not be as important as once believed. It is clear that although PAF is a potent modulator of platelet aggregation and release, it can promote the pathophysiologic process of hyperacute rejection by various other pathways.[8–12] Furthermore, rats with a defect in platelet aggregation exhibited the same time course and morphologic features of hyperacute cardiac rejection as in normal rats,[6] and platelet aggregation was demonstrated not to be essential in a model of renal xenograft rejection.[25]

In summary, these studies further confirm the central role of platelet-activating factor in the inflammatory cascade that destroys kidneys undergoing hyperacute rejection. Furthermore, this report introduces a novel, reproducible, and potentially effective therapeutic approach to this difficult problem, which relies on a better understanding of the basic pathophysiologic process of inflammation and which utilizes as its basis, a synthetic receptor antagonist that specifically inhibits the potent and unusually diverse spectrum of biologic activities of one of the key mediators of classical inflammation.

DISCUSSION

DR. EDWIN W. SALZMAN (Boston, Massachusetts): This is a very interesting paper, but there are several concerns I have about some of the details of the use of the inhibitor of platelet activating factor (PAF).

One of the most striking things about PAF is its species specificity. There is evidence, for example, in humans, although perhaps not in rabbits or in dogs, that the action of this agent is mediated through cyclo-oxygenation of arachidonic acid, and ultimately through the generation of prostaglandin endoperoxides and thromboxanes. These processes are totally blocked by aspirin, and I wonder if the observations made on these animals would be relevant in humans. Might one not expect that in humas the effect of aspirin would be as great as the effect of the specific inhibitor of PAF?

The second question relates to the dose of prostacyclin that was used, which is about 40 times the maximum tolerable dose in humans. Is there reason to believe that the findings with such a large dose of this prostaglandin would be relevant to the human situation?

Finally, we have seen that the histology after the graft finally failed was different in the animals treated with the antagonist to PAF and with prostacyclin. This is a situation in which there is virtually total paralysis of platelet function, and I wonder if the author would comment further on the presumed difference in mechanism of graft failure in the animals receiving the PAF antagonist.

DR. P. O'LEARY (Dallas, Texas): I enjoyed your paper very much. I have one question.

It looked to me as though the platelet count did not fall as far in the treated animals, but the extraction arterial to venous was as great. I wonder if you attempted to quantify the extraction of platelets as they passed through the kidney.

DR. M. WAYNE FLYE (St. Louis, Missouri): You state that there is abrogation of the hyperacute rejection, but in fact, the graft still fails at about 400 minutes. Your histology shows some clearing; however, it does not show the expected deposition of fibrin and platelets onto the endothelium. Would you comment on why the graft fails even though there is some prolongation of survival?

DR. COURTNEY M. TOWSEND, JR. (Galveston, Texas): That was a very nice study. There was a lot of work in it. It was very well presented. I wondered why you had to give the prostaglandins in addition to the PAF antagonist in the pig-to-dog model and did not apparently do that in the rat model.

DR. WILLIAM E. NEVILLE (Newark, New Jersey): This was a beautifully presented paper and their results were stimulating.

As I look back at what our group did in the 1960s and early 1970s on heterologous cardiac transplants in animals, I realize now that I should have continued with this work. However, we did not have the drugs that today seem to prevent early rejection between certain heterologous animals. We initially inserted the hearts of calves, sheep, goats, and pigs orthotopically into dogs on cardiopulmonary bypass using only Ringer's lactate to prime the pump oxygenator. The hearts were initially pink and contracting but deteriorated rapidly. Histologic and electromicroscopic studies showed microcirculatory red cell agglutination without fibrin despite platelet aggregation and inflammatory reaction. We then reversed the experiements and placed dog hearts into calves, sheep, goats, and dogs using the same technique. All of the transplanted hearts were easily defibrillated and adequately maintained the circulation until the dogs were killed hours later. Microscopic examination of the dog hearts showed few ultrastructural changes. The capillaries were invariably patent with no significant alterations of the endothelial cells. The myocardium only showed some patchy interstitial edema and slight mitochondrial swelling and glycogen depletion. The reason for this striking contrast in the two groups was not clear; but we reasoned and published that it might have something to do with the disproportion between the red blood cells and capillaries, thus disregarding an antigen–antibody reaction.

I would like to see the group from Pittsburgh use this relatively new drug alone or in combination with other antiplatelet drugs to see whether the Schwartzman reaction could be prevented in xenograft hearts inserted into dogs on cardiopulmonary bypass. We definitely need heterologous organs for transplantation but we do have much to learn regarding the use of these organs in humans.

DR. NICHOLAS L. TILNEY (Boston, Massachusetts): I also enjoyed the paper very much. We have been looking at a slightly different model in a rat heart graft system, so-called accelerated rejection that occurs about 36 hours after transplantation instead of in a few minutes as occurs in a presensitized rat.

In the beginning of the process, we found more or less what these authors have found, a very accelerated rejection that is primarily a humoral event. There are a few infiltrating cells; however, most of which are activated cells bearing interleukin II receptors on their surfaces.

We can abrogate this early rejection and get grafts out to about 3 or 4 weeks using either cyclosporine in various doses or monoclonal antibodies directed against the interleukin 2 receptors. Regardless of treatment, the grafts ultimately reject at about 3 weeks, but the primarily humoral rejection has been converted to a primarily cellular one, an extremely interesting observation.

I would like to aske the authors whether they had a chance to look at the infiltrating cell populations during the time their grafts are still viable, because I believe they will find these are a very interesting cell subgroup and mostly interleukin 2 receptor positive.

DR. LEONARD MAKOWA (Closing discussion): I would like to thank all the speakers for their helpful comments and interesting questions.

Many of your questions have concentrated on the importance of platelets in the overall process of hyperacute rejection and, therefore, I will try to cover these together. There is no doubt that platelets play a role in this process. However, over the last 20 years, since this entity was described, there has been a hangup on the importance of platelets and the major role that they play in the overall pathophysiology of this process. Many investigators had demonstrated platelet consumption by kidneys that were undergoing hyperacute rejection by studying platelet gradients between the renal artery and vein of these kidneys. Histologically, platelet accumulation and aggregation was a major feature of the final pathologic process. Nonetheless, it is now clear that the role and the importance of platelets in this process is just one small component of a much bigger picture, and that the entire evolution of hyperacute rejection must be redefined.

There is considerable evidence in the literature that indicates platelets are not the sole or major contributor to the process of hyperacute rejection. These experiments have demonstrated that the identical clinical and histopathologic entity of hyperacute rejection can occur in the face of platelet depletion, or in animals with a hereditary deficiency of platelet function. In fact, it now appears that other cellular components, especially the neutrophil, may play an equal or even more important role.

Currently, hyperacute rejection must be considered the end product of a set of complex nonspecific inflammatory reactions, which are initiated by a specific antigen–antibody reaction. I tried to demonstrate some of these contributory inflammatory arms in the first slide, and to emphasize their resiliency and redundancy. Thus, many alternative backup inflammatory systems can result in the same set of functions and final pathologic process. The relative importance of each of these inflammatory pathways is as yet unknown, and furthermore, the relative importance of blocking or inhibiting the biologic activity of any one specific mediator remains to be fully defined.

I must re-emphasize that the designation of the mediator that we are discussing today, as platelet activating factor, is a misnomer. PAF plays a role in most of the classical mediator systems of the acute inflammatory process, in the generation of arachidonic acid metabolites, and in the generation of oxygen free radicals, etc. Although PAF is one of the most potent inducers of platelet aggregation and release, and thus by this mechanism plays a contributory role in hyperacute rejection, there is now clear evidence that establishes PAF as a central candidate in the overall evolution of this inflammatory process and as a key biological mediator in the pathogenesis of antibody-mediated hyperacute allograft rejection. This lead to our hypothesis that antagonism of PAF-induced reactions offered a potential therapeutic approach to this entity by inhibiting many of the key inflammatory pathways.

It is true that one of the actions of the PAF antagonist is to inhibit the cyclo-oxygenase pathway, thereby inhibiting the formation of various biologically active autocoids of the arachidonic acid cascade, as well as interfering with platelet function. Aspirin exhibits these same specific properties, but does not influence the numerous other inflammatory pathways as the PAF antagonist can. Dr. Najarian's group described a set of elegant experiments in Transplantation Proceedings in 1974, where the effect of aspirin was evaluated in this same model of pig-to-dog renal xenografts. They found that the mean graft survival time of 5 minutes in control animals was increased to 21 minutes by aspirin treatment. In fact, the addition of dextran to aspirin treatment further increased the mean graft survival time to 45 minutes. At that time, these were considered significant results. Obviously, the numerous backup pathways could overcome this single-pronged approach in such a severe xenograft model. That is why we have initially taken the approach of multipharmaceutical therapy, and demonstrated a synergistic effect by combining a prostaglandin with the PAF antagonist.

In our studies, we consistently achieved renal xenograft survival of 3 to 4 hours and in a few cases achieved 9-hour survival. These results significantly surpassed previously published reports using this same pig-to-dog model, which we believe is probably the most severe experimental model of hyperacute rejection known.

I agree that the dose of prostacyclin that we have reported in these particular studies today was too high. We did observe some hypotension in these animals. Subsequently, we have repeated these studies using a much lower dose of prostacyclin and have achieved the same efficacy. Similarly, for prostaglandin E_1, we have used dosages as low as 0.01 μg/kg/min, which is well tolerated in humans.

One of the problems with the studies that I have described to you today, is that based on our subsequent rat studies, we probably were not using enough of the PAF antagonist. In these studies, we used 5 mg/kg. From subsequent studies of hyperacute rejection using a model of heterotopic cardiac transplantation in hypersensitized rats, we have learned two critical points. A much higher dose of the drug can and should be given, and the dose given before revascularization is the key for efficacy. In fact, we have demonstrated significant prolongation of cardiac allograft survival in this model using 15 or 20 mg/kg given 4 minutes before revascularization.

It appears that it is much easier to overcome this process in the rat heart model using the PAF antagonist alone. As I already mentioned, this may be due to a dosage and scheduling inefficiency in the xenograft model reported today. However, in the xenograft model we are probably dealing with a much more potent initiating immunologic reaction. Therefore, the trigger for this overall process may be different, and may require a modified therapeutic approach, *i.e.*, that of utilizing polypharmaceutical therapy. Alternatively, we must appreciate the contributions of the different microvasculatures of the kidney and the heart.

I agree completely with Dr. Tilney, that the importance of the rat model should be emphasized. Unfortunately, these initial studies were presented in the closing two slides, but it is apparent that in the rat model, we have converted the process of hyperacute rejection into one of classical cell-mediated rejection. We have not as yet had the opportunity to characterize the infiltrating cells in the hearts that underwent classical rejection. We are currently in the process of combining the PAF antagonist with standard immunosuppression in this model. We certainly agree that the combination of the ability to overcome the inflammatory process resulting from the initial antibody insult and of controlling cell-mediated rejection with appropriate immunosuppression, at least in the homograft rat heart model, may allow us to overcome the entire process of hyperacute rejection.

Long-term Evaluation of Aortic Valvotomy for Congenital Aortic Stenosis

KEVIN J. TVETER, M.D., JOHN E. FOKER, M.D., PH.D., JAMES H. MOLLER, M.D.,* W. STEVES RING, M.D.,

Aortic valvotomy (AV) for relief of congenital aortic stenosis (AS) is a palliative operation, and the purpose of this study was to determine the long-term benefit. After analyzing the symptoms at time of operation, 177 patients were separated by age at AV: newborns (1–14 days) 26, infants (2 weeks–1 year) 19, and children (≥1 year) 132. The newborn with critical AS typically presents with severe cadiac failure and the infant with moderate failure, whereas children may be asymptomatic. In the newborn group, final diagnosis has been made exclusively by noninvasive cardiac echogram since 1984. The presence of a hypoplastic left ventricle (HLV) and/or endocardial fibroelastosis (EFE) are the most important determinants of mortality. Operative survival was 11 of 13 (85%) in the newborn group if HLV/EFE were not present. No operative deaths for AV occurred after 1965 in children. When present, a preoperative electrocardiographic strain pattern resolved in 80% of patients. Of 33 reoperations (21%), four were required 1.0 (0.5–2) years later for newborns, five were required for infants 7.2 (1.5–20) years later, and 24 were required in children 11.0 (1.5–25) years later. These included 10 repeat valvotomies and 23 aortic valve replacements (AVRs) with a 91% survival rate. In summary, although valves of patients with congenital AS are morphologically abnormal, valvotomy is beneficial. It was found that (1) the operative survival rate has been 100% over the past 20 years for children and currently is greater than 80% in newborns in the absence of HLV/EFE; (2) reoperation rate is higher in newborns and infants; (3) benefit was shown by a sharp decrease in obstruction initially and improved ECG later; (4) long-term follow-up revealed a subset of patients who are asymptomatic and have only mild residual obstruction over 20 years after AV.

AORTIC VALVOTOMY (AV) for congenital aortic stenosis is a palliative operation, and considerable valve deformity persists despite relief of obstruction. Nevertheless, AV is widely performed because of the poor outlook for patients with severe stenosis. Althogh many series report initial benefit, longer follow-up has shown an increasing reoperation rate, attrition by late deaths, and return of symptoms in a significant number of patients.[1-5] One recent series has even concluded that all patients will require reoperation within 20 years of the initial valvotomy.[6] A contributing factor to this pessimistic outlook may be that previous follow-up measurements of left ventricular–aortic (LV–Ao) pressure differences by cardiac catheterization were done almost exclusively on symptomatic patients.[1-6] These studies showed significant residual pressure gradients, and the conclusion has been drawn that inexorable and relatively rapid aortic valve deterioration is the fate of these patients. To determine if this conclusion is correct, evaluation of an entire group of patients who had undergone AV would be necessary.

The purpose of this study, therefore, was to obtain this long-term follow-up data. Because AV under direct vision was first performed at this institution in 1955, a long-term analysis of these patients was possible. We attempted to obtain studies on all patients, whether asymptomatic or symptomatic, who had not had cardiac catheterization or had an echocardiogram done within the last 2 years. These data would allow us to examine several important questions, including (1) whether or not the operative approach and results have changed over the past 30 years, (2) the clinical spectrum and corresponding prognoses of these patients and, most importantly, (3) the long-term benefit of AV for a patient with significant congenital aortic stenosis.

Methods

Patient Population

During the period under review (December 2, 1955 to November 30, 1986), 177 patients under 25 years of age had aortic valvotomy for congenital aortic stenosis. There were 124 males and 53 females. All AVs were done under direct vision using a transaortic approach, and all but one, the first patient in this series, were performed on cardiopulmonary bypass. The first patient had direct vision valvotomy during a period of hypothermic inflow occlusion.[7] Review of the operative technique has shown relatively little variation over the period under study. Using hypothermia with or without cardioplegic arrest, the aortic incision typically was extended toward the noncoronary sinus. Evacuation of the left ventricle provided visualization of the valve and revealed the commissural fusion. Usually (see Results), a bicuspid aortic valve was encountered with the major fused commissure located anteriorly. Care was taken to evenly divide the fused commissural ridge, and the incision was usually carried to the annulus itself. When a unicommissural valve was encountered, only two incisions were made in an attempt to create a bicuspid valve. Only in the rare instance of a clearly tricuspid valve were three incisions made.

Associated Cardiac Defects

There were 67 significant associated cardiac defects (excluding patent foramen ovales) among the 177 patients. A patent ductus arteriosus occurred 23 times. Coarctation of the aorta was present in 17 patients, a subaortic membrane was present in two patients, a ventricular septal defect was present in two patients, and a coronary ostial membrane was found in one patient. Significant mitral regurgitation was present in 18 patients and was more prevalent in the younger patients. Among newborns, 11 of 26 (42%) had significant mitral regurgitation or stenosis, including four patients with a dysplastic mitral valve.

Diagnosis

In all except six cases, the clinical diagnosis was confirmed before operation either by cardiac catheterization with direct pressure measurements or echocardiography with doppler based pressure estimations. By cardiac catheterization, pull-back measurements yielded peak-to-peak LV–Ao systolic pressure differences. This pressure difference was commonly used as the gradient for determining preoperative status and follow-up results. The mean pressure differences were used for calculation of the valve area by the Gorlin formula. More recently, echocardiography including doppler determinations have been increasingly used to estimate the LV–Ao pressure differences. With echocardiographic analysis, the mean systolic pressure differences were used rather than the peak-to-peak instantaneous gradients that tend to overestimate the obstruction.[8]

Echocardiographic techniques were also used to assess the left ventricular chamber size and determine if endocardial fibroelastosis (EFE) were present to assess the adequacy of the left ventricular chamber. Early in the series, a hypoplastic left ventricle (HLV) was diagnosed when the transverse diameter of the left ventricle fell below the normal range. More recently, the contours of the chamber have also been taken into account. An HLV tends to have a spherical cavity without the usual greater longitudinal dimension. Currently, if the transverse diameter is less than 12 mm and the LV cavity spherical in contour, then the newborn is judged to have an HLV.

In the presence of significant EFE, virtually the entire endocardium including the papillary muscles of the LV are echo reflective to a depth of approximately one fourth of the wall thickness. Newborns meeting these criteria were judged to have EFE. Before the use of echocardiography, this diagnosis was made only at postmortem examination.

Electrocardiographic Analysis

A standard 12-lead electrocardiogram (ECG) was used to provide additional information on the severity of obstruction. Patients over 1 year of age were judged to have left ventricular hypertrophy (LVH) if the R-wave in V-6 was 25 mm or greater or the S-wave in V-1 was 25 mm or greater in height. The diagnosis of strain was made by T-wave flattening or inversion or S-T depression in the lateral precordial leads.

Patient Follow-up

There were 22 operative deaths; therefore, 155 patients were available for potential follow-up study. Follow-up for this study began with analysis of patient records from the University of Minnesota and outside records and patient contact by questionnaire and telephone. By these methods we determined there were 12 late deaths, six patients who currently are lost to follow-up, and two patients could not be traced after discharge. Unfortunately, the first patient, now over 31 years post AV, is among those currently lost to follow-up. Total follow-up is 1865 patient years with mean follow-up of 12.1 years (range: 0.5–29.5 years). This includes 39 patients followed up for more than 20 years and 18 patients followed up beyond 25 years. Only nine patients were followed up less than 10 years, although 51 patients

have had a valvotomy less than 10 years before the time of analysis.

Follow-up was accomplished when the patient's history and current condition was determined by return of the mailed questionnaire. The questionnaire was supplemented whenever possible by direct contact and review of current medical records. The patient was considered studied when the LV-Ao pressure difference was determined either by echocardiogram or cardiac catheterization. When the interval from the previous study exceeded 2 years, a repeat study was strongly encouraged. Although this has not been accomplished in all cases, postoperative pressure data are now available up to 28 years after valvotomy.

Statistical Analysis

Objective data were calculated as the mean ± SD. Standard actuarial techniques were used to calculate survival, freedom from reoperation, and freedom from symptoms. Pressure differences (LV-Ao) were calculated using paired data for the individual patient and both the range and standard deviations determined.

Results

To subdivide the obviously broad clinical spectrum of congenital aortic stenosis and allow a more meaningful analysis, several parameters were reviewed. The high mortality of AV in infancy and the very low risk in children older than 1 year has long been recognized.[3,9] Further subdivision would seem appropriate because, in general, a 1-day-old infant is at much greater risk than is a 1-month-old infant. We analyzed the symptoms at the time of first operation to determine how this subdivision should be made. An age categorization emerged that seemed to correlate with clinical severity and operative result (Table 1).

Patients were judged to be in severe cardiac failure if two or more factors were present, including clinical shock, need for preoperative blood pressure support, assisted ventilation, or acidosis. We found 25 of 26 patients operated on from 1–14 days of life were in severe cardiac failure. Within this group, 22 of 26 patients were operated on from 1–7 days of age.

Moderate cardiac failure as judged by physical examination, chest x-ray examination, and the need for diuretics and/or digitalization was characteristic of infants operated on from 15 days to 1 year of age. For children 1 year of age and older, 47% were asymptomatic, and if symptoms were present, they were suggestive of later developing problems of aortic stenosis. Analysis, therefore, was made on these three age groups: newborns (1–14 days of age), infants (15 days–1 year of age), and children (over 1 year of age).

Valve morphology was tabulated from the operative reports, and the difficulties of this determination at the time of surgery must be acknowledged. The nomenclature of Edwards[10] was used regarding unicuspid, bicuspid, or tricuspid congenital aortic stenosis. As a reflection of the increased severity of the valve abnormality in the younger patient, 16 of 26 (62%) newborns had a unicuspid valve, whereas 7 of 19 (37%) infants and only 9 of 132 (2%) children had this deformity. A bicuspid valve was the most common type of deformity (76% overall) and the tricuspid valve was relatively rare (6% overall).

Operative survival has continued to increase during the study. No early deaths were recorded in children since 1965 or in infants since 1977. The newborn group, however, had a low (12 of 26 or 46%) overall survival rate, as has been frequently reported.[3,9] Because of this high mortality, further analysis was made to determine the risk factors. Analysis revealed the presence of a hypoplastic left ventricle (HLV) or endocardial fibroelastosis (EFE), and these were associated with an extremely poor prognosis. No patient (0 of 7) with HLV and EFE and only one of six (17%) patients with EFE alone survived the operation. In contrast, with an adequate LV and without EFE, survival was 11 of 13 (85%) patients. The improved recent survival rate may also result in part from using echocardiography exclusively since 1984 to confirm the preoperative clinical diagnosis. No newborns have been subjected to preoperative cardiac catheterization since 1983, which may mean they reach the operating room in better condition.

Both the newborn and infant survivors were burdened with a much higher reoperation rate than the patients over 1 year of age who had AV. For the combined newborn-infant group, 11 reoperations were required during 153 patient years of follow-up for a reoperation/patient year ratio of 0.072. For children, however, the ratio was only 0.013 (22 of 1712). The reoperation rate for the newborn-infant group, therefore, was 5.5 times that for children.

Children and young adults (1–25 years of age) comprised the largest group (132 patients), and a longer fol-

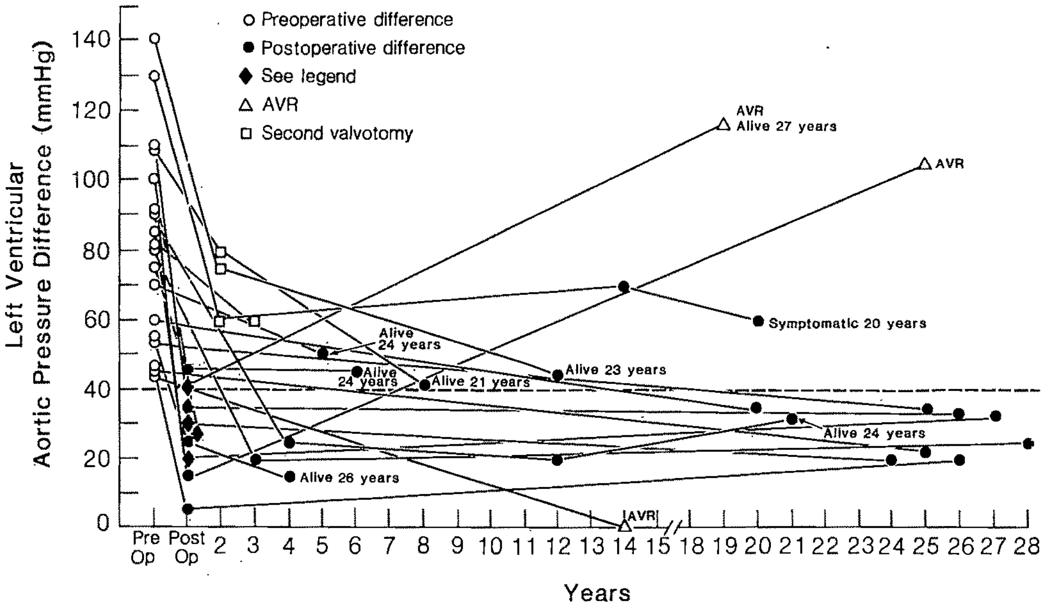

FIG. 1. Paired LV-Ao pressure differences for patients 1 year of age or older undergoing aortic valvotomy. Not all patients had intraoperative measurements and these patients (◆) have a postoperative measurement estimated from follow-up studies. For patients without recent follow-up studies, their survival since valvotomy is indicated.

low-up period was possible. Paired data were used to assess the initial relief of obstruction by AV. The preoperative value was compared with the early postoperative value, usually determined at the time of operation by direct pressure measurement. We subdivided the patients into those with moderate (<75 mmHG) or severe (>75 mmHg) preoperative LV-Ao pressure differences to determine if AV was as effective in relieving severe stenosis as moderate stenosis. Where paired data were available, AV was nearly as effective in releiving severe stenosis (from 103 ± 24 mmHg to 19 ± 17 mmHg, N = 29) as moderate stenosis (from 53 ± 9 mmHg to 13 ± 10 mmHg, N = 18). The mean absolute and percentage reduction, consequently, was greater in the group with severe stenosis.

Preoperative ECGs were obtained in 104 children (79%). Fourteen (13%) had normal ECGs, 55 (53%) had LVH, and 35 (34%) had LVH with strain. Follow-up ECGs done 6.3 years (range: 0.25–27 years) after AV revealed improvement in 52 (58%) patients with preoperative LVH or LVH with strain. In addition, the strain pattern in 28 patients (80%) had resolved after AV, including 12 patients (34%) who had normal ECGs.

Long term follow-up of the LV-Ao pressure differences was possible in 17 patients (Fig. 1). Among these patients, three had an AVR 4, 17, and 25 years after AV and a fourth patient died suddenly at 25 years and, presumably, should also have had a valve replacement. Nine patients, however, 20–28 years after initial AV, are without pressure evidence of a significant increase in the degree of obstruction.

Actuarial analysis provides a prediction of outcome for the patient population. The actuarial survival, freedom from reoperation, and freedom from symptoms are presented in Figure 2. Bacterial endocarditis was uncommon in our series (5 episodes, no deaths) and was not subjected to actuarial analysis.

Because of the many difficulties involved in a study of this type, including late attrition, patients lost to follow-up, and inability to obtain late LV-Ao pressure studies, a compilation of the group is also very informative. The fate of patients (≥1 year of age at operation) who had aortic valvotomy 20 or more years ago are presented in Table 2. The original patient group numbered 58 patients, and four were excluded from analysis. There were three postoperative deaths for technical reasons involving cardiopulmonary bypass early in the series. These patients were among the first operated on for this lesion and there is general agreement that the mortality in this patient group now approaches zero. These patients were, therefore, excluded from analysis. The fourth patient lived far away from the hospital and returned home after discharge. No follow-up information was obtained; therefore, this patient was also excluded.

Table 2 provides what we believe is the fairest analysis of the fate of patients who had an AV at least 20 years previously. The attrition rate was similar to that seen in other studies. The need for aortic valve replacement along with the four patients who had a second AV produced a reoperation rate of 15 of 54 patients (28%). A surprising number of patients are either asymptomatic currently or were so at the time of last contact. The absence of symptoms does not always indicate the absence of significant residual problem; however, nine patients have been restudied and show only a mild (less than 40 mmHg) residual LV-Ao pressure difference. For these nine patients, the mean LV-Ao pressure difference was determined by echocardiography at the time indi-

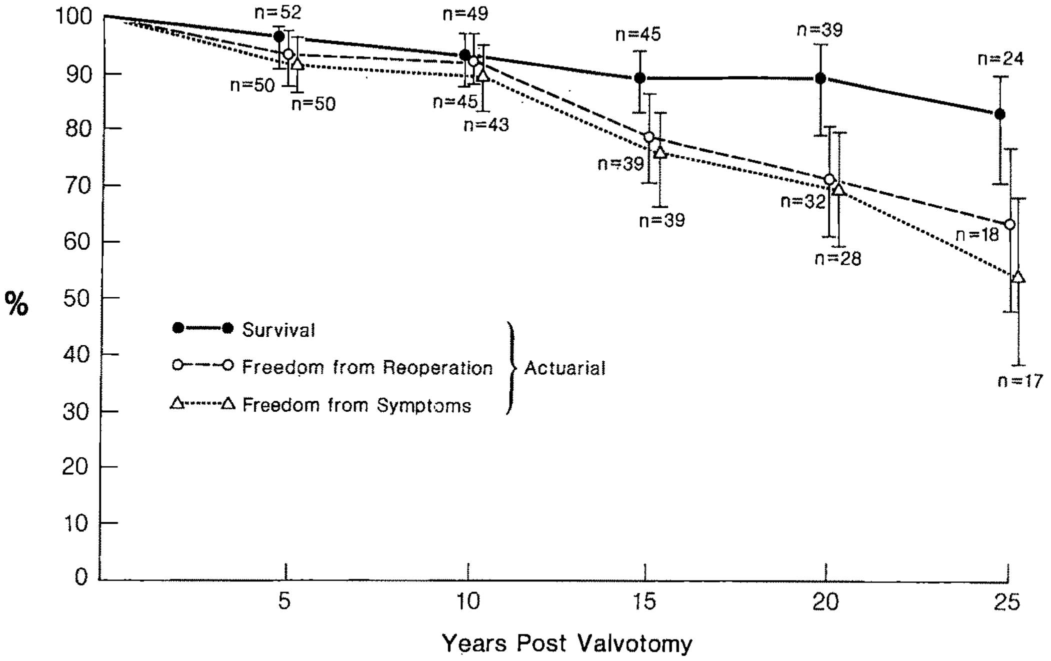

FIG. 2. Actuarial analysis of survival, freedom from reoperation, and freedom from symptoms for children undergoing aortic valvotomy. At each time point, the actuarial figure ± SD is given.

cated after AV: 20 years, 24 mmHg; 21 years, 35 mmHg; 24 years, 20 mmHg; 25 years, 23 mmHg; 25 years, 35 mmHg; 26 years, 35 mmHg; 26 years, 20 mmHg; 27 years, 35 mmHg; and 28 years, 25 mmHg. The remaining 25 asymptomatic patients who comprise 46% of the total group have not been restudied to determine whether or not they have a significant LV-Ao pressure difference. These data show that a significant subset exists that has only mild residual obstruction 20 years or more after AV. Additional patients may be members of this group but cannot be included because either no objective data are available or where, as in one case, the rare occurrence of palpitations prevents inclusion.

One of the important detrimental consequences of AV is the production of significant aortic regurgitation (AR). No preoperative AR was present in 77% of the children, and the effects of AV on AR in the presence or absence of preoperative AR are presented in Tables 3 and 4. For the entire series, 12 AVRs were done primarily for AR, whereas only seven were done primarily for aortic stenosis. Both lesions contributed to the need for valve replacement in two patients and the reason for valve replacement was unknown in an additional two patients for a total of 23 AVRs (23 of 155 patients, 15%).

Discussion

Aortic valvotomy is widely accepted as the initial operative treatment of children with significant congenital aortic stenosis. Our data confirm that AV is effective initially in relieving the obstruction but the degree of valvar deformity encountered at operation is often dismaying. The reported relatively prompt reappearance of significant obstruction with return of symptoms and the need for a second operation confirms the palliative nature of AV.[1-5] Because the valve deformity is not corrected and only the obstruction is relieved to varying degrees, it is reasonable to conclude that AV at best delays valve replacement. The most pessimistic recent prediction has been that all patients will require reoperation within 20 years.[6]

Previous reports, however, have almost exclusively studied patients who have again become symptomatic and would be expected to have significant aortic valve problems. This study represents the first attempted follow-up of all patients, whether symptomatic or asymptomatic after AV. Analysis of this group of patients has allowed several significant conclusions to be drawn.

The first finding was that the operative technique of valvotomy has changed little, if any, over 30 years, whereas survival continues to improve. There were several early deaths, however, due to technical difficulties with cardiopulmonary bypass as would be expected with these pioneering efforts. The results have long been satisfactory, in terms of operative risk, for the group operated on at 1 year of age or older. No early deaths have occurred since 1965 as has been found in other series.[3] Results have also greatly improved in the infant group (15 days–1 year) and there has been no deaths over the past 10 years.

It is universally recognized, however, that the newborn group has had significant operative mortality.[3] The first report of a high survival rate in infants up to 3 months of age at operation appeared recently.[11] Our results also have shown a striking improvement. In the absence of severe accompanying abnormalities of the left ventricle, survival rates of 90% are to be expected even when the operation is done within the first 2 weeks of life. We have had six survivors 1–2 days of age at AV; therefore, very young age and grave condition are not the dominant risk factors. By retrospective analysis, we found the presence of HLV and significant EFE are the major determinants of failure.

Infants over 15 days of age are typically in congestive failure, but do not require pressor and ventilator support in preparation for AV. Nevertheless, the valve abnormality is severe and, as a reflection, the reoperation rate is over five times that of children. The actual reoperation rate for newborns and infants may be even higher because the follow-up period is significantly shorter than for children. There also has not been sufficient length of follow-up to determine if the long-term outlook for the newborn and infant groups differs.

It is the group operated on at 1 year of age or older, however, that has provided the most detailed and surprising long-term information. Our series, particularly the group of patients 20–30 years after AV, not only extends the period of AV follow-up by almost 10 years but, more importantly, contains pressure data on asymptomatic patients (Table 2).

As with other series, we also found a large group of patients with significant residual problems. Eight of the 12 late deaths were clearly related to aortic valve disease, and 28% of patients already have required a second operation. Follow-up of 25–30 years was available for only 18 patients, and it is anticipated that additional reoperations will be necessary as more patients live 30 years after the initial AV. Although a large number of patients have had late problems, the percentage is much less than some predictions.[6] Most series have shown a reoperation rate of 16–41% with a mean follow-up of 7–17 years.[1] Our series shows a similar reoperation rate with a longer follow-up.

TABLE 3. *Appearance of Valvar Regurgitation after Aortic Valvotomy*

	No. of Patients
No preoperative regurgitation	101
Postoperative regurgitation	
1+	13
2+	16
3+	7
4+	4
Total	40 (40%)
Valve replacement required	7 (7%)

On the other hand, our data also reveal a significant percentage of patients who show no discernible return of obstruction with objective follow-up of 5–28 years (Fig. 1 and Table 2). To more accurately assess the course of children after AV, we examined in detail the patients furthest from AV. We attempted to follow up and restudy all surviving patients who had AV 20 or more years ago (Table 2). Although not all patients have been restudied, a large percentage (63%) are currently asymptomatic or were at last contact. For nine patients (17%), recent study has revealed only mild aortic valvar obstruction. An additional nine patients (17%) are asymptomatic and had only mild obstruction at the time of last study. Consequently, a significant proportion of these patients have evidence of relief of obstruction more than 20 years after AV.

A more accurate and extended natural history of AV is provided by this report, but, of course, complete an-

swers await life-long follow-up. It is possible that even the most favorable results will also fail with time because of calcification and other mechanisms of increasing valve damage. Nevertheless, this study demonstrated for the first time that a significant subset of patients receive long-term (greater than 20 years) relief of aortic valvar obstruction. Rather than a continuously progressive and relatively rapid reobstruction, this subset of patients enjoys extended benefit.

In apposition to the favorable group, there was significant attrition to late deaths (11%), a high reoperation rate (28%), and reappearance of symptoms (6%). For these patients, progression of valve dysfunction has been more rapid. One of the important consequences of AV is the production of significant AR. Precise analysis of the role of AV is difficult because our data also suggest that the preoperative incidence of AR increases with age. No discernible preoperative AR was present in patients under 1 year of age and an increasing incidence was observed the older the patient at the initial AV. In addition, when AR is assessed after operation by echocardiographic techniques, the severity may be overestimated. Nevertheless, 12 patients required valve replacement for AR.

We have found that more children require late aortic valve replacement for aortic regurgitation than for the recurrence of obstruction. Other studies have found the reverse to be true.[2,5,6] Although our incidence of valve replacement for regurgitation is not higher than other published results, replacement for recurrent obstruction appears to be less frequent. A possible explanation for the difference in the incidence of valve replacement for recurrent obstruction might be in the operative technique itself. Some authors recommend ending the valvotomy before the annulus and state that residual obstruction is preferable to the production of significant regurgitation.[3,4] In most of the patients in this series, valvotomy was carried to the annulus itself to provide maximum relief of obstruction. Our reoperation data would suggest that somewhat better relief of obstruction was achieved at no increased risk of significant aortic regurgitation. Because of the small numbers involved, these data are not conclusive. At the other end of the spectrum, Ankeny et al. have advocated creating a tricuspid valve whenever possible without an apparent increase in AR.[2] Other authors have recommended against this practice in all but the most favorable circumstances.[12] These divergent views are difficult to reconcile but, at the least, our data suggest that as complete relief of stenosis as is possible by creating a bicuspid valve does not result in a significant increase in AR.

DISCUSSION

DR. HARVEY W. BENDER, JR. (Nashville, Tennessee): I would like to congratulate Dr. Foker on a nice presentation and to thank him and his coauthors for bringing this important long-term data to our attention.

We are currently looking at our experience with critical aortic stenosis in the newborn and would certainly agree with the comments made in the presentation today, in that this is a high-risk group and in our institution nonsurvival was clearly associated with pulmonary hypertension, small left ventricles, the presence of a patent ductus arteriosis at the time of presentation and in younger age at presentation.

With regard to long-term follow-up data, from your reported high incidence of reoperation in the children operated on less than 1 year of age, I would assume that reoperation in those individuals was related to aortic stenosis and that in this particular group of patients a number of the valves are quite dysplastic at the time of initial operation and a high, incidence of restenosis could be anticipated.

From data mentioned in the presentation and that published in the abstract, the fact that aortic regurgitation either increased or appeared as a new finding in approximately 40% of patients after operation would suggest that, the cut at the time of valvotomy was at least in some patients in areas where there was no commissural support. The fact that these individuals then went on to have a relatively low incidence of reoperation over the next three decades would suggest that mild to moderate aortic regurgitation is indeed a well-tolerated lesion.

This then raises the possibility that percutaneous balloon valvuloplasty may have a role in young children as their initial intervention.

DR. GEORGE A. TRUSLER (Toronto, Ontario, Canada): I congratulate the authors on their fine presentation and superb results. Although I realize that the main thrust of the paper has to do with the long-term results of aortic valvotomies in children over 1 month or at least over 1 year of age, I would like to ask the authors about the neonatal group which gives us most trouble. We admit that some infants have a hypoplastic left ventricle and EFE and are definitely inoperable, but there are other children where the left ventricle is borderline in size.

We found that the size of the aortic valve ring was helpful in deciding the adequacy of the left ventricle. We have not had any survivors who have a ring less than 5.5–6 mm in diameter relative to their size. I wonder if the authors would comment on how they judge whether the left ventricle is too small or an aortic valve ring is too small, and do they have any comment on the use of the valve ring size as an indicator?

Finally, is there a place for transventricular valvotomy when the size of the left ventricle and the valve ring is critical?

DR. JOHN E. FOKER (Closing discussion): I would like to thank the discussants for their kind remarks and their willingness to discuss this paper at this late hour.

It is clear that every one has far and away the most difficult time with the newborn group. What we have done is looked back to see what have been the determinants of survival in a retrospective analysis. Despite their critical condition at presentation, survival seems to be governed by whether or not the left ventricle has potential for adequate function. We need more data on what determines if a left ventricle will be inadequate. I realize that it remains a bit subjective, but a hypoplastic left ventricle in the view of our cardiologists is not only small but also consists of a spherical shape, with a longitudinal dimension no greater than the transverse dimension. In terms of size, a transverse dimension of less than 12 mm qualifies as a hypoplastic left ventricle.

Dr. Trusler, we have not used the absolute size of the aortic annulus as a means of determining whether these children will do well or not. I believe that that certainly is an excellent suggestion, and as Dr. Bender stated and all of us know, it is these very young patients who have very severe stenosis and in whom the relief will be incomplete. The annulus will not grow well and they will require repeat operation much sooner.

We have looked carefully at the question of aortic regurgitation in these patients. In most cases we do a more complete valvotomy than often reported in the literature and carry the incision to the annulus as opposed to stopping short of it. It does not appear that our postvalvotomy regurgitation rate is significantly greater than that reported in the literature. Although more than half of the valves that came to replacement in our series were done primarily for regurgitation, the incidence does not appear higher than reported. Recently, regurgitation has been assessed mainly by echocardiography and some degree of regurgitation was found in about 40% of postvalvotomy patients. As you know, echo can spot small degrees of regurgitation and currently it tends to be overcalled. A longer time and more data will be needed until we can judge the significance of the echo findings.

Valvotomy in the newborn is sometimes difficult, as is determining where the commissures are, particularly when they have a unicommissural valve. Nevertheless, we attempt to locate the major area of fusion and divide it and I believe this will provide the best relief with the least regurgitation. With its drawbacks, I believe that valvotomy is still preferable to balloon dilation. Balloon dilation, which was pioneered at Minnesota by Jim Lock, who is now at Boston, may produce a greater frequency of significant regurgitation. I am skeptical that it will prove to be as satisfactory for initial treatment as an operation.

The role of balloon dilation, however, may be in place of a second valvotomy because the commissural incision already has been made. Balloon dilation would not be as likely to tear out into the cusp itself and may be as good as a repeat valvotomy.

Finally, we have had no experience that I am aware of with transventricular valvotomy.

Ileal Pouch–Anal Anastomosis for Chronic Ulcerative Colitis

Long-term Results

JOHN H. PEMBERTON, M.D., KEITH A. KELLY, M.D., ROBERT W. BEART, JR., M.D., ROGER R. DOZOIS, M.D.,
BRUCE G. WOLFF, M.D., and DUANE M. ILSTRUP

The aim of this study was to determine the long-term outcome among 390 patients with ulcerative colitis who underwent ileal J pouch–anal anastomosis and whether patient or operative factors influenced results. The combined operative morbidity rate for the pouch–anal anastomosis and the subsequent closure of the temporary ileostomy was 29% (bowel obstruction, 22%; pelvic sepsis, 5%), with one death due to pulmonary embolus. The probability of a successful outcome at 5 years was 94%. Of the 24 patients who failed (6% of total), 18 did so within 1 year (4%), three during year 2 (1%), three during year 3 (1%), and none thereafter. Stool frequency (7 stools/24 h), the occurrence of pouchitis (14%), and satisfactory daytime continence (94% of patients) remained stable over 4 years after operation, whereas nocturnal fecal spotting decreased (51% of patients to 20%). Women had more spotting than men, whereas patients over 50 years old had more stools per day than those 50 years or younger. In conclusion, ileal pouch–anal anastomosis achieved a reasonable stool frequency and satisfactory continence in patients with ulcerative colitis over the long-term. These results support the ileal pouch–anal anastomosis as a safe, satisfactory alternative to permanent ileostomy.

From the Departments of Surgery and Medical Statistics and Epidemiology, Mayo Medical School, Rochester, Minnesota

SINCE THE REPORT by Martin and colleagues in 1977,[1] ileoanal anastomosis and, more recently, ileal pouch–anal anastomosis has become a popular surgical alternative among some surgeons for patients with chronic ulcerative colitis. The reasons for this popularity are severalfold. The disease is "cured" by the colectomy, proximal proctectomy, and distal endorectal mucosal resection. Reasonable enteric continence is maintained because the anal sphincters are preserved. The reservoir capacity of the distal bowel is restored by incorporating an ileal pouch. The necessity for ileostomy is eliminated.

The impact of such a curative yet continence-preserving operation could be profound; appropriately timed surgical intervention might become more acceptable to patients and their physicians and, in turn, earlier referral for operation, when conditions for a successful outcome are optimal, would be assured. The potential attractions of the ileal pouch–anal anastomosis, however, must be balanced by the fact that the operation is relatively new and the long-term results unknown.

Since our survey of the literature 5 years ago,[2] which detailed the clinical results of 25 series of ileoanal patients during the preceding 48 years, 66 additional reports have been published. None of these past studies, however, has documented the clinical and functional results of the operation in a large group of patients with a single disease, operated on in a single institution, using the same operative technique, with a follow-up over the longer term. Therefore, our aims were to investigate the clinical results of patients operated on only for ulcerative colitis, all of whom had an ileal "J" pouch–anal anastomosis performed at the two Mayo-affiliated hospitals. We also sought to determine whether the functional results improved, deteriorated, or remained stable over time, and whether operative or patient factors influenced results.

Patients and Methods

Between January 1981, and January 1986, 522 patients underwent ileal pouch–anal anastomosis for either ulcerative colitis or familial polyposis coli at Mayo. Four hundred thirty-two patients had the operation per-

formed for ulcerative colitis using the two limb "J" shaped ileal reservoir design similar to that described by Utsunomiya and associates.[3] Three hundred ninety patients have been followed for 6 months to 5 years (mean: 2.3 years) and form the basis of this report.

One half of the patients were men. The mean (±SD) age of the group was 31 ± 9 years. The patients passed a mean (±SD) of 9 ± 5 stools/day before operation. Moreover, 15% of patients had intermittent (2 times/week or less) loss of small amounts of stool (spotting) and 5% were more frequently and grossly incontinent before the operation. One half of the patients (49%) complained of sexual difficulties; 21% stated they did not engage in any sexual activity because of their disease and an additional 28% reported their activity was reduced abnormally. Symptoms of urinary urgency, frequency, and difficulty with the urinary stream were reported by 5% of the patients.

Abdominal colectomy, proximal proctectomy, resection of the distal rectal mucosa, ileal J pouch–anal anastomosis, and construction of a temporary diverting ileostomy comprised the first stage of the operation. The rectal mucosal resection was conducted from below, beginning at the dentate line and including the columns of Morgagni. The dissection proceeded proximally to 1–2 cm above the levator ani muscle complex; the resulting cuff of remaining rectal tunica muscularis was therefore 3–5 cm in length.

The "J" pouch was constructed from two 15–20-cm limbs of terminal ileum that were either stapled[4] or sutured together. The pouch was pulled through the short rectal muscular cuff and anchored circumferentially to the internal sphincter and puborectal muscle. Sutures were then placed such that the sensitive anoderm,[5] which was left *in situ,* was anastomosed to the mucosa of the pouch at the level of the dentate line (Fig. 1).

Three hundred sixty-three patients (92%) had a diverting ileostomy (loop, 95%; Brooke, 5%) established concomitantly, whereas 27 patients did not. The temporary stoma was placed 25–30 cm proximal to the pouch. After tests were later performed to determine the integrity of the anastomosis and the function of the anal sphincters, the ileostomy was closed at a second operation. The stoma was resected and an end-to-end anastomosis constructed in 38%, whereas the remaining patients had simple closure. The midline incision was reentered in 17% of the patients because adhesions prevented the safe closure of the ileostomy through a peristomal incision. The mean (±SD) interval from ileal pouch–anal anastomosis to ileostomy closure was 95 ± 60 days (median: 76 days).

A data file was established for each patient that contained preoperative, postoperative, and follow-up information. Preoperative data included stool frequency, history of incontinence, and whether sexual or urinary problems were present. Postoperative data included mortality, morbidity (pelvic infection, intestinal obstruction, wound infection, and others), use of medication, degree of continence, and stool frequency at dismissal after closure of ileostomy. Follow-up data included stool frequency, degree of continence, stool consistency, whether gas could be discriminated from stool; use of medication; sexual and urinary problems; occurrence of pouchitis; and failure of the operation. Follow-up of all patients was initiated at 6 months after closure of the ileostomy and conducted yearly thereafter by a data clerk. At no time did a surgeon enter data into the file or conduct follow-up surveys.

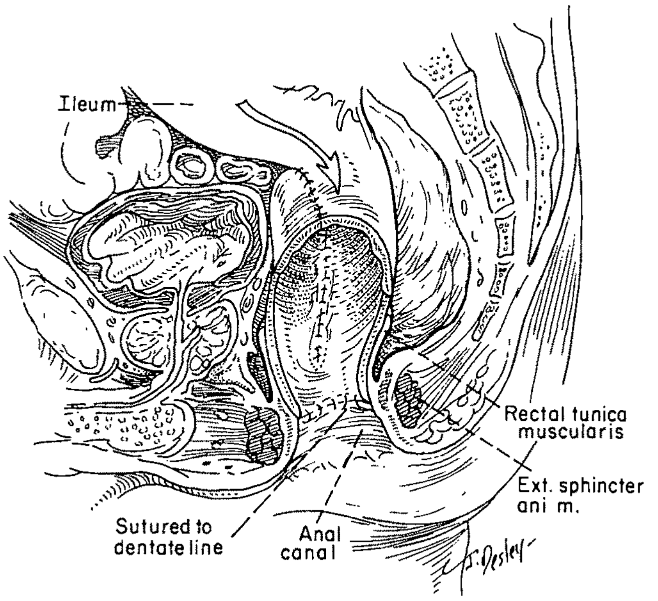

FIG. 1. Diagram of completed ileal "J" pouch anastomosed to the internal sphincter and the anoderm.

Although difficult to define precisely, incontinence during the day and night was recorded as none, spotting (1–2 episodes/week), or frequent and gross (more than 2 episodes/week). Pouchitis was identified as a syndrome manifest as frequent watery, often bloody stools, urgency, incontinence, abdominal cramping, malaise, and fever. An episode of pouchitis was considered to have occurred if these symptoms were present for 2 or more days and was promptly relieved (within 48 hours) by the administration of metronidazole, 250 mg q.i.d. Failure of the operation was defined as establishment of a permanent ileostomy, with or without excision of the pelvic pouch.

Analysis of Data

Proportions were compared in two or more groups with chi-square tests or, where appropriate, with Fisher's

TABLE 1. *Postoperative Morbidity after Ileal Pouch–Anal Anastomosis and after Closure of the Ileostomy in 390 Patients*

exact test. Changes over time of an event within individuals were analyzed with the sign test or with signed-rank tests for ordinal variables. Ordinal variables were compared in two or more groups with rank-sum procedures. The probability of the occurrence of an event in a fixed period was modeled multivariately with the logistic regression model. Comparisons of continuous variables were made with student's t-test or, where appropriate, with rank-sum tests. Survivorship free of pouch excision was estimated by the Kaplan-Meier method. Comparisons of survivorship curves were made with log-rank tests. Survivorship was modeled multivariately with Cox's proportional hazards model.

Results

Clinical Outcome

Early. One of the 390 patients (0.2%) had a massive pulmonary embolus and died 2 weeks after dismissal from the initial operation. Overall, 29% of patients had a postoperative complication after either the initial or the second operation (Table 1). After the first operation, the most frequent complication was small bowel obstruction, which occurred in 51 patients (13%). Twenty of the 51 patients (5% overall) required reoperation, primarily to lyse adhesions, whereas the remainder resolved spontaneously. Pelvic sepsis occurred in 5% of the patients. Pelvic sepsis was manifest clinically as fever, leukocytosis, and localized abdominal tenderness and, on computed tomographic (CT) scan, either as a phlegmon or an obvious abscess. One third of the patients were treated successfully by antibiotic therapy alone, whereas the other two thirds required operative drainage. Abdominal wound infections occurred in 3% of patients. Urinary retention was a transient problem in 7% of patients, but required intermittent catheterization in less than 2%.

After closure of the ileostomy, 9% of patients had a small bowel obstruction for which operative correction was required in 5%. Anastomotic leakage at the site of the closure occurred in 2% and usually required re-establishment of the ileal stoma. All such patients, however, had re-establishment of intestinal continuity subsequently.

Late. The principle late complications were anastomotic stricture and pouchitis. Many patients had a filmy, web-like stricture at the anastomosis at the time of ileostomy closure; these were easily dilated and did not recur. Five per cent of the patients, however, had persistent strictures that required dilation intermittently. Pouchitis occurred at variable times throughout the postoperative period in 14% of patients; the initial onset of symptoms varied from 1 to 2 months after closure of the ileostomy to as long as 5 years after closure. The mean (±SD) interval from operation to occurrence of pouchitis was 16 ± 14 months. Four per cent of patients had multiple episodes. Administration of metronidazole (250 mg q.i.d.) nearly always resulted in a prompt response. Several patients, however, required low-dose metronidazol therapy (250 mg q.d.) continuously to prevent recurrence of the syndrome.

Sexual dysfunction occurred in 11% of the men and 12% of the women overall. Three men (1.5%) were impotent, seven (4%) complained of retrograde ejaculation, and the remainder reported lack of motivation or fatigue as the causes of sexual inactivity. Dyspareunia was the principle sexual complaint in women and occurred in 7%, while 3% of women stated that the fear of leakage of stool inhibited sexual relations.

Functional Outcome

Early. At the time of dismissal from the hospital after closure of the ileostomy, the patients had a mean (±SD) stool frequency of 6 ± 2 stools/day with 1 ± 1 stools at night. Sixty per cent of the patients were always continent, 36% had occasional fecal spotting, and 4% had episodes of gross incontinence. Fifty-five per cent of the patients were placed on antidiarrheal medication, and 56% were dismissed using stool bulking agents.

Late. Nearly all patients had a favorable outcome over the long-term (Fig. 2). Only 24 of the 389 patients (6%) had a permanent ileostomy established and, therefore, failed the operation. The causes of failure, alone or in combination, were recurrent pouchitis, multiple stools, gross nighttime fecal incontinence, and granulomatous ileitis. Of the 24 patients who failed, 18 failed within 1 year (4% of the total patients operated), three

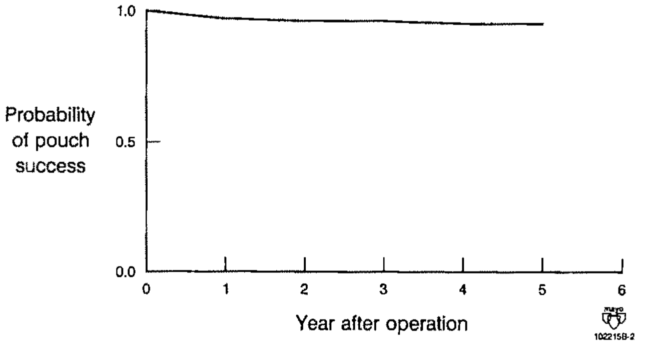

FIG. 2. The probability of successful outcome with functioning pouch against year after operation. No patient failed after 3 years.

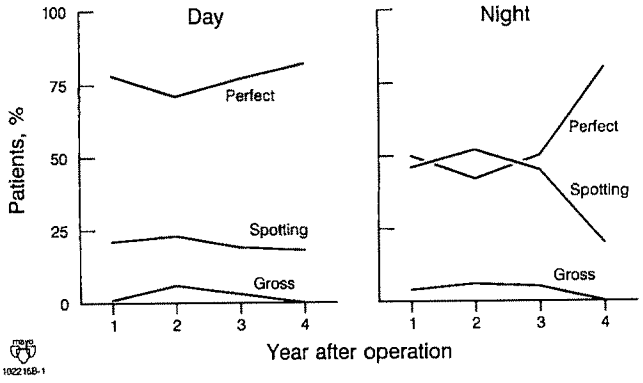

FIG. 3. Daytime and nighttime continence after ileal pouch–anal operation against the years after operation. Perfect = no fecal leakage. Spotting = fecal spotting of underclothes, 3 cm or less in diameter, two times or less per week. Gross = gross fecal incontinence more than two times per week. Data points are connected for illustrative purposes.

during the second year (1%), three during the third year (1%), and none thereafter.

All patients could evacuate the ileal pouch spontaneously; none required intubation. Table 2 and Figure 3 detail the stool frequency, pattern of continence, ability to discriminate gas from stool, and use of medication from 6 months to 5 years after ileal pouch–anal anastomosis. The daytime and nighttime stool frequency as well as the pattern of daytime continence did not change as the patients were followed after operation. In contrast, the incidence of nocturnal incontinence and dependency on medications declined. Moreover, the ability to discriminate gas from stool appeared to improve. By a mean of 2.3 years after operation, 33% of the patients had solid stools, 58% had semiformed stools, and 8% had liquid stools. Whereas the mean ± SD stool frequency was 9 ± 5 stools/day before operation, it had decreased to 6 ± 2 stools/day after operation ($p < 0.001$).

To determine whether clinical and functional results had improved as experience with the operation increased, results in the first 195 patients were compared with those of the second 195 patients (Table 3). Although the overall rate of complications did not differ between the groups, the incidence of some complications, such as the need to reoperate for obstruction after the initial operation and the rate of small bowel obstruction after the second operation, were less among the latter 195 patients. Moreover, urinary problems occurred with less frequency in the more recent patients. Functionally, however, the stool frequency and degree of continence were no different between groups at 1 year. Therefore, although some aspects of perioperative morbidity appeared to improve, the impact of that improvement on later function was nil.

A criticism of these data is that they are based on a comparison between different patient populations, and that factors other than time might have produced these differences. However, a subset of the patients ($N = 93$) had follow-up data available both at 1 year after operation and again at 3 years after operation (Table 4). The findings in this group were nearly identical to those of the larger group. Stool frequency and daytime continence remained stable, whereas nighttime incontinence clearly improved ($p < 0.05$).

Determinants of Outcome

Stool frequency. Older patients had more stools during the day than did younger patients at a mean of 2.3

TABLE 2. *Functional Results of Ileal Pouch-Anal Anastomosis from 6 Months to 5 Years After Operation in 389 Patients*

	Follow-up

TABLE 3. *Comparison of Clinical and Functional Results of Ileal Pouch–Anal Anastomosis Between the First 195 Patients Operated On and the Second 195 Patients*

	Group of Patients		
	First	Second	p
Mean age (years)	31	31	NS
Sex (men:women)	1:1	1:1	NS
Overall complications (% of patients)	31	26	NS
Reoperation for obstruction after IPAA (% of patients)	10	4	<0.02
Obstruction after ileostomy closure (% of patients)	13	3	<0.01
Urinary retention (% of patients)	11	3	<0.04
Mean stool frequency ± SD at 1 year			
Day	6 ± 2	6 ± 3	NS
Night	1 ± 1	1 ± 1	NS
Never incontinent at 1 year (% of patients)			
Day	75	80	NS
Night	47	48	NS

years after operation (≤50 years, 6 ± 3 stools/day; >50 years, 8 ± 4 stools/day; $p = 0.05$). Older patients did not, however, have more stools at night. Stool frequency was not different between men and women. Postoperative small bowel obstruction did not predispose to increased stool frequencies. Not surprisingly, we found that the greater the number of stools, the more frequently patients were incontinent (Table 5). Whether patients had pouchitits or ultimately failed the operation could not be predicted by the preoperative or immediate postoperative stool frequency.

Incontinence. The age of the patients did not correlate with the ability to achieve continence after ileal pouch–anal anastomosis. Patients who had postoperative bowel obstruction were no more likely to be incontinent at follow-up than those who did not. Women, however, had more fecal spotting than did men both during the day and night (day: women, 33%, *vs.* men, 14%, $p < 0.001$; night: women, 56%, *vs.* men, 44%, $p < 0.02$). Although patients who were incontinent before operation were more often incontinent early after closure of the ileostomy ($p < 0.001$), such early incontinence did not influence the ability to achieve continence later.

Yes, gross	10.2 ± 3.9*	3.4 ± 3.0*

* $p < 0.001$ rank-sum test.

Pelvic sepsis. The development of pelvic sepsis was not correlated with age or gender of the patients. Importantly, pelvic sepsis did not appear to affect the degree of early or late continence achieved by the patients nor the early or late stool frequency. Furthermore, patients who had pelvic sepsis were no more likely to fail the operation than those who did not. However, if pelvic sepsis occurred, closure of the ileostomy was delayed appreciably (no sepsis, mean interval between ileal pouch–anal anastomosis and closure = 94 days, *vs.* sepsis = 141 days, $p < 0.002$).

Pouchitis. The occurrence of pouchitis did not correlate with the age or sex of the patients. Patients in whom pouchitis developed were no more likely to have had pelvic sepsis or other postoperative complications than those who did not. Moreover, sexual and urinary problems did not occur with any higher frequency in patients who had episodes of pouchitis.

Sexual and urinary dysfunction. Older patients did not have more sexual problems before operation than younger patients, nor did men have more sexual difficulties before operation than women. However, older patients had more sexual dysfunction after operation than did younger patients (no problem, mean age: 30 years *vs.* problem, mean age: 36 years; $p < 0.001$). In addition, patients with sexual problems tended to have a slightly higher stool frequency than those who did not and were more likely to be incontinent during the day and night. The incidence of both sexual and urinary dysfunction did not differ between men and women. Finally, pelvic sepsis did not predispose patients to later sexual or urinary problems.

Multiple Regression Analysis

Using a Cox proportional hazards model, multivariate analysis of age, occurrence of pelvic sepsis, incontinence (before operation or at dismissal), and preoperative and dismissal stool frequency showed no significant effect on either ultimate failure of the operation, late stool frequency, or development of pouchitis. However, the incidence of incontinence at follow-up was significantly affected by the preoperative stool frequency; the more stools before ileal pouch–anal anastomosis, the more likely patients were to be incontinent after operation (beta weight: 0.13; $p < 0.03$).

Discussion

Patients with chronic ulcerative colitis are "cured" of their colitis by proctocolectomy. Sometimes lesser operations, such as ileorectostomy, are performed in selected patients with good results. Complete removal of *all* diseased colonic mucosa, however, is the ideal central goal of surgery for ulcerative colitis. The ileal pouch–anal anastomosis operation accomplishes this goal, retains the usual transanal anatomic pathway for defecation, and maintains reasonable continence. However, because the operation is new and unproven, its widespread acceptance as a surgical alternative awaits documentation that it is safe, has acceptable morbidity, achieves its promised clinical and functional goals in most patients, and performs predictably over time.

This study found that ileal pouch–anal anastomosis can be performed safely, but that morbidity was high; 29% of patients had a postoperative complication. The major complications were obstruction of the small intestine, pelvic infection, and pouchitis. Overall, 22% of patients had a small bowel obstruction in the immediate postoperative period. Five per cent of these patients required reoperation after the initial procedure, and an additional 5% after closure of the ileostomy. This 10% reoperation rate, although greater than desirable, is similar to the 7–13% incidence of reoperation for obstruction reported after proctocolectomy and permanent ileostomy[6–9] and the 15–20% incidence reported after ileorectostomy.[10,11] Construction of a loop ileostomy might predispose to obstructive complications,[12] such as torsion of the afferent limb about the mesentery of the stoma. We agree with others,[13] however, that episodes of obstruction were related more to postoperative adhesions than to the type of ileostomy used. Our experience with other types of stomas, or with no stoma at all, has shown no clear advantages over the loop configuration. Therefore, we continue to use this stoma in most patients.

Pelvic infections occurred in 5% of the patients. Although Becker and Raymond[13] reported no pelvic sepsis in 100 patients who had ileal pouch–anal anastomosis, Williams and Johnston, summarizing the results of nine series, found the mean rate of pelvic infection to be 18%.[14] Indeed, the rate of pelvic sepsis reported previously from our institution was 11%.[15] The decrease in the rate of pelvic sepsis in the current report is substantial and may reflect improved techniques for excising the rectal mucosa, use of a shorter muscular cuff, and more effective drainage of the pelvic space.[4] We could not find a correlation, however, between the occurrence of pelvic sepsis and impaired function, the development of late complications, or failure of the operation. Nevertheless, the sequelae of pelvic infections can be devastating; pelvic fibrosis, anastomotic stricture with overflow incontinence, persistent sinuses, and fistulae can lead to incapacitating dysfunction and ultimate failure of the operation.

The most vexing medical problem in our patients continued to be pouchitis. This syndrome occurred with no predictability and at various times after operation. The cause of pouchitis is obscure, but resembles the syndrome seen in patients with continent ileostomies. In these patients, bacterial overgrowth in the pouch[16] and in the proximal small intestine[17] has been described. O'Connell et al.[18] documented similar bacterial overgrowth in patients after ileal pouch–anal anastomosis. However, they found no correlation between such overgrowth and a poor result. Because such patients respond to metronidazole, pouchitis is likely caused either directly by bacteria, or by a mucosal response to the presence of bacteria within the pouch. Not all patients with crampy abdominal pain and watery diarrhea after ileal pouch–anal anastomosis, however, have pouchitis. In patients who do not respond rapidly to metronidazole, outflow obstruction from the pouch, secondary to narrowing at the anastomosis, may cause increased stool frequency and incontinence.

In terms of ultimate failure of the operation, the 6% failure rate reported here is similar to that reported by others.[12,14] Because the number of patients who failed was small and the reasons for failure so varied, no single factor was found to correlate significantly with excision of the pouch. It was reassuring, however, that most failures (75%) occurred early, during the first year, and that no patient had a delayed failure (>3 years).

In terms of the number of stools and the degree of continence achieved by the patients, the long-term functional results of ileal pouch–anal anastomosis were relatively stable. We reported earlier that stool frequency improved in the first 6–18 months after operation.[15] The current series shows that after this initial period, the mean daytime and nighttime stool frequency and the level of daytime continence vary little from 1 to 5 years after operation. That the stool frequency did not decline with time may be partially explained by our findings that stool frequency is directly related to the daily amount of stool output and indirectly related to the threshold volume and to the efficiency of pouch emptying.[19] Threshold volume is that volume of enteric content present in the pouch that triggers waves of high pressure. Such pressure waves are uncomfortable, herald the call to stool, and if large enough, may overwhelm the resting and squeeze pressures generated by the anal sphincters. The efficiency of evacuation can be measured using radiolabeled artificial stool and gamma camera imaging.[20]

Because most patients evacuate 50–60% of the threshold volume (which is approximately 45% of the maximum pouch capacity of approximately 320 mL)[19] and because the mean output of stool per day is between 400–800 mL, patients will naturally evacuate four to eight times per day. It follows, therefore, that stool frequency may be decreased by either decreasing the total output per day, increasing the efficiency of emptying, or increasing the threshold volume. Of these, the easiest to achieve would be to increase the threshold volume by increasing the maximum capacity. To this end, several workers have advocated a "W"-shaped pouch, which apparently provides a larger initial volume than that of the "J" design and consequently results in a lower stool frequency and improved continence.[21,22] It will be important, however, to determine if the advantages of such higher capacity are offset by more inefficient emptying of the pouch.

Although daytime continence remained stable after operation, encouragingly, the incidence of occasional fecal spotting at night decreased from 51% at 6 months to 20% at 4 years after operation and gross incontinence decreased from 4% to 0%. The incidence of both, however, rose slightly at 5 years. This finding might be caused by gender sampling bias; whereas the ratio of women to men was 1:1 at each interval from 6 months to 4 years, at 5 years it was 2:1. Overall, we found women had more daytime and nighttime incontinence than men at each follow-up interval, an observation that differs from our earlier report.[15] The reasons for this finding are unknown. However, women generally have more problems with fecal continence than men.[23] Thus, our results may merely reflect a gender predisposition to incontinence that persists after ileal pouch–anal anastomosis.

The single preoperative factor that was found by multivariate analysis to have influenced continence after ileal pouch–anal anastomosis was the preoperative stool frequency. Although no studies have documented the impact of severity of disease on the functional outcome of patients after ileal pouch–anal anastomosis, this aspect of our results suggests that the more decompensated the patient before operation, in terms of stool frequency, the more problems with continence after operation.

We confirmed our earlier report that serious sexual problems were relatively few after ileal pouch–anal anastomosis. However, we found that three men (1.5% of the total at risk) were impotent. After proctocolectomy and permanent ileostomy for inflammatory bowel disease, the rate of impotency ranges between 5% and 12%,[14] whereas after ileorectal anastomosis, no patients have been reported to be impotent. Our results, therefore, fall in between these extremes and are in keeping with the observation of others[12,14] that difficulty with erection after ileal pouch–anal anastomosis can occur. The 4% incidence of retrograde ejaculation is similar to that reported by others[13,14] and is probably caused by disruption of the pelvic sympathetics. Although this incidence is lower than the 9% reported earlier from our institution,[15] the problem remains troublesome.

The major functional disturbance in women continued to be painful intercourse (7%), the incidence of which, although unchanged from our previous report, continues to be substantially lower than the 53% reported after ileorectal anastomosis.[24] In addition, fear of leakage of stool inhibited sexual relations in an additional 3%; indeed, the higher the stool frequency and rate of incontinence, the more likely patients were to have sexual problems. Reassuringly, however, the potentially serious complication of pelvic infection did not appear to predispose patients to later sexual dysfunction.

In summary, ileal pouch–anal anastomosis is a safe operation but carries a significant risk of complications. If a complication such as pelvic sepsis or small bowel obstruction occurs, however, it does not appear to predispose the patient to unacceptable stool frequencies, more incontinence, or an increased chance of failure. The functional parameters of stool frequency and daytime continence, which improved early after operation,[15] reached a plateau by 2 years and remained stable thereafter. Nighttime incontinence and dependency on medications, however, continued to diminish.

Our data show that the best results with ileal pouch–anal anastomosis occur in young, male patients who are not compromised severely before the operation. There is no question, however, that the operation is not perfect, that it is complicated, that some patients are not candidates, that morbidity, particularly obstruction and pouchitis, remain troublesome, that incontinence, although improving with time, affects patients adversely, and that failures continue to occur. Balancing these problems are the observations that the great majority of patients with ileal pouch–anal anastomosis achieve satisfactory enteric continence, maintain willful defecation, retain essentially normal urinary and sexual function, and do not have a stoma. Although no operation can make a patient with chronic ulcerative colitis "normal," of the curative surgical procedures available today, that which comes closest to the norm is ileal pouch–anal anastomosis. Based on these long-term results, ileal pouch–anal anastomosis can be recommended to the majority of patients who require operation for chronic ulcerative colitis.

DISCUSSION

DR. ARNOLD G. CORAN (Ann Arbor, Michigan): I would like to congratulate the authors on an excellent series, probably the largest series of endorectal pullthroughs reported thus far in the literature.

I would also like to thank them for asking me to discuss their paper. I do so with great humility since our experience at the University of Michigan is far less than theirs.

Since 1977, we have done 80 straight endorectal pullthroughs without a reservoir on patients with ulcerative colitis and familial polyposis who range in age from 4 to 48 years. Six of these patients were reconverted to a Brook ileostomy of which three were done because of dissatisfaction with stool frequency.

Daytime continence was achieved in all of these patients within 1 month after closing the temporary ileostomy and nocturnal incontinence occurred in the first year in six of these patients and then finally disappeared.

(Slide) The mean stool frequency in this group declined progressively over the first 3 years to 8 per 24 hours, which compares favorably with the six reported in the current series.

We have also analyzed the stool frequency by age groups above and below 18 years of age and above and below 30 years of age and could find no statistical difference. We also analyzed them by gender and again found no differences. This is consistent with our finding as you will see in the next slide (Slide) that the neorectum progressively dilates over this 3-year period, finally achieving what appears to be a normal rectal reservoir capacity 2–3 years after the endorectal pullthrough.

I would like to ask the authors three questions: how did they specifically obtain their follow-up data on stool frequency and continence? We found that frequent and close follow-up of our patients is necessary to determine what the actual frequency is. For example, we find sometimes that a stool frequency can vary by 100% if, in the case of a college student, they are getting ready for final exams, if there is marital strife, etc. I have seen patients with an average frequency of three stools a day increase their frequency to 10 or 12 under emotional stress.

Second, how exactly was the endorectal dissection done? Was any of it done from above or below or both ways, and in those cases, was the intact mucosal-submucosal tube removed so that they feel assured that all the potential disease has been removed?

Third, were there times when the "J" pouch could not be performed because of significant tension at the anastomosis?

I have occasionally had to do a "J" pouch because the tension at the anastomosis with a straight pullthrough was too great and *vice versa.* I am wondering that the authors did in the cases where there was too much tension.

Essentially, it appears that the results with the straight endorectal pullthrough in our much smaller series and the results with the ileal pouch anal anastomosis are similar in terms of continence, frequency, and complications. I do believe that the straight pullthrough is somewhat easier to do and takes less time. In general, the operation takes us about 3.5–4 hours and we seldom use blood.

Probably, as has been the experience with Hirschsprung's disease, the most important factor in the results of this operation is the experience of the surgeon.

DR. ERIC W. FONKALSRUD (Los Angeles, California): I would like to congratulate Drs. Pemberton, Kelly, and their colleagues at the Mayo Clinic for providing us with a very carefully performed detailed analysis of the long-term excellent results after the endorectal ileal pullthrough procedure with a "J" reservoir for ulcerative colitis excluding the polyposis patients.

Although the operative technique used by each of the five surgeons from their hospital was similar in this series with little variation during the 5-year period of study, the optimal technique for the pullthrough procedure for colitis may not as yet have been determined as was mentioned by Dr. Coran.

In a recent review of 1771 patients compiled from reports from 17 different hospitals using various types of reservoir, the failure rate was remarkably similar in this large group, with 7.2% failures when no reservoir was used, 5.6% with the "J", 6.4% with the "S", and 4.2% with the lateral reservoir. Nonetheless, the incidence of complications varied considerably, and the average follow-up was less than that reported today.

The authors report only slightly better results in the last 195 patients compared with the first 195 in their manuscript; a somewhat different observation than that for most other hospitals where there has been a steep learning curve with improvement in results as modifications in technique have been made. In our experience with 165 patients at the UCLA Medical Center in which the lateral ileal reservoir was used in 141, 6 patients (4%) were failures and returned to permanent ileostomy and 14 (10%) were given a temporary ileostomy, eight of which have subsequently been closed. Over 60% of the reoperations performed in our series were performed in the first 50 patients. Only two of the last 100 patients were failures and the incidence of reoperation was greatly reduced.

The authors indicate essentially stable results after the first year as determined by return to the ileostomy, stool frequency, and daytime continence, but note an increase in pouchitis at 16–18 months after operation. In our experience, pouchitis also was noted in over 35% of our early cases and was heralded by an increase in stool frequency, gas, and diarrhea more than 1 year after operation. In all but one of these patients the reservoir had elongated or enlarged causing reservoir stasis and increase in bacterial growth, poor emptying, and a decrease in absorption of bile acids. Reoperation to shorten the reservoir to a length of 12–15 cm and repair of any outlet obstruction has relieved the symptoms in almost all patients. We now rarely construct a reservoir longer than 12–15 cm at the initial operation. It appears that the initial results are good with a big reservoir but become worse as the reservoir enlarges with time.

My first question to the author is: have they observed a direct relationship between the size of their reservoir and the development of pouchitis in later years since some of their reservoirs were 20 cm or longer? It would appear that the more complex pouches such as the "S" and more recently the "W" may be even more prone to late distention with stasis and may also be technically difficult to revise in subsequent years.

The authors report a somewhat higher incidence of sexual and bladder dysfunction than that reported in many other series. The second question is: do you believe that removing the rectal muscle down to within 3–4 cm of the dentate line is necessary since a slightly longer muscle cuff in males may be a bit safer and not alter the long-term results?

The authors have used the same technical operation for all patients with colitis. It appears that obese patients, those with severe anal sphincter spasm, and children, will do better with a short reservoir of 10–12 cm in length or no reservoir at all as Dr. Coran just mentioned and as was used in 15 of our patients during the past 2 years. Question number three: from your large clinical experience, have you considered tailoring the operation to the anatomic and physiologic differences between your patients? With this in mind should we not refer to this operation as the endorectal ileal pullthrough rather than the pouch procedure?

Again I compliment the authors on their pioneering work in this field and for providing us with an excellent detailed analysis of their long-term results with a very large series of patients.

DR. MALCOLM C. VEIDENHEIMER (Burlington, Massachusetts): It was with great pleasure that I received the manuscript from the Mayo Clinic. The Mayo experience so closely parallels our own that I have little to add in the way of criticism or critique for this paper.

We have now performed this operation for more than 200 patients. We have 23 who had an "S" pouch, and the surgeon in our group who used the "S" pouch abandoned it about 1.5 years ago and joined the others in our group in using the "J" pouch. The "J" pouch, we believe, is more easily fashioned.

I would like to ask the Mayo people who I know have had experience with straight end-on anastomoses and with the "S" pouch, why they have chosen to use the "J" pouch? Has there been something they have learned that has put them into the "J" pouch field?

The results of our work have been very similar to the results reported today from Mayo. We have a 15% incidence of pouchitis. One incidentally was in a patient with familial polyposis whose ileostomy had not yet been closed. I certainly do not have an understanding as to why people get pouchitis.

Pelvic sepsis occurred in 4% of our patients, all of whom had inflammatory bowel disease. The other problems with the pouch, which include leak at the staple line, leak at the ileoanal anastomosis and anal stricturing, resulted in the occurrence of some type of pouch problem in nearly one quarter of our patients. Fortunately, most of these problems have been resolved.

As with the Mayo experience, our patients have been functionally satisfactory. They average five bowel movements in 24 hours and less than one of these movements occurs at night.

The sexual function of our patients has been somewhat better than that reported by Mayo, but on the other hand, we, the doctors, were doing the questioning, and patients go out of their way to try to please the doctor. Perhaps the impartial observer approach used by Mayo Clinic would be a better test of true function.

Twelve per cent of our patients, whether males or females, have ended up having a pregnancy after our operation.

The operation, we believe, is a great operation. It is now the operation of choice. In 1980 and 1981, we did three cases each of those years. This past year we did in excess of 70.

I would like to ask the authors some questions. Despite a large experience with inflammatory bowel disease, we frequently make the mistake of operating on a patient with ulcerative colitis only to find that clinically and histologically they have Crohn's disease. Did they have a problem with this in their patients reported today? And was there a relationship between complications and Crohn's disease?

Is there a difference in the results of your patients reported today with ulcerative colitis from those who you have treated for familial polyposis, especially in respect to complications?

I know that you have removed some pouches, and I wonder in your removal of these, what have you found histologically about regeneration of mucus membrane? Dr. Ravitch a few years ago reported that Dr. Snyder had noted a case of carcinoma in a person having this procedure done. In investigating this further, Dr. Ravitch, I have found that that patient had an anal canal cancer and not an adenocarcinoma. Nevertheless, the risk of regenerating mucosa and its neoplastic tendency is something that needs our constant concern.

DR. HEBER H. NEWSOME, JR. (Richmond, Virginia): Our series is smaller than that of the Mayo Clinic, as is every other series, but an important question has been addressed that I believe is the age factor.

You mentioned that the stool frequency was higher in the age over 50. We are surprised that the soilage rate is not higher because the sphincter, in our experience, tends to relax slightly as age progresses.

The direct question is have you measured sphincter function in older people? Could you give us a little more detailed breakdown of your data in the older population? Is there an age limit that you might use to exclude patients?

DR. KEITH A. KELLY (Closing discussion): First of all, I would like to thank the discussants for their thoughtful comments on our paper.

To start with Dr. Coran's questions, we obtained our follow-up data using an independent observer, a nurse practitioner. She contacted all the patients at periodic intervals and elicited, we believe, a more objective follow-up than we, the patients' physicians, could have done.

The endorectal dissections were all accomplished *via* the perineal approach. None were done *via* the abdominal approach. The anus was dilated slightly, and a small Gelpe retractor was used in the anal canal to provide access to the rectal lumen. We resected the mucosa from the dentate line to a point about 4 or 5 cm proximal to the line. The rectum was transected at that point, and more orad portions removed entirely.

Dr. Coran wonders whether there were times when the "J" pouch could not be used. In answer to that there were. In about 4% of patients, a "J" pouch would not have reached the dentate line. In these patients an "S" pouch was used. Another 2 or 3 cm in length is possible with the "S" pouch.

The disadvantage of the "S" pouch, is that its efferent limb may obstruct outflow from the pouch. Some of our "S" pouch patients have had to use a catheter to empty the pouch. In contrast, all of our patients with a "J" pouch can empty the pouch voluntarily and spontaneously.

Eric Fonkalsrud raises a number of good points. I certainly agree with him that this operation is not perfect as yet. We need to continue to explore methods of improving it. He wonders whether "pouchitis" might be due to a mechanical problem either at the ileal pouch–anal anastomosis or within the pouch itself. Our data suggest, however, that this may not be the case. We have seen terminal ileal inflammation in individuals with a straight ileoanal anastomosis (no pouch) and with no mechanical obstruction. Also, the incidence of pouchitis is much less in patients with familial polyposis, and yet such patients would be subject to the same mechanical problems as those with ulcerative colitis. Lastly, we have studied the emptying of the "J" pouch using scintigraphic techniques, and found that those patients with pouchitis emptied their pouches just as well as patients who had no pouchitis. Therefore, it seems unlikely that pouchitis is solely a mechanical problem. My own hunch is that pouchitis may arise in some way from an interaction between the luminal bacterial or their products and the intestinal wall.

Dr. Fonkalsrud wonders whether we are making our rectal mucosal cuff too short and, therefore, predisposing our patients to sexual problems. We stay close to the rectal wall during the pelvic dissection and away from the sympathetic and parasympathetic nerves innervating the bladder and genitalia. We make our cuff 4–5 cm in length. Perhaps by making it longer, we would preserve sexual function better.

We have not as yet tailored the operation to specific anatomic differences among the patients. Our goal was to create a pouch with a capacity similar to that of the normal rectum, which is around 350–400 mL. The "J" pouch does this quite well. Perhaps as we study our subjects further, we can identify patients in whom special tailoring should be done.

Dr. Veidenheimer asked why we make the "J" pouch rather than other types of pouch. We believe the "J" pouch is the easiest pouch to make. It can be constructed using sutures in about 15 minutes or using staples in about 10 minutes. The "J" pouch has an adequate size. It empties well without the need for a catheter.

He raises the difficult question about what do we do with patients who have Crohn's disease or in whom we cannot clearly rule it out. It is not always easy to separate Crohn's and ulcerative colitis, even when all the data are in. We discuss the possibility of "indeterminant colitis" with the patients before operation, and explore their opinion on what they want to do if their colitis cannot be clearly separated from Crohn's colitis. Nearly all patients want to proceed with the ileal pouch–anal operation and take their chances. That is usually what we end up doing.

We have observed patients with indeterminant colitis who have had the operation. They generally have done well. Thus, it is interesting to speculate as to whether or not we should explore the use of this operation in patients with Crohn's disease limited to the large intestine.

Are there differences between the responses of colitis patients to operation and the responses of patients with familial polyposis? Yes, there are. Fewer postoperative complications occur in familial polyposis patients. For example, no cases of pelvic sepsis occurred in our series of polyposis patients. Interestingly enough, the stool frequency is nearly identical as we observe both groups for several years after operation.

Have we left rectal mucosal behind, that could possibly predispose patients to long-term problems with carcinoma? We have removed the pouches of 24 patients who had a poor result from the operation. We looked at the specimens carefully for evidence of residual rectal mucosa. In about 15% we found small nests of residual rectal mucosa between the ileal pouch and the rectal tunica muscularis. Whether or not these nests would turn into cancer over the long term is unknown. The nests are not exposed to the luminal flora or to luminal carcinogens. Also, the amount of mucosa left is extremely small, making the chance of developing a cancer also small.

A question on age limit was asked. We started out saying nobody over 50 years, but then we had a healthy 55-year-old who asked, "What about me? I would like the operation." Therefore, we operated on this patient, and then we operated on a 60-year-old and then a 62-year-old. Our oldest patient is 64 years old. If older patients have a strong anal sphincter and healthy digestion and absorption, they should be considered. We have not operated on anyone over age 65 as yet.

I would like to close by thanking the members of the Association who have done so much to bring this operation forward; especially, Dr. M. Ravitch, Dr. D. Sabiston, Dr. L. Martin, and Dr. O. Beahrs, who did the first of these operations in adults at the Mayo Clinic.

Delayed Surgery and Bone Marrow Transplantation for Widespread Neuroblastoma

THOMAS J. MOSS, M.D.,*[||] ERIC W. FONKALSRUD, M.D.,† STEPHEN A. FEIG, M.D.,*[||] CARL LENARSKY, M.D.,*[||]
MICHAEL SELCH, M.D.,‡[||] JOHN WELLS, PH.D.,§[||] and ROBERT C. SEEGER, M.D.*[||]

From 1983 to 1986, 21 patients with poor prognosis neuroblastoma were treated with bone marrow transplantation. This regimen included induction chemotherapy, delayed surgical resection, local irradiation, and intensive chemoradiotherapy followed by infusion of allogeneic or autologous marrow. This therapeutic approach resulted in a 57% long-term survival rate (follow-up: 14–48 months), which appears to be approximately three times superior to conventional chemotherapy in a comparable group of children. In addition, complete resection was possible in 11 of 17 patients operated on after induction therapy. Recurrence in the primary site after bone marrow transplantation occurred in only one of 18 evaluable patients. Thus, this approach almost always eradicates primary tumor in patients with neuroblastoma with advanced disease.

From the Departments of Pediatrics, Surgery,† Radiation Oncology,‡ Medicine,§ and Jonsson Comprehensive Cancer Center,[||] UCLA School of Medicine, Los Angeles, California*

THE MAJORITY OF PATIENTS with neuroblastoma are found to have widespread disease at diagnosis. Their survival, if they are older than 1 year, is less than 10% with conventional therapy.[1] Surgery, which is important for the successful outcome of patients with localized disease, has not been shown to improve survival for children with widespread involvement.[2–4] Two factors most likely responsible for these poor results are the inability to perform complete surgical resection because of widespread disease and the inability of chemotherapy to control metastatic disease.

Recent advances in multimodal therapeutic approaches for Stage III and IV neuroblastoma have resulted in some improvement in the survival rate. Complete surgical resection of the primary tumor has been facilitated by delaying the definitive operation until after initial chemotherapy. This approach has been useful in the treatment of other tumors and has been shown to affect survival for patients with neuroblastoma who have a large primary tumor with minimal or no metastases.[5–8] Bone marrow transplantation (BMT) has also been reported to improve clinical outcome of patients with widespread neuroblastoma.[9–11] This regimen includes induction chemotherapy, delayed surgery, interim chemotherapy, and autologous or allogeneic bone marrow transplant.

The purpose of this study was to determine (1) resectability of primary neuroblastoma after induction chemotherapy; (2) sites and frequency of tumor recurrence after multimodal therapy and BMT; and (3) the toxicity and efficacy of BMT.

Materials and Methods

Patients

Neuroblastoma was diagnosed according to standard clinical and pathologic criteria. Stage III disease was defined as primary tumor extending in continuity beyond the midline with or without bilateral regional node disease. Stage IV disease included all patients with remote tumor involving multiple sites such as bone, bone marrow, organs, soft tissues, or lymph nodes. Patients were eligible for study if they were over 1 year old but less than 19 years old at the time of diagnosis and if they had Stage IV or poor prognosis Stage III disease. Patients

Submitted for publication: April 24, 1987.

with poor prognosis Stage III disease included those with elevated serum ferritin (greater than 142 ng/mL),[12] increased N-*myc* oncogene copy number (more than 10 as determined by Southern analysis of DNA from primary tumor),[13] or unfavorable tumor histopathology (Schimada classification).[14]

The transplanted patients were divided into two groups, both of whom initially received conventional chemotherapy. Group 1, which included two patients with Stage III disease and 12 patients with Stage IV disease, received intensive chemotherapy and were transplanted before progressive disease developed. Group 2, which comprised seven patients with Stage IV disease, had already developed progressive disease when they received intensive chemoradiotherapy and transplant. Progressive disease was defined as either regrowth of primary tumor, new bone metastases, or one log increase in bone marrow metastases before pretransplant chemoradiotherapy.

Induction Chemotherapy

All 21 patients who had transplantation received conventional chemotherapy initially. Although induction therapy consisted of many regimens, most patients received combinations of the following drugs: cyclophosphamide, vincristine, dacarbazine, doxorubicin, teniposide, and cisplatin.

Surgery and Local Irradiation

Operation was performed to aid in the initial diagnosis and/or before bone marrow transplantation. If definitive surgery was performed at the time of diagnosis, debulking was attempted. Otherwise the operation was deferred until after induction chemotherapy. Delayed operation was not performed if patients were considered unresectable or if computed tomography and/or magnetic resonance imaging demonstrated complete response of the primary tumor to chemotherapy. After recovery from operation, another course of chemotherapy was administered to prevent tumor recurrence immediately before transplant.

Local irradiation was given to all patients with residual primary or metastatic tumor. For residual primary tumor, radiation was delivered to the tumor bed as outlined by surgical clips. If the tumor was deemed inoperable than total abdominal or thoracic radiation (with shielding of uninvolved lung fields) was administered. For metastatic disease, radiation was delivered to bone lesions that were positive by both technetium scan and skeletal survey. A total dose of 10 Gy was given to abdominal sites and 20 Gy to nonabdominal sites (2 Gy/day on consecutive days).

TABLE 1. *Pretransplant Intensive Chemoradiotherapy Regimen (VAMP-TBI)**

Days Before Transplant	Therapeutic Agent
−9	Cisplatin, 90 mg/m^2 IV
−8	No therapy
−7	Teniposide, 150 mg/m^2 IV, doxorubicin, 45 mg/m^2 IV
−6	L-phenylalanine mustard, 140 mg/m^2 IV
−5	L-phenylalanine mustard, 70 mg/m^2 IV
−4	Teniposide, 150 mg/m^2 IV
−3	TBI, 333 rad, 8–10 rad/min
−2	TBI, 333 rad, 8–10 rad/min
−1	TBI, 333 rad, 8–10 rad/min

* For patients less than 2 years old or weighing less than 12 kg, the doses of agents was changed to cisplatin, 3.5 mg/kg; doxorubicin 1.7 mg/kg; L-phenylalanine mustard, 5.4 and 2.7 mg/kg; teniposide, 5.8 mg/kg.

Pretransplant Intensive Chemoradiotherapy

This consisted of teniposide, doxorubicin, L-phenylalanine mustard, and cisplatin from days −9 to −3 and fractionated total body irradiation (10 Gy total dose, 3.33 Gy/day at a rate of 5–10 cGy/min on days −3, −2, and −1 (day 0 equals day of marrow infusion) (Table 1).

Bone Marrow Harvest

Marrow harvesting was performed on the anterior and posterior iliac crests bilaterally under general anesthesia in the operating room (average time 60 minutes). A cell count of the removed marrow was performed during the procedure to ascertain the volume of marrow to be extracted. Allogeneic recipients received the marrow transplant on the day of harvest. Autologous recipients had their marrow harvest usually at the time of delayed operation for tumor resection (under the same anesthesia), which was 4–8 weeks before transplant. Storage of the marrow was achieved using standard cryopreservation techniques (liquid nitrogen).[15]

Bone Marrow Transplantation

Nine patients received bone marrow from HLA-MLC matched, nonidentical siblings. The average number of nucleated marrow cells infused was 3×10^8/kg. Infusion of marrow was *via* a central venous catheter over 60–90 minutes. These patients were given methotrexate after BMT for prophylaxis of graft *versus* host disease (10 mg/m^2 on days 1, 3, 6, 11, and then weekly to 100 days).

Twelve patients had no histocompatible donor and therefore received autologous marrow. No tumor cells were detectable by immunoperoxidase staining with antineuron-specific enolase serum and antineuroblastoma cell surface monoclonal antibodies (antibodies 390,

HSAN 1.2, 459, and 126-4). The limit of sensitivity of this test is one neuroblastoma cell per 10^5 normal cells when 3×10^5 bone marrow mononuclear cells are evaluated.[16] Preparation of autologous marrow included: equilibrium density centrifugation over Ficoll-Hypaque (seven patients); sedimentation with Hetastarch and filtration through nylon wool (one patient); and sedimentation, filtration, and incubation with monoclonal antibodies (antibodies 390, 459, HSAN 1.2, BA-1, and RB 21-7 or 459, BA-1, and 126-4) and goat antimouse immunoglobulin coated with magnetic beads (four patients, two of whom had marrow involvement at harvest). Autologous recipients were given 1×10^8 nucleated marrow cells per kilogram. The exact methodology for harvesting, cryopreservation, and infusion of bone marrow has been previously reported.[17] No further therapy was given after transplantation.

Recovery phase

Patients were placed in strict isolation once the absolute neutrophil count was below 500/mm^3. All patients received broad-spectrum antibiotics once they had a fever greater than 38 C during strict isolation. Patients were removed from isolation once their absolute neutrophil count reached 500/mm^3 for 3 consecutive days (approximately 4–5 weeks after marrow infusion). Platelet and hemoglobin levels were maintained at 30,000/mm^3 and 12 g/dL, respectively. Platelet transfusions were administered every 2–4 days, and packed red cell transfusions were given every 3–5 days for approximately 6 weeks in accordance with our protocol developed for bone marrow transplantation in leukemic children.

Results

Disease Status at Diagnosis

There were 19 patients with Stage IV disease, 18 of whom had marrow disease. All of these children had involvement of distant bones. There were two patients with Stage III disease, one of whom had occult marrow involvement at the time of bone marrow harvest. The age at diagnosis ranged from 14 months to 13 years with a mean of 4.9 years. The primary tumor sites are listed in Table 2.

Surgery

A summary of operative results is shown in Table 3. For primary tumor at diagnosis, resection was attempted for eight patients: complete resection was achieved for two patients, partial resection with gross tumor remaining was performed for three patients, and biopsy only was done for three patients. Delayed resection of the primary tumor was performed on 17 patients: complete resection was possible for 11 patients, partial resection with less than 50% of gross tumor remaining was performed for two patients, partial resection with greater than 50% gross residual tumor was performed for two patients, and no tumor was found for two patients, both of whom had complete resection of primary tumor at the first operation. Delayed operation was performed within 3 months before BMT for 13 patients. Four patients had surgery at an earlier time (9, 12, 18, and 26 months before BMT), none of whom displayed evidence of primary tumor recurrence at the time of transplant.

Toxicity and Fatal Complications during the First Month after BMT

Toxicity included severe oral mucositis, enteritis, and skin desquamation and was worse among patients receiving allogeneic marrow. Death occurred in five patients during the first month after transplantation. The causes of these early deaths were renal failure (2 patients), hepatic veno-occlusive disease (1 patient), disseminated candidiasis (1 patient), and bacterial sepsis (1 patient). All of these deaths occurred before documented engraftment. Autopsy performed on four patients did not demonstrate residual primary or metastatic tumor.

Late Complications

One patient receiving autologous marrow failed to successfully engraft with platelets and died of cerebral hemorrhage 3 months after BMT. One patient died of bacterial infection 3 months after transplantation. Both patients did not have residual primary or metastatic tumor at autopsy.

Survival/Relapse

Fourteen transplant recipients survived more than 3 months after transplant and were considered to be at risk for relapse. Twelve of these patients had delayed operations, nine of whom had complete resection. Relapse and subsequent death occurred in six patients (between 4 and 10 months after transplant), and only one patient, who had less than 50% resection, had viable primary tumor at autopsy. The remaining eight patients, two of whom did not have delayed surgery, are surviving 14–48 months (median: 32 months) after transplant. Two relapses occurred in these patients (12 and 18 months after transplant) and subsequent remission was achieved in one patient with further chemotherapy, whereas the other patient is alive with stable disease. Summary of the sites of tumor relapse are shown in Table 4.

Transplant before Progressive Disease Versus *after Progressive Disease*

We analyzed disease-free survival for two groups of patients: those transplanted before their disease had progressed and those transplanted afterwards. All disease-free survivors are in the group transplanted before development of progressive disease (Table 5). Overall survival is 57% for patients transplanted before progressive disease *versus* 0% for patients treated after progressive disease ($p < 0.001$). Patients with progressive disease before transplantation were generally older and further from diagnosis. At this time there does not appear to be an advantage of either autologous or allogeneic transplant with respect to disease-free survival (Table 5).

Discussion

Complete resection of the advanced primary neuroblastoma is facilitated by induction chemotherapy. These findings confirm previous reports that surgery performed after initial chemotherapy is more effective for removal of primary tumor.[3,5–8] Combining delayed surgery with local irradiation and intensive chemoradiotherapy is effective for eradicating primary tumor, and appears to result in improved survival.

The overall survival of our patients compares favorably with previous reports of bone marrow transplantation for poor prognosis neuroblastoma. Pritchard et al.[9] reported three long-term disease-free survivors of 12 children who received autologous transplants after high-dose melphalan. August et al.[10] reported four long-term survivors of 10 patients transplanted after multiagent conditioning. Our findings combined with these published results suggest increased efficacy of bone marrow transplantation compared with conventional chemotherapy for widespread neuroblastoma.

The most important factor for determining outcome was the timing of the transplant. All patients transplanted after progression of disease died of toxic complications or tumor relapse. These children had in general received more therapy before transplantation and this may have contributed to poorer tolerance to the intensive chemoradiotherapy conditioning regimen. Also, neoplastic cells resistant to conventional chemotherapy may be less responsive to intensive therapy.

Toxic mortality associated with the intensive chemoradiotherapy (VAMP-TBI) was acceptable for autologous but not for allogeneic marrow transplantation. The increased toxicity after allogeneic transplantation is probably due to methotrexate and graft *versus* host disease. Because of the excessive toxicity in this and a larger series,[11] we do not recommend VAMP-TBI for allogeneic BMT. Less toxic regimens currently are being tested.

Our data indicate that the combination of delayed operation, local irradiation to residual tumor, intensive chemoradiotherapy, and bone marrow transplantation is an effective means of eradicating primary tumor in widespread neuroblastoma. Overall survival appears to be improved compared with conventional chemotherapy.[11] Current studies include the use of aggressive induction chemotherapy, surgical removal of the primary tumor at 16 weeks, intensive chemoradiotherapy and transplantation at 20 weeks, and removal of residual neuroblastoma cells from autologous marrow. These new approaches will hopefully improve the long-term outcome for children with neuroblastoma.

Acknowledgments

We thank Dr. P. Marangos for providing antineuron-specific enolase serum, Dr. R. Reisfeld and Hybritech Inc. for providing monoclonal antibodies 126-4 and BA-1, respectively, and Dr. J. Ugelstad and Sintef for providing magnetic beads.

DISCUSSION

DR. JAY L. GROSFELD (Indianapolis, Indiana): We have been interested in this tumor for many years and reviewed our own cases of neuroblastoma at the James Whitcomb Riley Hospital for Children at Indiana University. We have treated 248 patients and, unfortunately, over 70% of the children have extensive disease at diagnosis.

Unlike Wilm's tumor where chemotherapy can actually achieve a cure, there has been no clear objective evidence to suggest that chemotherapy cures patients with neuroblastoma. Cellular kinetic studies indicate that the vast majority of the neuroblastoma cells are in a resting phase and, therefore, are not amenable to tumor kill with convention chemotherapy and irradiation. Therefore, the authors have taken a more intensive chemoradiation approach in attempts to cure metastatic disease.

Resection of a primary cancer in patients with metastases has always been somewhat controversial. In support of the author's observations, however, we have noted that none of our Stage IV (metastatic) patients have ever survived if the primary tumor was not resected. Residual disease is usually found at delayed primary or second-look laparotomy despite chemotherapy.

We have had a number of Stage IV patients who responded to chemotherapy, had extended survival (5–6 years), and then late recurrence with subsequent death. The relatively small number of patients in this study leads us to question the authors' conclusions that 50% of these high-risk patients with metastases will survive.

The data presented document an increase in the length of survival, but is the actual cure rate being changed?

Unfortunately, our experience with bone marrow transplantation for neuroblastoma has not been as encouraging as the authors'. On the other hand, most of our patients have been transplanted because of relapse or progressive disease. The important point that our colleagues have told us is that you cannot wait for progression of disease to occur if you expect to attempt to cure the patient with a bone marrow transplant.

In reviewing their data, an unfortunate fact is that seven of the 21 patients (33% mortality rate) died as a result of treatment.

Of the remaining 14 patients, six relapsed soon after intense therapy, and of the eight late survivors, there were another two cases of relapse. Invariably, patients who relapse usually die. One might anticipate more relapses with time.

The validity of the statistical data is questionable because of the small number of patients and the relatively short length of follow-up.

I have some questions for the authors. Did relapse occur in the two patients with tumor demonstrated in the autologous bone marrow? Was the technique of using monoclonal antibodies successful in purging the marrow? In your selection of Stage III patients, is site an important factor? For instance, should Stage III patients with primary tumors in the neck or pelvis be grouped in the same fashion as patients with primary tumors at the celiac axis? At our institution, all Stage III neck and pelvic patients have survived with conventional therapy. I would hesitate to subject those patients to potentially lethal chemoradiation and bone marrow transplantation. Has DNA aneuploidy or diploidy been an important flow cytometry observation in your patients? Is this used in the selection process?

Only time will tell if this new intense treatment is just another frustrating attempt to chase metastatic cancer or whether this will improve the cure rate of this troublesome, pediatric tumor. Cure for metastatic neuroblastoma is a goal that thus far has been most elusive.

DR. JAMES A. O'NEILL, JR. (Philadelphia, Pennsylvania): I congratulate Drs. Moss, Fonkalsrud, and their coauthors for bringing this to the attention of a surgical audience as well as for their results. Dr. Moss is a pediatric oncologist, and this sort of paper is not frequently presented at surgical meetings; yet, it is extremely valuable that we hear about it.

This study addresses a significant problem in neuroblastoma patients since most have Stage IV or what we would call metastatic disease. You should know that their study was one of the first, if not the first, to use this particular regimen described.

My own comments are based on 38 patients with neuroblastoma treated at the Children's Hospital of Philadelphia in virtually the same fashion except for minor variations in chemotherapy approach. The results have been tabulated as of November 1986.

Our results would generally support your conclusion as you looked at your primary goals, that resectability of primary disease can be enhanced with this regimen, and that when relapse occurs, it is usually elsewhere other than the primary site.

You also have shown the effects of toxicity of this intensive regimen in patients who have bone marrow transplantation. However, I am not sure that either you or we have proven the efficacy of bone marrow transplantation. If we take your figures, your overall survival at 3 years is 8 of 21 patients or 38%. If we take our figures at 3 years, it is 15 of 38 patients, or 39%, which is almost identical. However, if one considers our patients who are alive with disease and consider them nonsurvivors, our estimation is that our long-term survival rate is going to be in the range of 25%. Would you comment on that particular point?

Second, as you did, we had a number of early deaths due to toxicity, and many of these were infectious in nature. It is here that we must improve our results, and perhaps this is where we have some hope.

In this respect our results have been so poor with allografts because of graft-versus-host disease and the methotrexate necessary to accomplish allografting in these patients, we have virtually abandoned this approach in favor of autogenous grafting and purging harvested marrow of tumor cells with monoclonal antibodies and then magnetic immunobeads that you have heard about. I might add parenthetically we have one well-functioning syngeneic graft.

Regarding the matter of these allograft problems, although I believe that you have pointed out something very valuable regarding the futility of bone marrow transplantation in patients with neuroblastoma and progressive disease, I have some concern about the figures, in that as one looks at the allograft–autograft component of each group, you have 4 of 14 patients who were transplanted before progressive disease with allografts and 5 of 7 in the group that were transplanted with progressive disease. Obviously, I am concerned that this factor of a greater number of allografts in the progressive disease group could well have biased your conclusion about the futility of transplanting patients with progressive disease.

Did you find a difference in results in patients with favorable *versus* unfavorable Shimada histology? Our own results would tell us that histology is the most important determinant of survival in patients with localized disease, that is, Stages I through III.

Finally, did patients who had complete resection of the primary tumor fare better than those who did not? In other words, did surgery make a difference? It seems to in localized neuroblastoma patients.

I believe this is an extremely important paper of a pioneering nature, and particularly for surgeons, with excellent data and results.

Dr. Paul S. Russell (Boston, Massachusetts): My experience with this is rather antiquated because back in the late 1950s we became interested in autologous bone marrow transplantation for acute lymphatic leukemia in children. Since that time, the chemotherapeutic regimens have improved greatly.

We wrote a paper about our approach in the *New England Journal of Medicine*, in 1959.[1] What we did was to harvest the marrow from patients who had drug-induced remission at a time when this marrow and peripheral blood was in a remarkable state of morphological normality. The bone marrow was then frozen and kept until later relapse of the disease. Patients were then given whole body irradiation in the lethal range and the bone marrow was reinfused. We had some nice remissions. We had a short series of patients with leukemia, I believe about half a dozen, but we also had one additional patient who had a neuroblastoma with dissemination.

My questions relate to the source of the marrow. If one uses autologous marrow it must be purged of the malignant cells. If the marrow comes from an allogeneic source, unless you are fortunate enough to have an HLA identical donor, it must be purged of potential graft-versus-host producing "T" lymphocytes by another form of purging. How good are you at purging the marrow of malignant cells from autologous donors? If this can be done reliably it would provide a treatment that could be used for a large number of patients, whereas with allogeneic marrow, you will encounter the dangers of immunosuppression and graft-versus-host disease.

It looks to me as if the way to go is to focus on trying to get rid of any malignant cells that are in the autologous marrow, perhaps saving it in the frozen state.

Dr. Stanley R. Friesen (Kansas City, Kansas): I noticed on your slide regarding prognosis that you had neurone-specific-enolase as a prognostic factor. I have considered that enzyme as a characteristic diagnostic feature of these kinds of tumors. I did not realize that it had a prognostic influence. Is the neurone-specific-enolase that you describe that which is present in the tumor or that which is circulating in the plasma?

Dr. Thomas J. Moss (Closing discussion): I would like to thank Drs. Grosfeld, O'Neill, Russell, and Friesen for their enlightening comments and questions.

Dr. Grosfeld, in terms of the late relapses, we share your concern since this may occur with neuroblastoma. As you indicate, our longest survival is 4 years, the longest survival reported thus far is 5 years. The international experience with bone marrow transplant and relapse is that the latest relapse thus far reported is 22 months after transplant. This does not mean that relapse will not occur within 3 or 4 years after transplant. We have to be guarded in our conclusions because of this, and we are evaluating this issue closely.

In terms of relapse in the autologous marrow, there was one relapse in a patient who had tumor cells removed at harvest. That patient relapsed first in bone, and then in bone marrow.

In the autologous marrows that were separated with Ficol Hypaque alone in which we did not remove tumor cells, there was relapse in approximately two thirds of those patients; across the country, it appears that two thirds of those patients had relapse in bone marrow first. From this experience, our concern was that we may be reinfusing tumor cells into the patient at transplant, and we therefore started our purging technique.

In terms of Stage III patients, we only selected two patients thus far. They were not selected by primary tumor site but by prognostic factors. These factors included increased serum ferritin, increased N-*myc* oncogene copy number and poor prognosis histology (Shimada classification). These patients have a survival rate of less than 20% with conventional therapy.

One of our stage III patients did have amplification of the N-*myc* oncogene; he was recently transplanted and is now alive at 14 months.

When the study was first started, the determination of N-*myc* oncogene was not performed. We are currently doing it in all patients. About one third of our patients have amplification of the N-*myc* oncogene, and we hope not to select out for that group because we want to see if our therapy can make a difference. It is too early to tell at this time.

Dr. O'Neill, you raise an important point about overall survival. Progressive disease is an important variable. The chemotherapy group was a nonrandomized but concurrent control group; we tried to make the control group as comparable as possible with the transplant group. The chemotherapy group chosen were those patients who had not developed progressive disease at 7 months after diagnosis. We picked that point because our transplant patients, who were transplanted before progressive disease, were on the average transplanted 7 months after diagnosis, therefore we hoped to remove that one variable. Unfortunately, with retrospective analysis one also has to be cautious in the judgments that one makes. It does seem that we can eradicate primary tumor with this regimen. I view this as a consolidation therapy.

The next step is defining the maintenance therapy after bone marrow transplant. We are exploring the use of retinoic acid, which is a differentiating agent. It has minimal toxicity and may differentiate those last few neuroblastoma cells that are present after transplant. This is a strange tumor that regresses sometimes without any reason; can retinoic acid be one way to induce a lasting remission? Retinoic acid does cause decreased expression of the N-*myc* oncogene, and we have studies to prove this. We are hopeful that this type of maintenance therapy, which has little toxicity, will prove useful.

Another possibility is treatment with monoclonal antibodies. There is an antibody to the GD_2 ganglioside that is relatively specific for neuroblastoma. It is currently being evaluated for therapy of patients who have developed progressive disease. It does have some efficacy, but, will this play a part in the maintenance therapy after bone marrow transplant? We are currently initiating studies to look at this particular treatment.

In terms of allogeneic toxicity, this is a valid and important point. We have recently become aware of this problem; approximately 50% of allogeneic transplants have a toxic death. Consequently, the Children's Cancer Study Group has decreased the methotrexate dose given to prevent graft-versus-host disease, and we also are altering the chemoradiotherapy regimen to make it less intense to see if this will reduce toxicity. We hope these changes will not alter tumor relapse, therefore we are wary of doing allogeneic transplants at this time.

In terms of autologous transplants, our toxicity is running about 10%, and we hope that if we can reduce relapse, autologous transplant may be the therapy of choice in the future. Conversely, allogeneic transplants do seem to have less relapse, but there are too few patients to even make a meaningful comment. In terms of overall survival, including those from other institutions in the country, this does seem to be holding as a general trend, but we will be cautious in our determination of what the ultimate outcome is.

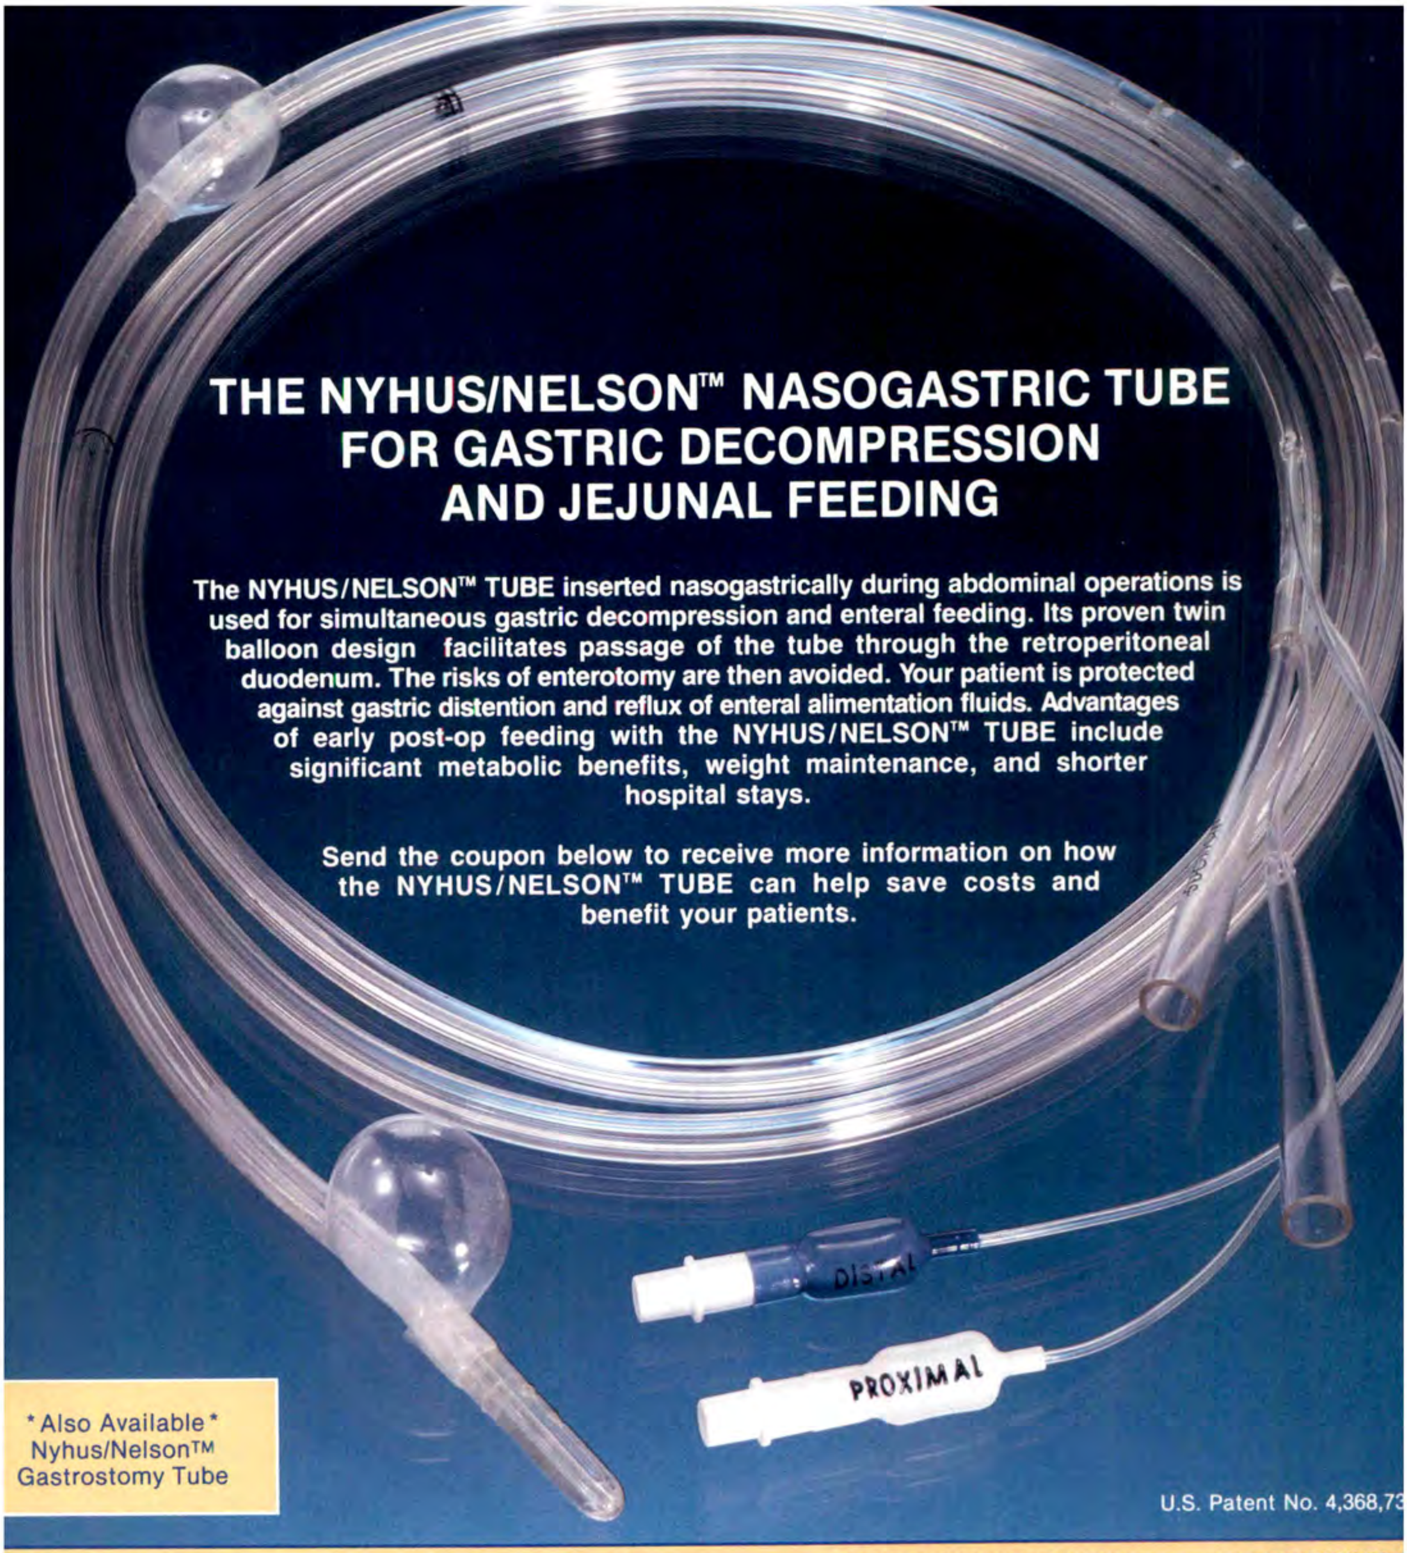
The vast majority of our patients had unfavorable histology, and we were unable to evaluate this factor compared with favorable.

Does surgery make a difference? There are too few patients to tell. Of the survivors, two had partial resection; the rest had complete resection. I believe surgery plays an important role for Stage III disease. This is one important point of the study, that delayed surgery does facilitate complete resection. It does point out that we are having problems in controlling bone and bone marrow metastases.

Dr. Russell, in terms of autologous bone marrow transplant and removal of the tumor cells we have developed an immunohistologic method to detect neuroblastoma cells in bone marrow. Of the five patients who we treated, two had demonstrable tumor in the harvested bone marrow. We can detect one tumor cell among 100,000 normal marrow cells. Since we infuse 10^9 cells per patient at transplant, we could infuse 10,000 tumor cells and not even know the difference. That is why we instituted the tumor purging. We can remove four logs of tumor cells experimentally with purging. We have done approximately 22 autologous purged marrows at this point, and we are able to clean out bone marrow consistently that has under 1% of tumor cells, although that may be a little optimistic in the sense that we have probably gone below the sensitivity of our testing. Significantly, of the 22 harvests, approximately 17 had tumor cells detected, which would have been ineligible for our previous study. We can now purge and remove these cells to allow these patients to be transplanted.

How many tumor cells will cause recurrence of tumor if infused? No one knows the answer. That is why maintenance therapy will be so important.

Finally, Dr. Friesen, neuron-specific-enolase (NSE) is of prognostic value for patients with Stage IV disease under one year of age, and it is an independent variable.



THE NYHUS/NELSON™ NASOGASTRIC TUBE FOR GASTRIC DECOMPRESSION AND JEJUNAL FEEDING

The NYHUS/NELSON™ TUBE inserted nasogastrically during abdominal operations is used for simultaneous gastric decompression and enteral feeding. Its proven twin balloon design facilitates passage of the tube through the retroperitoneal duodenum. The risks of enterotomy are then avoided. Your patient is protected against gastric distention and reflux of enteral alimentation fluids. Advantages of early post-op feeding with the NYHUS/NELSON™ TUBE include significant metabolic benefits, weight maintenance, and shorter hospital stays.

Send the coupon below to receive more information on how the NYHUS/NELSON™ TUBE can help save costs and benefit your patients.

Also Available
Nyhus/Nelson™
Gastrostomy Tube

U.S. Patent No. 4,368,73

ce the tip of the tube has been advanced he second portion of the duodenum, the ximal balloon, which is still in the stomach, be grasped and pushed through the orus. As the proximal balloon approaches second portion of the duodenum the al balloon can be grasped at the ligament reitz and the tip of the tube advanced into jejunum.

The only parenteral

q12h dosage means cost-effectiveness

- ☐ Cost per day less than Tagamet* Injection q6h**
- ☐ May result in fewer I.V. set-up charges, less nursing time, less pharmacy time, lower administrative costs

Efficacy

Prompt, persistent, predictable pH control for many patients

Tolerability

Excellent tolerability profile—even in critical care patients

Dosing intervals may need to be prolonged or dosage reduced in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine. PEPCID® I.V. (Famotidine, MSD) is contraindicated in patients who are hypersensitive to any component of this medication. The adverse reactions reported for PEPCID Tablets may also occur with PEPCID I.V. In addition, transient irritation at the injection site has been observed with PEPCID I.V.

H_2 antagonist with q12h dosage

Indicated in some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.

The recommended dosage is 20 mg q12h.

INJECTION, 20 mg/2 mL

q12h **Pepcid® IV**

(Famotidine|MSD)

For a Brief Summary of Prescribing Information, please see the following page.

TABLETS
Pepcid®
(Famotidine|MSD)
20 mg and 40 mg

ORAL SUSPENSION
Pepcid®
(Famotidine for Oral Suspension|MSD)
40 mg per 5 mL

INJECTION
Pepcid® IV
(Famotidine|MSD)
20 mg per 2 mL

Contraindications: Hypersensitivity to any component.

Precautions: ***General:*** Symptomatic response to therapy does not preclude the presence of gastric malignancy.

Patients with Severe Renal Insufficiency: Longer intervals between doses or lower doses may be needed in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine (see Clinical Pharmacology and Dosage and Administration sections of Prescribing Information).

Information for Patients: The oral suspension should be shaken vigorously for 5-10 seconds prior to each use, and unused constituted oral suspension should be discarded after 30 days.

Drug Interactions: No drug interactions have been identified. Compounds tested in man include warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In rats and mice given oral doses up to approximately 2500 times the recommended human dose for active duodenal ulcer, there was no evidence of carcinogenic potential, no evidence of a mutagenic effect, and fertility and reproductive performance were not affected.

Pregnancy: *Pregnancy Category B*—There are no adequate or well-controlled studies in pregnant women. Use during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether famotidine is secreted into human milk; however, it is secreted into the milk of lactating rats. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: No dosage adjustment is required based on age but may be necessary in severe renal impairment (see Clinical Pharmacology section of Prescribing Information).

Adverse Reactions: The adverse reactions listed below have been reported during domestic and international clinical trials in approximately 2500 patients. In the placebo-controlled clinical trials, the incidence of adverse experiences with PEPCID Tablets, 40 mg at bedtime, was similar to that with placebo.

Incidence Greater than 1%: The following adverse reactions have been reported to occur in more than 1% of patients on therapy with PEPCID in controlled clinical trials and may be causally related to the drug: headache (4.7%), dizziness (1.3%), constipation (1.2%), and diarrhea (1.7%).

Causal Relationship Unknown: The following other adverse reactions have been reported in clinical trials. While a causal relationship could not be established for these infrequently reported events, causality cannot be excluded. *Body as a Whole*—Fever, asthenia, fatigue. *Cardiovascular*—Palpitations. *Gastrointestinal*—Nausea, vomiting, abdominal discomfort, anorexia, dry mouth, liver enzyme abnormalities. *Hematologic*—Thrombocytopenia. *Hypersensitivity*—Orbital edema, conjunctival injection. *Musculoskeletal*—Musculoskeletal pain, arthralgia. *Nervous System/Psychiatric*—Paresthesias; grand mal seizures (single report); psychic disturbances including depression, anxiety, decreased libido, hallucinations (single report); insomnia; somnolence. *Respiratory*—Bronchospasm. *Skin*—Alopecia, acne, pruritus, rash, dry skin, flushing. *Special Senses*—Tinnitus, taste disorder.

The adverse reactions reported for PEPCID Tablets may also occur with PEPCID Oral Suspension or PEPCID I.V.; in addition, transient irritation at the injection site has been observed with PEPCID I.V.

Management of Overdosage: There is no experience to date with deliberate overdosage. Up to 640 mg/day have been given to patients with pathological hypersecretory conditions with no serious adverse effects. In the event of overdosage, treatment should be symptomatic and supportive. Unabsorbed material should be removed from the gastrointestinal tract, the patient should be monitored, and supportive therapy should be employed.

Dosage and Administration: ***Duodenal Ulcer:*** The recommended adult oral dosage for active duodenal ulcer is 40 mg h.s.; most patients heal within 4 weeks, and it is rarely necessary to use the full dosage for longer than 6 to 8 weeks. A regimen of 20 mg b.i.d. is also effective. For maintenance therapy, the recommended oral dosage is 20 mg h.s.

Pathological Hypersecretory Conditions (e.g., Zollinger-Ellison Syndrome, Multiple Endocrine Adenomas): The dosage varies with the individual patient; the recommended adult oral starting dosage is 20 mg q6h, but some patients may require a higher starting dosage. Dosages should be adjusted to individual patient needs and continued as long as clinically indicated; up to 160 mg q6h have been administered to some patients with severe Zollinger-Ellison syndrome.

Oral Suspension: The Oral Suspension may be substituted for Tablets for those patients who cannot swallow tablets.

Directions for Preparing PEPCID Oral Suspension: Prepare suspension at time of dispensing. Slowly add 46 mL Purified Water. Shake vigorously for 5-10 seconds immediately after adding the water and immediately before use.

Stability of PEPCID Oral Suspension: Unused constituted oral suspension should be discarded after 30 days.

Intravenous Administration: In some hospitalized patients with pathological hypersecretory conditions or intractable ulcers, or in patients who are unable to take oral medication, the recommended intravenous dosage is 20 mg q12h. For preparation of solutions for injection or infusion and for compatible diluents, please see Prescribing Information. Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Concomitant Use of Antacids: Antacids may be given concomitantly if needed.

Dosage Adjustment for Patients with Severe Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance less than 10 mL/min), the elimination half-life of famotidine may exceed 20 hours, reaching approximately 24 hours in anuric patients. Although no relationship of adverse effects to high plasma levels has been established, to avoid excess accumulation of the drug, the dosage may be reduced to 20 mg h.s. or the dosing interval may be prolonged to 36 to 48 hours as indicated by the patient's clinical response.

How Supplied: Tablets, containing 20 mg or 40 mg famotidine, with hydroxypropyl cellulose, hydroxypropyl methylcellulose, iron oxides, magnesium stearate, microcrystalline cellulose, starch, talc, and titanium dioxide as inactive ingredients, in bottles of 30 and unit-dose packages of 100; Oral Suspension, containing per 5 mL after constitution with 46 mL Purified Water, 40 mg famotidine, with citric acid, flavors, microcrystalline cellulose and carboxymethylcellulose sodium, sucrose, and xanthan gum as inactive ingredients, and sodium benzoate 0.1%, sodium methylparaben 0.1%, and sodium propylparaben 0.02% added as preservatives, in bottles of 400 mg famotidine for constitution; Solution for intravenous injection, containing 10 mg famotidine per mL, with L-aspartic acid 4 mg, mannitol 20 mg, and water for injection q.s. 1 mL as inactive ingredients, and benzyl alcohol 0.9% added as preservative to the multidose vial, as 10x2-mL single-dose vials and as 4-mL vials.

Upper Extremity Ischemia Caused by Small Artery Disease

JOSEPH L. MILLS, M.D.,* ERIC I. FRIEDMAN, M.D.,† LLOYD M. TAYLOR, JR., M.D.,‡ and JOHN M. PORTER, M.D.§

From the Division of Vascular Surgery, Oregon Health Sciences University, Portland, Oregon

One hundred patients with ischemic finger ulceration had detailed prospective evaluation to determine the incidence of associated diseases, response to treatment, and natural history of the condition. A potentially serious associated disease was detected in each patient including autoimmune disease in 54%, Buerger's disease in 9%, arteriosclerosis obliterans in 9%, hypersensitivity angiitis in 22%, and miscellaneous diseases in 6%. Conservative treatment with soap and water scrubs, antibiotics, and local resection/debridement resulted in long-term healing without recurrence in 88% of patients. Most recurrences occurred in patients with autoimmune disease, usually scleroderma or CRST.

A MAJORITY OF PATIENTS with peripheral ischemia suffer from atherosclerotic occlusive disease of the large arteries supplying the lower extremity. It has been estimated that only 5% of patients with limb ischemia have symptomatic involvement of the upper extremity.[1] Ischemic digital ulceration or gangrene may develop in patients with severe upper extremity ischemia. Although large artery atherosclerosis is the most common cause of lower extremity ischemia, small artery occlusive disease of the palmar and digital arteries of diverse causes is a frequent cause of upper extremity ischemia.[2]

Upper extremity ischemia caused by small artery occlusive disease occurs with sufficient infrequency that little has been published describing its evaluation and treatment. The underlying small artery etiology in a patient with ischemic digital ulceration is often considered only after extensive evaluation fails to reveal proximal arterial obstruction or a cardiac or proximal arterial embolic source. Similarly, optimal treatment of upper extremity ischemia resulting from small artery disease has not been defined. Multiple investigators, usually citing anecdotal information derived from personal treatment of a small group of patients, have reported benefit from various forms of treatment, including vasodilators,[3,4] prostaglandins,[5] antiplatelet therapy,[6] and thoracic sympathectomy.[7] None of these is of proven benefit.

In the past 15 years, over 900 patients with vasospastic or occlusive small artery disease of the upper extremity have been prospectively evaluated and treated in the Clinical Research Center at The Oregon Health Sciences University as part of an ongoing research protocol conducted by the Division of Vascular Surgery. One hundred of these patients had upper extremity ischemia of sufficient severity that they presented with ischemic digital ulceration or gangrene. The prospectively accumulated data pertaining to this subgroup of patients have been reviewed to determine the incidence and distribution of underlying associated diseases, the tests that reliably diagnose associated diseases, the forms of treatment most likely to result in a favorable clinical response, and the natural history of the condition. The results of the review form the basis for this report.

Methods

The records of over 900 patients with small artery disease who have been prospectively evaluated, treated,

and enrolled in an ongoing investigational protocol in the Clinical Research Center (CRC) over the past 15 years were reviewed. A subset of 100 patients was identified who had at least one episode characterized by the occurrence of ischemic digital ulceration with full thickness skin loss or frank gangrene with extensive tissue necrosis. All patients had small artery obstruction documented objectively by digital plethysmography (obtained in 100% of patients) and magnification hand arteriography (performed in 75%).

Each patient was admitted to the CRC and had a detailed evaluation, which is outlined in Table 1. Each patient was carefully questioned in an effort to exclude known causes of digital artery occlusion such as frostbite,[8] repetitive trauma ("hypothenar hammer syndrome"),[9] accidental intra-arterial drug injection,[10] proximal embolic source,[11] drug ingestion (ergot intoxication),[12] and environmental toxin exposure, including heavy metals and vinyl chloride.[13] Signs and symptoms of connective tissue disease were specifically sought in the history and physical examination, including alopecia, xerostomia, xerophthalmia, aphthous lesions, dysphagia, arthralgias, arthritis, rash, myalgias, myopathy, and sclerodactyly. Palpation of peripheral pulses, palpation for cervical ribs and clavicular abnormalities, and auscultation of the supraclavicular fossa for bruits were routinely performed to identify potential embolic sources such as subclavian artery aneurysm or proximal atherosclerosis.

Upper extremity digital photoplethysmography and segmental arterial pressures and waveform recordings were obtained in all patients, as previously described.[14] Segmental leg arterial pressures and treadmill walking were performed if indicated by clinical history or abnormalities detected on physical examination. A digital hypothermic challenge test (Nielsen test)[15] was obtained in patients with a history of digital cold sensitivity. Arteriography using a transfemoral approach and selective catheter techniques, with views from the aortic arch to the fingertips, was performed in 75% of patients. Magnification hand arteriography as described by Rosch from our institution was routinely included.[16]

The laboratory evaluation of patients with small artery disease is outlined in Tables 1 and 2, and was directed toward the detection of serologic abnormalities associated with autoimmune diseases. The details and methodologies of these tests have been described.[17-19] Radiographic evaluation consisted of chest and hand roentgenograms in all patients. Barium swallow, barium enema, and intravenous urography were performed selectively based on the results of the history, physical, and laboratory evaluations. Patients with acute finger ulceration or gangrene were examined weekly in the CRC. Ischemic lesions were photographed on each visit. All patients were treated conservatively with soap and water cleansing, debridement of necrotic tissue, fingernail removal if required to facilitate drainage of infection, and culture-specific antibiotics. Delayed phalangeal amputation, when necessary, was performed to conserve maximal digital length. Numerous vasodilator medications were used to treat painful acute ischemia as well as chronic obstructive Raynaud's symptoms. No thoracic sympathectomies were performed. After initial healing, all patients were followed up permanently at 6–12-month intervals. Serial noninvasive vascular laboratory and serologic tests were obtained at each visit.

Results

Demographics

The study population of 100 patients consisted of 64 women and 36 men with a mean age of 46 years. Associated conditions and risk factors were frequent; 68% were cigarette smokers, 7% had hypertension, 9% were hyperlipidemic, and 5% had diabetes mellitus. Forty-one patients (41%) had acute onset of finger ischemia, whereas 59% had chronic upper extremity digital ischemia.

Plethysmographic and Angiographic Results

All patients had profound obstruction of the palmar and digital arteries documented objectively by photoplethysmography and arteriography. The diagnosis of small artery obstructive disease was made in each patient by the combination of normal arterial pressures and waveforms in all arteries proximal to the wrist, and obstructive digital photoplethysmographic waveforms in multiple fingers associated with multiple finger blood pressures at least 30 mmHg below brachial artery pressure.[20] No patient with finger ulceration had digital artery vasospasm alone. A representative tracing of a 24-year-old man with sudden onset finger ischemia and resultant ulceration secondary to hypersensitivity angiitis showed the typical flattened obstructive waveform characteristic of digital artery occlusion (Fig. 1). Magnification hand arteriography (Fig. 2) confirmed the presence of massive digital artery occlusions, with normal proximal arteries. In 25 patients, arteriography was deferred because plethysmography documented bilateral diffuse digital artery obstruction and an underlying connective tissue disease had been diagnosed according to the criteria stated.

Associated Diseases

Using the methodical evaluation outlined above, an underlying disease responsible for palmar and digital arterial occlusion and ischemic finger ulceration and gangrene was diagnosed in each patient. The associated diseases detected in these patients are listed in Table 3. The diagnosis of associated autoimmune disease was made by strict adherence to the criteria established by the American Rheumatism Association[21] and in routine consultation with the Division of Immunology at our University hospital. Autoimmune disease was diagnosed in 54% of the patients in this series. Digital artery occlusion caused by various autoimmune vasculitides is well described.[22]

Twenty-two patients had sudden onset of pain and distal finger cyanosis that rapidly progressed to ulceration or gangrene over 48–72 hours. Most of these patients were young (mean age: 36 years) and previously healthy; seven were female smokers taking oral contraceptives. All serologic tests for underlying autoimmune disease were negative both initially and during long-term clinical follow-up in this patient group. Fixed palmar and digital artery obstruction was documented by plethysmography and/or angiography in each patient. The acute ischemic event resolved with conservative treatment in every patient, and no recurrences have been observed with follow-up extending to 15 years. We reported the first ten patients with this condition in 1977 and termed it hypersensitivity angiitis with rapid onset vascular occlusion (ROVO).[23] Although our designation of this condition as hypersensitivity angiitis in the absence of tissue confirmation remains speculative, its similarity to the accepted hypersensitivity angiitides appears to us sufficiently close to warrant use of this classification.

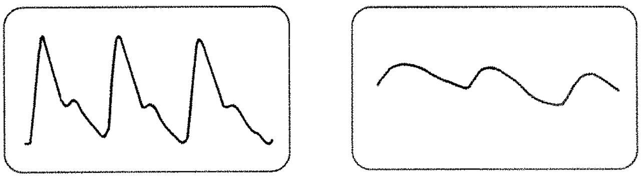

FIG. 1. *Left*, normal finger photoplethysmograph (PPG) showing normal upstroke and dicrotic notch. *Right*, PPG tracing in patient with finger ischemia demonstrating obstructive flattened waveform and absent dicrotic notch characteristic of digital artery obstruction.

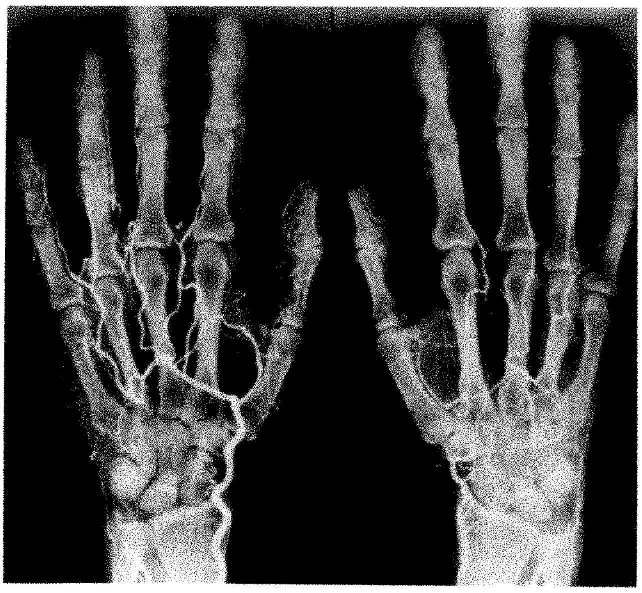

FIG. 2. Magnification hand arteriogram showing massive organic occlusion of the palmar and digital arteries with absence of complete filling of the superficial arch and occlusion of multiple proper digital arteries.

Buerger's disease is a condition occurring predominantly in young male smokers. It is characterized by the occurrence of segmental occlusions of the small arteries in both the lower and upper extremities. Objective clinical criteria recently reported from our institution[24] were used to establish the diagnosis in nine patients in the current series. An additional nine patients had widespread large artery atherosclerosis that also involved the distal upper extremity and digital arteries as documented by arteriography. All of these patients, as well as those with Buerger's disease, were cigarette smokers.

TABLE 4. *Response of Ischemic Finger Ulceration to Conservative Treatment*

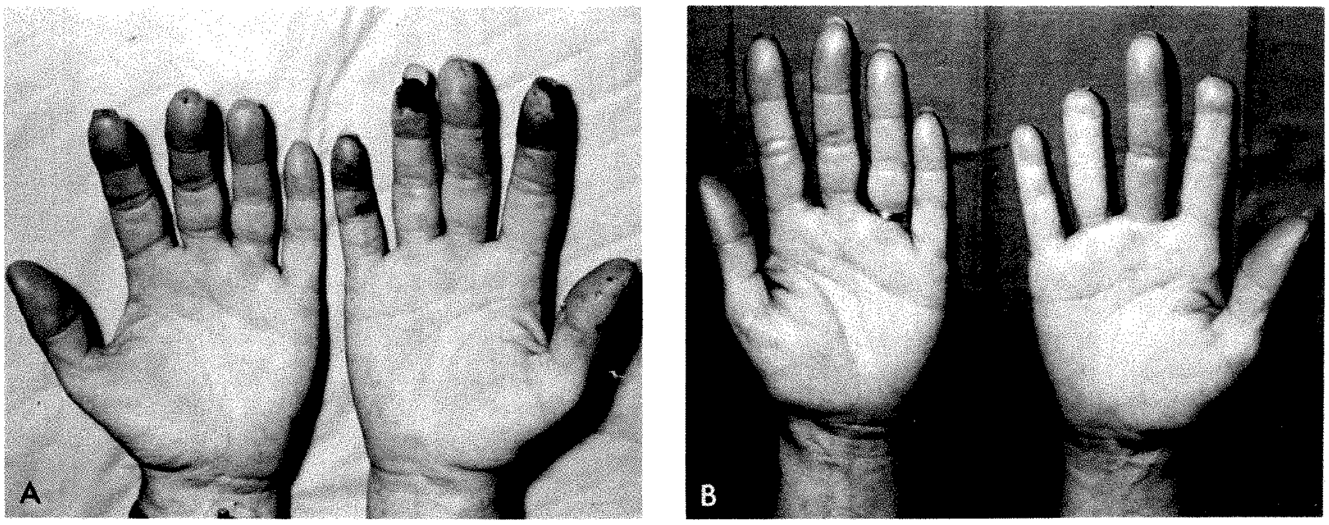
	Recurrent ulceration, tissue loss	11
	Hand amputation	1

An underlying diagnosis of malignancy was made in four patients with finger gangrene. Digital artery obstruction associated with malignancy has been described previously by us and others.[25,26]

Long-term Follow-up and Response to Therapy

All patients were treated using the conservative protocol described above. In addition to aggressive local treatment, numerous medications have been used over the past 15 years, both to treat patients in the acute phase of ischemia with active ulcerative lesions, as well as to treat subsequent Raynaud's syndrome, which occurred in 52% of patients after healing of the ischemic digital ulcerations.[27] The pharmacologic agents used included vasodilators, antiplatelet drugs, hemorrheologic agents, and immunosuppressive drugs directed at the active underlying autoimmune process (steroids, azathioprine, penicillamine). Early in our experience, we used Bier block or intra-arterial reserpine in 31 patients to achieve a regional sympathetic block,[28] followed by oral guanethidine and phenoxybenzamine. Symptomatic and angiographic improvement in vasospasm was documented in a number of patients for several days after parenteral treatment, but no consistent benefit was noted with long-term oral drug administration. We currently use a calcium channel blocker (nifedipine or diltiazem) alone or in combination with prazosin, with variable results. Currently, most patients also receive pentoxifylline. Although selected patients occasionally improve dramatically, the response to these drugs has not been predictable or reliable. We currently regard no vasoactive drugs of proven efficacy in the treatment of these patients.

Using the regimen described, with follow-up extending to 15 years (mean: 4 years), 88% of patients had complete healing without recurrent ulceration (Table 4). In 16 patients, a conservative mid-distal phalangeal amputation using a flap technique analogous to standard below-knee amputation was performed to relieve pain associated with unremitting distal finger ischemic pain. A representative photograph of ischemic digits before and after treatment is shown in Figure 3. In 12 patients, recurrent tissue loss or ulceration despite conservative care developed. Each of these patients had autoimmune disease, most frequently scleroderma (7 patients, Table 5). Cigarette smoking had no consistent relationship to outcome; although 68 patients in the series were smokers, only 20 successfully quit smoking. Half of the 12 patients with recurrent tissue loss had never smoked cigarettes. In contrast to those with autoimmune disease, patients with Buerger's disease, atherosclerosis (ASO), and hypersensitivity angiitis all did well and had



FIGS. 3A AND B. *A*. Initial presentation of a patient with gangrene of multiple fingers associated with hypersensitivity angiitis. *B*. Demonstrates complete healing after conservative treatment alone.

no recurrent finger ulceration or gangrene during follow-up.

Discussion

A careful analysis of the prospectively accumulated data in this group of 100 patients with advanced occlusive disease of the palmar and digital arteries associated with ischemic finger ulceration serves to establish the natural history of the condition. The occurrence of ischemic finger ulceration invariably signals the presence of a potentially serious associated disease. The methodical evaluation of these patients as outlined above has resulted in an accurate diagnosis in all, although careful long-term follow-up has been required to establish the diagnosis of associated disease in certain patients. The majority of these patients (54%) had an underlying autoimmune disorder. Optimal patient management required participation by a rheumatologist or immunologist to coordinate systemic treatment regimens. Our simple conservative local finger treatment program of vigorous local cleansing with plain soap and water with minimal debridement of necrotic and infected tissue, accompanied by the administration of culture-specific antibiotics, was followed by healing without recurrent tissue loss or ulceration in 88% of patients with follow-up to 15 years.

Other investigators have published healing rates for other forms of treatment of upper extremity digital gangrene. A 75% healing rate followed treatment with intravenous prostaglandin E1 infusion.[29] Similar rates of healing have been attributed to the performance of cervicothoracic sympathectomy.[7,30] These results clearly are no better than the 88% permanent healing rate without recurrence reported in the current series with conservative treatment only. We performed no thoracic sympathectomies in these patients, although 11 patients had had sympathectomy, all without benefit, before referral to our center. We find no evidence that regional sympathectomy is of any demonstrable benefit either in accelerating initial healing or in controlling chronic, persistent vasospasm, when associated with arterial obstruction.

Hypersensitivity angiitis (ROVO) is an especially interesting condition. Its clinical course resembles an immune vasculitis with distribution limited to the small arteries of the hand. Interestingly, there appears to be no systemic toxicity. None of the 22 patients in the current report who had this condition experienced a recurrence, often despite the persistence of risk factors such as cigarette smoking. Long-term improvement was associated with the development of collateral arterial circulation, as

the initial major digital artery obstruction invariably persisted as documented by serial photoplethysmography and repeat arteriography in several patients.

As noted above, we have used a variety of vasoactive medications in these patients directed at improving circulation through relief of associated vasospasm. We are unconvinced that any of these drugs have been of benefit in healing the digital ischemic ulceration, although occasionally they have appeared helpful in the symptomatic treatment of obstructive Raynaud's syndrome, which frequently follows the episode of ischemic ulceration. Our recent anecdotal experience with the hemorrheologic agent pentoxifylline has been encouraging in a small number of patients with ischemic ulceration, although to date no controlled study has been performed.

Our opinion concerning the requirement for arteriography in the evaluation of these patients has changed over the years. Until recently, all patients with ischemic finger ulceration had arteriography to document digital artery occlusion and to rule out a proximal embolic source. We currently believe that if finger gangrene occurs in a patient in whom a firm diagnosis of associated disease has been established and in whom digital photoplethysmography is diffusely abnormal bilaterally, arteriography is unnecessary. If no diagnosis has been established, and particularly if symptoms and signs are unilateral, angiography from the aortic arch to the fingertips should be performed to detect surgically correctible proximal large artery lesions that may be responsible for the digital ischemia.

During this 15-year period while we evaluated and treated 100 patients with finger gangrene caused by small artery disease, we encountered only six patients with finger gangrene caused by large artery disease, most frequently giant cell arteritis with involvement of the axillary artery.[31] Certainly in our experience, proximal large artery disease of the upper extremity is far less likely than palmar and digital small artery occlusive disease to cause profound finger ischemia with ischemic ulceration. It is unknown whether this reflects the relative incidence of these two conditions in the population or pecularities of our local referral pattern.

The results of this review indicate that the occurrence of ischemic finger ulceration invariably heralds the presence of a potentially serious underlying disease process and that methodical evaluation of these patients should result in an accurate diagnosis. The natural history of ischemic finger ulceration in 88% of our patients has been long-term healing without recurrence after conservative treatment. We are unconvinced that any therapy improves on vigorous local cleansing, debridement, antibiotics, and conservative amputation/debridement. We find no evidence that thoracic sympathectomy or vasodilator drug therapy significantly benefits these patients.

Discussion

DR. HENRY T. BAHNSON (Pittsburgh, Pennsylvania): I presume there was no frost bite or did you exclude frost bite in that group of patients?

DR. HERBERT I. MACHLEDER (Los Angeles, California): Over the past several years, Dr. Porter and his co-workers have presented a series of valuable observations documenting many characteristics of upper extremity digital ischemia. The combination of their unique therapeutic approach and excellent results have encouraged us to critically review our own management of these patients.

It has become evident to me that even in this large series of patients, there are some hazards in drawing generalized conclusions from one facet of such a disparate group of diseases. For example, in our experience at UCLA, patients with hypersensitivity vasculitis and those with leukocytoclastic vasculitis have a self-limited course that seems to be dependent on exposure to environmental or endogenous allergens. The disease process is related to removal or persistence of this allergen, which can be either a chemical, medication, pharmacologic agent, or a mycotic or bacterial infection. Once this event is controlled, the vasculitis usually regresses and rarely returns. In this self-limited type of disease, long-term pharmacologic therapy or sympathectomy is clearly irrelevant.

On the other hand, connective tissue and autoimmune vasculitic disorders are characterized by exacerbations and remissions, which usually require a long-term commitment to therapy. We have studied a group of 20 of our most severely ill patients, with severe systemic autoimmune disease, using long-term thoracic duct drainage as an immunosuppressive agent.

Evidence of vasculitis begins to resolve rapidly after the onset of immunosuppression. Within 3 weeks there is no longer any clinical evidence of the vasculitic lesions or digital ischemia. Usually within 2–3 months, vasculitis can no longer be demonstrated by biopsy of previous lesions. Dermal-epidermal junctions or vascular endothelium no longer show deposition of IGG and beta-1-C or immune complexes.

Clearly in this group of patients digital ischemia is a barometer of the underlying systemic disease and cannot be viewed as an isolated phenomenon. Our approach therefore has been to direct therapy towards the underlying disease process. I wonder if the excellent results achieved by the group in Oregon can be attributed to control of the underlying autoimmune or collagen vascular disease rather than the specific measures directed at the secondary manifestations.

Another example would be polyarteritis, which is very sensitive to immunosuppressive therapy. A large group of these patients have been studied by a randomized controlled trial and have demonstrated that the addition of Imuran® to the usual prednisone regimen can significantly change the outlook for these patients. Mean survival can be augmented from 5 years to 12 years and the 5-year survival rate can be changed from 50% to 80%.

Management of digital ischemia, then, in our institution, has been subordinate to the systemic therapy, which is probably the most important factor influencing the course of digital gangrene. Nevertheless, we have been considerably more liberal in our use of sympathectomy and pharmacologic therapy, as a palliative measure, than indicated in this current series.

Dr. Wiley Barker and I reported our results with 53 patients, 81% of whom were relieved of their symptoms. These results from sympathectomy are comparable, but not quite as good as Dr. Porter's 85–88% remission.

We have found that a number of additional symptoms, such as Raynaud's phenomenon, digital hypersensitivity to cold, and digital hypersensitivity to touch, precede frank ulceration and often continue after healing. These symptoms can be favorably influenced by a more aggressive therapeutic approach, and may reduce what is often considerable physical and occupational disability.

I have two questions for the authors: how did you treat the 12% of patients who failed the conservative management program? The second question is: nonrecurrence of digital ischemia in Buerger's and scleroderma is certainly very unusual in our experience. This suggests much better control of the underlying disease process than we have been able to manage. What is your primary approach to therapy then in these difficult autoimmune diseases?

PROFESSOR JAN NIELUBOWICZ (Warsaw, Poland): I want to save the time for Poland. I am a general and vascular surgeon, and have been very much interested in this question that has been presented.

I congratulate the authors for their very nice and interesting presentations, and I want to make some comments concerning the nonhealing ulcers in Buerger's disease and in Raynaud's phenomenon.

I have studied these patients very much, and as you know, everybody thinks that Poland is the native country for Buerger's disease, which is not true because you find it everywhere in the world.

I made a study of about 120 patients whom I gathered during the years of my work in Warsaw. I published and presented it at the international meeting in Tokyo some 8 years ago, and that has been published in the *Journal of Cardiovascular Surgery.* I have two remarks, I believe, that all these patients get Buerger's disease, which is proved by histopathologic studies, in the course of 4 or 5 years, and 80 or 85% lose their fingers.

The second remark that I want to make is that interestingly enough, when all fingers of the extremities are amputated, their natural course of life is just the same as anybody's life. What Dr. Bahnson is showing to me, 99% of them are heavy smokers. Then the next comment that I want to make if on Raynaud's phenomenon, which frankly speaking, people have not worked on since Raynaud's original description. We do not know the mechanism of this pain during the cyanotic phase of Raynaud's phenomenon. I proved that the pain phase is due to the opening of the natural arterial venous communications. This makes the periphery ischemic. In Raynaud's phenomenon, we do the sympathectomy only in cases of severe pain.

I agree with the speakers that although the pain disappears or diminishes, it reappears after 6 months; therefore, the indications for that type of operation are very limited.

DR. FRANK COLE SPENCER (New York, New York): I rise primarily to comment briefly and ask two questions.

This is a remarkable follow-up for which we are all indebted for what is one of the most careful, long-term studies of an unusual disease in the world. It well demonstrates the need for randomization of different forms of therapy, especially with long-term chronic diseases.

Concerning etiology, about 75% of the patients were considered to have an autoimmune disease, 50% were considered to have a clear autoimmune disorder, and 25% were considered to have "hypersensitivity angiitis." There were only four patients with a malignancy.

The vascular episodes in both groups appeared to be acute ischemic episodes, resulting from an embolus or a trombosis. There were acute symptoms with tissue necrosis, subsiding with simply soap and water wound care; yet the disease did not recur. The recovery with simple wound care, I suppose, is due to both lack of progression of the underlying disease as well as the growth of collateral circulation.

Hence, the major question is: what is the basic disease? Why didn't it recur? Certainly the ischemic phenomena are similar to those with Buerger's disease, which is notorious for its recurrence and chronicity.

My other question relates to the descriptive term "hypersensitive angiitis." Is this an established entity or primarily an adjective that describes a syndrome in someone who has immunologic findings of an autoimmune disease but not other abnormalities that permit a precise diagnosis?

DR. MORTON M. WOOLLEY (Los Angeles, California): Infants and children with scleroderma are not infrequently seen because of painful subcutaneous abcesses. The abscess generally occurs around a central calcium deposit. I would like to ask the authors if the adult patients described in their manuscript have an underlying collection of calcium in association with the cutaneous ulcerations.

DR. ISRAEL PENN (Cincinnati, Ohio): I would like to comment on another autoimmune disease, namely diabetes mellitus. Kidney transplantation has significantly prolonged the lives of many patients with juvenile onset diabetes who have chronic renal failure. Unfortunately, the metabolic disturbances persist and many patients get progressive vascular disease. Virtually every transplant surgeon has had the disappointing experience of having to perform a significant number of lower extremity amputations in these individuals. In addition, there are occasional patients who also have small vessel disease involving the palmar and digital vessels and present with painful ischemic ulcers of the fingers. Unfortunately, these lesions do not respond to conservative treatment and the patients end up with multiple amputations of their fingers.

I would appreciate if you would describe your experience with diabetic patients.

DR. JOHN M. PORTER (Closing discussion): As you can all tell from the presented material the objective of the study was descriptive. Before making the observations reported herein, we did not know the natural history of ischemic finger ulcerations nor did we know the associated disease processes routinely present in these patients.

Dr. Machleder and I have shared an interest over the years in small artery disease, especially of the upper extremity. He observed accurately that hypersensitivity angiitis might normally end when the offending antigen is removed. Although true, we frequently do not know the identity of the offending antigen.

We did not identify specific chemical toxins in our patients, and, as noted in the manuscript, our use of the term "hypersensitivity angiitis" is speculative. The arteritis which we hypothesize bears only remote resemblance to either leucocytoclastic angiitis or hypersensitivity angiitis of Zeek.

The immunology group at UCLA has been among the leaders in the definition and treatment of autoimmune disease, and Dr. Machleder's comments directed towards specific immune therapy including lymph duct drainage are most interesting. We did not embark on a specific therapeutic program such as this, and I have no further comments in that area. His observation that the Raynaud's syndrome if frequently improved by sympathectomy is in my opinion partially true but generally irrelevant.

I find that one can accurately categorize the Raynaud's syndrome into two specific categories: obstructive and spastic, with careful adherence to a variety of vascular laboratory and serologic testing. Patients with spastic Raynaud's syndrome will frequently respond well to sympathectomy. In the main, however, they do not require such extreme therapy. Patients with obstructive Raynaud's syndrome respond poorly to sympathectomy and I believe it is generally contraindicated in this group.

Dr. Machleder asked how we treated the 12% of patients who failed. We had no specific therapy in these patients other than finger debridements and local wound care.

I observe that we do not recommend and have never used proximal finger amputation as initial therapy. If one performs finger amputation through the proximal or midphalanyx, primary healing can be achieved in almost 100% of patients, but at the expense of sacrifice of finger length. As conservation of finger length is so important for hand function, we performed fingertip conservative resectional debridement in the majority of these patients in an effort to preserve maximal length.

Professor Nielubowicz' comments are appreciated concerning the progression of Buerger's disease. Our patients with Buerger's disease whom we have recently reviewed have almost all displayed progression of disease in relationship to cigarette smoking. I personally had doubts about this relationship until our recent review, which again validated these historic observations.

Any benefit in the healing of ischemic fingertip ulceration from thoracic sympathectomy in my opinion remains completely anecdotal. Without question, if one performs a sympathectomy in the course of a program of treatment for fingertip ischemic ulceration including debridement antibiotics, and scrubs, the ulcers will heal in about 85% of patients. Our contention is that the same treatment program without the thoracic sympathectomy will produce identical results.

Dr. Spencer perceptively asks why the ischemic finger ulcers did not recur since our treatment was only supportive and nonspecific. I believe this is the most fascinating observation in this patient group. One would expect if the patient has serious underlying small artery disease, sufficiently severe to cause finger ulcer, and all we offer if local treatment, the ulcer should recur within weeks or months. Interestingly, in 88% of our patients, this did not happen. I report this as an observation on the natural history of this disease for which I have no explanation. I do believe that any future study evaluating various therapeutic regimens must be measured against the natural history of the condition as presented herein. I believe that is the most important observation we have made to date.

Dr. Woolley, we did find finger calcification in certain patients, although I observe that the finger calcifications were more of the diffuse variety. We did not find the very localized calcium deposits that sometimes occur.

Interestingly, only 9% of this patient population had diabetes. We have a large group of diabetic patients in our clinical series. In fact, in our peripheral arterial bypass series, about 55% of our patients are diabetics. I have no explanation for the small number of diabetics in the ischemic finger ulceration group.

Splenectomy for Primary and Recurrent Immune Thrombocytopenic Purpura (ITP)

Current Criteria for Patient Selection and Results

ONYE E. AKWARI, M.D., F.A.C.S., F.R.C.S.C.,* KAMAL M. F. ITANI, M.D.,* R. EDWARD COLEMAN, M.D.,† and WENDELL F. ROSSE, M.D.‡

From the Departments of Surgery, Radiology,† and Medicine,‡ Duke University Medical Center, Durham, North Carolina*

Of 565 patients with thrombocytopenia admitted to Duke University Hospital between 1975 and 1985, 100 had splenectomy. Ninety-eight patients had failed chronic immunosuppressive therapy and three patients had acute intracranial bleeding or total absence of platelets in the peripheral blood smear, and had urgent splenectomy. At primary splenectomy, accessory spleens were identified and resected in 18% of patients. There was no operative mortality. Fifty-eight patients had an excellent response to splenectomy and their steroids were tapered off within 3 weeks. Thirteen patients had a poor response to primary splenectomy of whom eight remitted spontaneously and five required accessory splenectomy resulting in complete remission in three patients. Twenty-nine patients were considered nonresponders, 25 of whom had radionuclide scanning for accessory spleens. Seven of these patients had accessory spleens identified but only four consented to accessory splenectomy. In three of the four patients, a complete remission was achieved. Neither platelet antibody titers nor measurements of platelet survival or turnover predicted platelet response to splenectomy. However, immune thrombocytopenic purpura (ITP) in older patients was significantly less likely to respond to splenectomy. These data support continuing use of splenectomy in selected patients with ITP and an aggressive search for accessory spleens in patients who relapse since they are easily localized at operation by hand-held isotope detector probe.

THE DEMONSTRATION IN 1913 that splenectomy benefited some patients with hemolytic anemia led Kaznelsón to advocate its use for the treatment of "purpura haemorrhagica" in 1916.[1] By 1926, Whipple[2] could identify 81 patients in the literature who had had splenectomy for immune thrombocytopenic purpura (ITP). Reports of successful cases by Spence[3] in 1928, and by Eliason and Ferguson[4] in 1932, brought the collected experience to 213 patients, and established splenectomy as the only definitive therapeutic procedure for ITP. Although this new mode of therapy became rapidly accepted, the mechanism responsible for the low platelet count in ITP and the efficacy of splenectomy in some of the patients were poorly understood. The leading hypothesis included a decrease in the rate of platelet formation from megakaryocytes because of splenic inhibition of these cells. Others believed that there was an increase in the rate of platelet destruction by the spleen.

An immune mechanism was first suggested by Marino[5] in 1905. Marino produced an antiplatelet antibody by injecting rabbit platelets into guinea pigs. A few years later, Ledingham[6] caused experimental purpura in animals by the administration of antiplatelet antiserums. However, little extension of these fundamental studies into clinical states of thrombocytopenia was made until in 1938, when Evans et al.[7] presented evidence of a thrombocyte agglutinating factor in the serum of patients with ITP. Their theory that a circulating antibody was responsible for the thrombocytopenia of ITP was later proved by Harrington et al.[8] by cross-transfusion between purpuric and normal volunteers. The relationship between circulating antibodies and splenectomy was dramatically established 2 years later by Harrington,[9] who showed that the thrombocytopenic effect on normal recipients given plasma from subjects with ITP was diminished in the absence of a spleen.

It was about this time that glucocorticoids were first demonstrated to be effective in the treatment of ITP.[10] With the introduction of even more powerful immuno-

---

Submitted for publication: April 24, 1987.

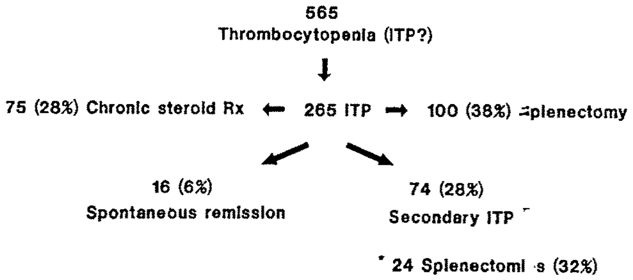

FIG. 1. One hundred patients with primary ITP had splenectomy. Twenty-four patients believed to have primary ITP had splenectomy, but in whom other diseases subsequently developed, were not included in the current study.

suppressive agents, such as azathioprine, cyclophosphamide, and the vinca akaloids, splenectomy was gradually relegated to a secondary role. Recently, hyperimmune globulin has also been demonstrated to be effective in restoring thrombocytosis, albeit transient, in selected patients with chronic ITP.

To assess the impact of this apparently changing role of splenectomy on our practice, we reviewed the experience at Duke University Medical Center. Our specific aim was to document our criteria of patient selection for splenectomy and to analyze the current results.

Materials and Methods

Patients

Between 1975 and 1985, 565 consecutive patients with thrombocytopenia of obscure cause were referred to the Hematology Section at Duke University Medical Center for evaluation and management (Fig. 1). Two hundred sixty-five of these patients satisfied the diagnostic criteria of ITP. In 16 (16%) of these 265 patients, the thrombocytopenic state remitted during a very short period of observation or treatment with low doses of steroids. These 16 patients were young, with an average age of 9 years. Seventy patients (28%) had sustained platelet responses on chronic therapy with steroids and were managed medically. Seventy-four patients (28%) who initially were believed to have primary ITP subsequently developed other diseases. Twenty-four patients in this group had had splenectomy before the onset of the secondary disease.

The remaining 100 patients (38%) identified as having primary ITP were the focus of this study. After evaluating the impact of splenectomy, each patient could be categorized as a *responder* or a *nonresponder*. Response was defined strictly by the patient's ability to sustain a platelet count (measured by the Duke Special Hematology Laboratory) of greater than 150,000/μL after primary and/or accessory splenectomy, and on no medical therapy during the follow-up period. Nonresponders failed to respond to primary and/or accessory splenectomy or relapsed after an initial response. Nonresponders required chronic immunosuppressive therapy to prevent their platelet counts from plunging into dangerously low levels.

Platelet Counts and Platelet Antibody Titers

Platelet antibody titer measurements were paired with their corresponding platelet counts, before and after splenectomy.

Before 1981, the platelet antibody titers were determined by a complement lysis inhibition assay using rabbit antihuman IgG. Since 1981, the antibody titers have been measured by a specific radioimmunoassay using a platelet radioactive antiglobulin test.

For the purpose of our analysis, the platelet antibody titers were standardized by dividing each measured value by the corresponding normal value for the technique of antibody measurement by which it was determined. Among the *responders,* 95 observations were made before splenectomy and 126 were made after operation. Fifty-eight presplenectomy and 123 postoperative observations were recorded in *nonresponders.* Platelet antibody titers in patients with accessory spleens were considered only when the measurements were made before primary splenectomy (preoperative titer) and again after accessory splenectomy (postsplenectomy titer).

The data were then normalized by taking the logarithmic transformation of both the standardized platelet antibody titer and of the corresponding platelet count. The partial correlation and regression coefficients between these two variables were then calculated for each category before and after splenectomy, blocking on individuals for whom there were multiple observations. The probability associated with testing each coefficient against the null hypothesis was calculated using the z-statistic for the partial correlation coefficients and the t-statistic for the regression coefficients. A chi-square test using Fisher's transformation was used to test the equality of the partial correlation coefficients, and the z-statistic was used to test the equality of the regression coefficients.

Platelet Survival and Platelet Turnover

Platelet survival and turnover were determined using autologous platelets labelled with indium III oxyquinoline. The platelet separation and labeling were performed according to techniques originally described by Thakur et al.[11] Blood samples are obtained at 15 minutes, 1 hour, 2 hours, 4 hours, and daily after injection of the radiolabeled autologous platelets. Two milliliters of whole blood from each sample and a standard of the injectate are counted on the last day of sample collection in an automatic scintillation well counter. Survival is calculated using a computer program that uses the gamma function (multiple hit) model.[12] The recovery of labeled platelets in the circulation is calculated from the activity per milliliter of each sample and from the estimated blood volume.

The platelet turnover was calculated by a standard formula:[13]

$$\text{platelets}/\mu\text{L/h} = \frac{\text{platelet count } (\mu\text{L}) \times 90\%}{\text{life span (hours)} \times \text{initial recovery}}$$

where the 90% figure represents the percentage of platelet recovery in normal subjects without spleens.

Eighteen patients had platelet survival studies, in 12 of whom the initial recovery was available for calculation of platelet turnover. The Pearson Product moment correlation coefficient was then calculated between both the logarithmic transformation of both platelet survival and turnover and the log transformation of the platelet count at 6 weeks after splenectomy. The probability associated with testing each coefficient against the null hypothesis of no linear relationship was then calculated.

Radionuclide Imaging of Accessory Spleens and their Intraoperative Localization Using a Hand-held Isotope Detector Probe

Eleven patients in whom ITP was refractory to primary splenectomy had conventional liver spleen scintigraphy with technitium 99 sulfur colloid to include anterior, posterior, lateral, anterior oblique, and posterior oblique images. If no splenic tissue is identified, a posterior image with increased intensity is performed to determine if a small amount of splenic tissue is present that is not detectable on the routine images. With the introduction of indium 111-labeled autologous platelets in 1981 at Duke University Medical Center, 19 of our patients with no response to splenectomy had an indium 111 radionuclide study. After injection of the radiolabeled autologous platelets, images are obtained with a wide field of view scintillation camera (Siemens LFDV, Siemens Medical Systems, Inc., Iselin, NJ) equipped with a medium energy parallel hole collimator. Symmetric 20% windows around the 173 Kev and 247 Kev photopeaks of indium 111 are used. Anterior, posterior, and left lateral views of the abdomen are obtained.

If an accessory spleen is detected, the patient is taken to the operating room within 12 hours of the radiolabeled platelet injection. A hand-held isotope detector probe is used for intraoperative localization of accessory spleens. The active detector, a cylindrical crystal of thallium-activated sodium iodide, detects gamma photon energies up to 160 Kev, is coupled to a photomultiplier by a light-pipe combination consisting of an inactive sodium iodide crystal and an acrylic coupler section. The active detector, photomultiplier, and electrical networks necessary in connecting the two are contained within a lead shield. Two 20-foot cables, one for high voltage and one for signal, connect the probe to its associated electronics. The probe is gas sterilized and used intra-abdominally during surgery to detect accumulation of indium 111-labeled platelets at the site revealed by the scan. The focus is removed and demonstrated *ex vivo* to have increased activity, whereas activity at the focus site is demonstrated to have returned to background levels. Finally, immediate pathologic confirmation of splenic tissue is obtained by submitting the resected specimens for frozen section examination.

TABLE 1. *Presentation of Immune Thrombocytopenic Purpura, Duke University 1975–1985*

Sign	Percentage of Patients (N = 100)
Easy bruising only	28
Routine platelet count	17
Petechiae, purpura, ecchymosis	14
Bleeding (gum, epistaxis, gastrointestinal, genitourinary)*	41

* Two patients with intracranial hemorrhage had urgent splenectomy.

Results

Demographic

There were 58 females and 42 males with an overall average of 41.4 years (range: 5–84 years). The ratio of blacks to whites was 1 to 4.

Presentation Diagnosis

A history of viral illness could be elicited from 19 patients. Seven patients received diazide, three patients received quinidine, and one patient gave a history of exposure to industrial solvents. The remaining patients had no recent infection or drug exposure that could be implicated in their thrombocytopenic state.

Abnormal bleeding was the most common sign of ITP, occurring in 41% of patients (Table 1).

Easy bruisability occurred in 28% and was associated with purpura, ecchymosis, or petechiae in 14 patients (14%).

In 17% of patients, the diagnosis was uncovered when an incidental complete blood count showed low levels of platelets (Table 1).

In addition to their clinical presentation, the diagnosis of primary ITP was supported by the absence of spleno-

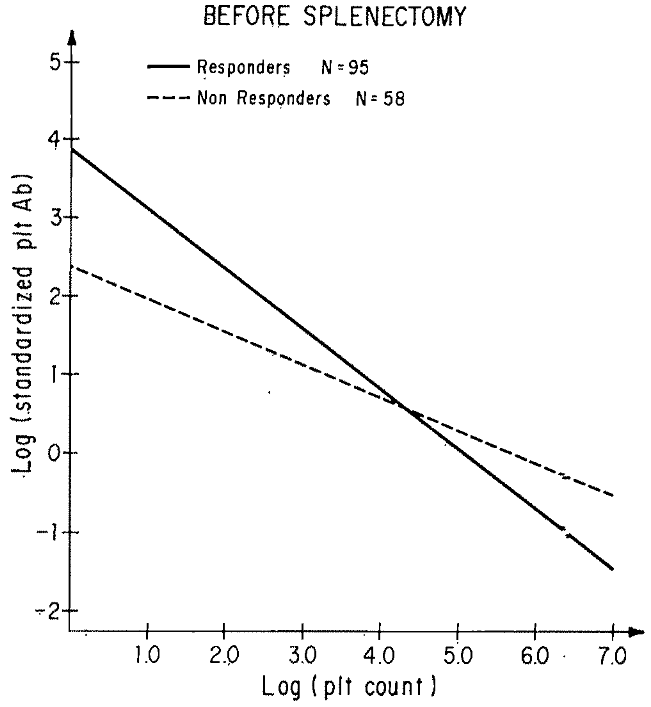

FIG. 2A. Regression lines between log (standardized platelet antibody titer) and log (platelet count) before splenectomy. Although the inverse relationship between these two variables is strongly negative ($p < 0.05$), there was no difference between responders and nonresponders ($p > 0.05$).

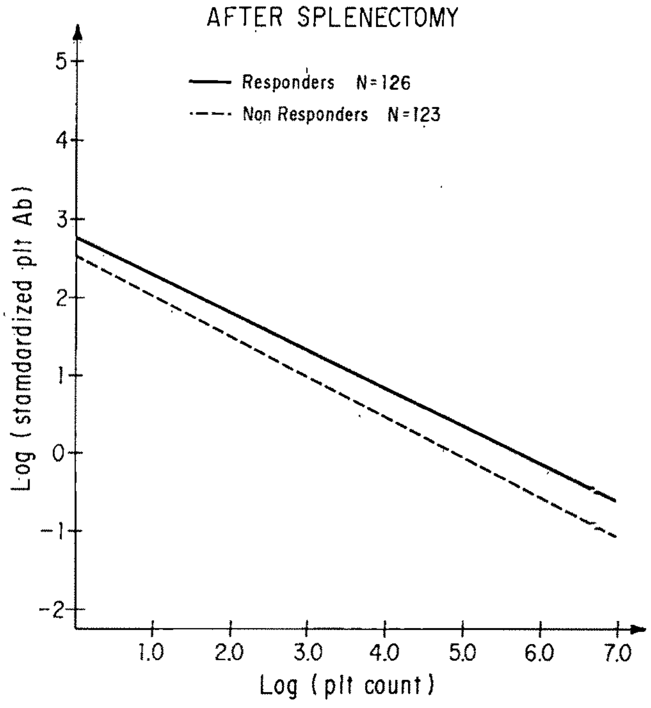

FIG. 2B. Regression lines between log (standardized platelet antibody titer) and log platelet count after splenectomy. Slopes of regression lines remain strongly negative ($p < 0.05$) and are not different from the preoperative values. After splenectomy, the slope of the regression lines are identical between responders and nonresponders.

megaly on physical examination and scintigraphic scans, low platelet counts associated with abnormally high titers of antiplatelet antibody, a bone marrow aspirate showing normal or increased number of megakaryocytes with decreased platelet budding, and normal maturation of the erythrocytic and granulocytic cell lines. Serologic tests were consistently negative for connective tissue disorders in all patients throughout the follow-up period (26–120 months).

Platelet Count and Platelet Antibody Titers

The overall average platelet count of the patients at presentation was 21,000/μL. The regression coefficients relating log platelet count and their corresponding log platelet antibody titers were negative in both responders (−0.77 ± 0.14) and nonresponders (−0.38 ± 0.18) before splenectomy (Fig. 2A). Although these coefficients were not different from each other ($p = 0.09$), they were significantly negative when individually tested against the null hypothesis ($p < 0.05$) (Figs. 2A and 2B).

Before splenectomy, the partial correlation coefficient between log platelet count and log platelet antibody titer for responders was −0.50 and was −0.31 for the nonresponders (Fig. 3). The difference between the two was significant ($p = 0.05$).

Platelet Survival and Platelet Turnover

Platelet survival, which is normally 200–220 hours, was shortened to an average of 61.5 hours in the 34 patients in whom it was measured. Average platelet turnover increased in 2179 platelets/μL/h (N = 1200–1600 platelets/μL/h) in 12 patients in whom it was calculated.

Initial Therapy

All patients represented failures of chronic nonoperative therapy, except for three patients who had urgent splenectomy (Table 2). Emergency splenectomy was advised in two patients with acute intracranial bleeding and in one patient who showed a total absence of platelets in repeated peripheral blood smears.

The average time from presentation and institution of medical therapy to primary splenectomy was 8 months (range: 0.5–96 months) (Table 2).

Fifty-one per cent of patients were unresponsive to prednisone at doses in excess of 60 mg/day. In 35 patients, prednisone was used in combination with other immunosuppressives (vincristine, cytoxan, or azathioprine), either because of the patient's inability to tolerate prednisone in high doses or because the prednisone dosage could not be tapered to lower levels without the platelet count dropping to clinically unacceptable low levels.

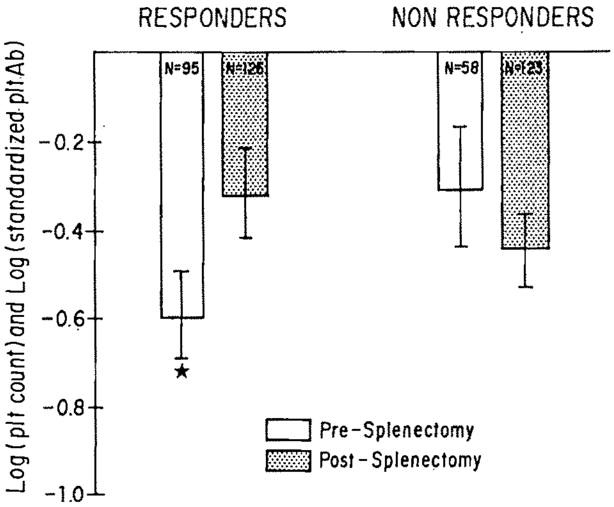

FIG. 3. The partial correlation coefficient between log (platelet count) and log (platelet antibody titer) in the responders before splenectomy was significantly higher (*$p < 0.05$) than in all other categories. The partial correlation coefficient between these two variables was not different in the nonresponders before and after splenectomy ($p > 0.05$).

Eleven per cent of patients had a good response to prednisone in the 20–60 mg/day dose range but unfortunately had severe side effects of steroid therapy or adverse effects of steroids on the patients' other coexisting medical conditions.

Although patients who ultimately responded well to splenectomy had been treated medically on average for a shorter time than had the nonresponders (7 months *vs.* 12 months), this difference is probably due to physicians' reluctance to refer older patients for surgical therapy (Table 2, Fig. 4).

Primary Splenectomy

All 100 patients received preoperative pneumococcal vaccination as well as steroid preparation. In general, the patients received 100 mg of hydrocortisone on the day before operation and approximately 300 mg of hydrocortisone on the day of surgery and the immediate postoperative period. The dosage of steroids was then gradually reduced depending on the patient's platelet response.

In an effort to investigate the possible role of preoperative infusions of intravenous gamma globulin for establishing preoperative thrombocytosis and thus obviate the need for platelet transfusions, we studied six patients. Four patients received 400 mg/kg/day of gamma globulin (IV-IG) on each of 5 days. Shortening the protocol, two patients were given 1000 mg/kg/day for 2 days. All six patients achieved platelet counts in excess of 100,000/μL and did not require perioperative platelet transfusion.

TABLE 2. *Therapy Before Primary Splenectomy, Duke University 1975–1985*

	Therapy No. of Patients				Duration (Months)
	$\bar{S}$	S + I	S	N	Average (Range)
Responders	39	19	10	3†	7* (0.5–96)
Nonresponders	12	16	1	0	12 (1–74)
Total	51	35	11	3	8 (0.5–96)

* Significantly shorter than in nonresponders. ($p < 0.05$)
† Underwent urgent splenectomy.
$\bar{S}$ = High-dose prednisone (50 mg) with poor response.
S + I = 20–40 mg of prednisone/day and one other form of immunotherapy with poor response.
S = 20–60 mg of prednisone/day with good response but intolerance.
N = No medical therapy before splenectomy.

Fifty-one patients with an average platelet count of 45,000/μL were given platelet transfusions during operation. The remaining 43 patients had an average preoperative platelet count of 83,000/μL on steroids and did not receive platelet transfusions.

The tail of the pancreas was protected during operation and every effort made to remove the spleen intact to avoid the liberation of fragments resulting in splenosis. Careful examination of the gastrocolic omentum, the retroperitoneum along the splenic vessels especially near the hilum, the bowel mesenteries, and the pelvis in the female patients, was performed in all cases. Eighteen patients (18%) had one or multiple accessory spleens at the time of primary splenectomy. Thirteen (72%) of

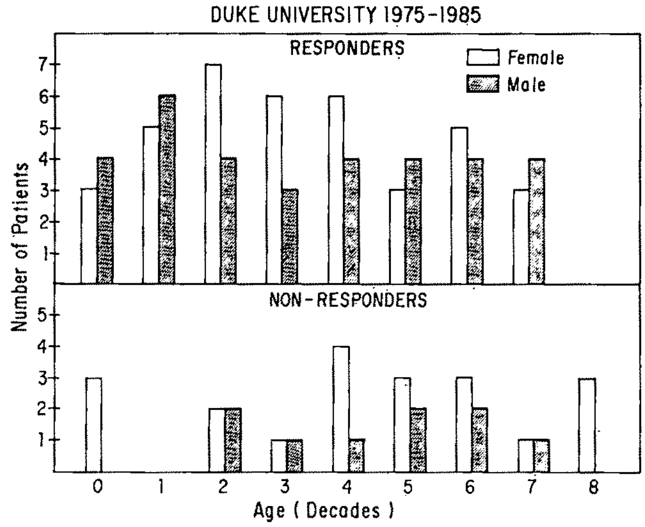

FIG. 4. Age and sex distribution in 100 patients who had splenectomy for ITP. The nonresponders (mean age: 49.3 ± 4.3) were significantly older than the responders (mean age: 38.2 ± 2.5; $p < 0.05$). The nonresponders were predominantly female but the gender differences did not achieve statistical significance ($p > 0.05$).

these accessory spleens were found in patients under 40 years of age.

The average weight of the spleen was 147 g (range: 39–340 g) and no distinctive alterations of their gross architecture were found. Histologic examination revealed an increased number of secondary follicles with large and active center in about 50% of patients. Sinusoidal dilatation in the red pulp was present in most patients.

Outcome after Primary Splenectomy

Seventy-one patients had a good response to splenectomy achieving a platelet count above 150,000/μL while receiving no medication. There were 38 females and 33 males with a mean ± SEM age of 38.2 ± 2.5 years (Fig. 4). Of these patients, 58 had an excellent response to primary splenectomy over a mean follow-up period of 10 months (range: 1–61 months); their steroid regimen was tapered within the first week after operation and they were completely off steroids an average of 2.3 weeks after operation. Another 13 patients had an initial poor response to primary splenectomy; eight remitted spontaneously during medical therapy for an average of 34 months (range: 1–84 months) after primary splenectomy and five had accessory splenectomy with good result in three of these patients who have required no further treatment.

After splenectomy the regression coefficient between the log platelet count and their corresponding log platelet antibody titers for these responders was −0.48 ± 0.15 and was not different from the presplenectomy coefficient of −0.77 ± 0.14 ($p = 0.17$) (Figs. 2A and 2B). However, the partial correlation coefficient was −0.32 and was significantly different from the presplenectomy value of −0.60 ($p < 0.05$) (Fig. 3).

Twenty-nine patients (29%) were considered nonresponders to primary splenectomy, and continued to require immunosuppressive therapy to maintain their platelet counts above dangerous levels. Included among the 29 patients were four patients who initially had a good response to primary splenectomy and subsequently had relapse of ITP, and three patients who required accessory splenectomy with no subsequent response. In these nonresponders, the regression coefficient of 0.38 ± 0.18 ($p = 0.45$) (Figs. 2A and 2B). The partial correlation coefficient for the nonresponders after splenectomy (−0.31) was not different from the presplenectomy coefficient (−0.45, $p = 0.37$) (Fig. 3).

The nonresponders were significantly older than the responders and although they were predominantly female, the gender differences did not achieve statistical significance (Fig. 4).

The Pearson correlation coefficient between the log preoperative platelet survival or turnover and the log postoperative platelet count were 0.017 and 0.33, respectively, which are not statistically significant ($p > 0.05$). Thus, neither platelet survival nor turnover predicted postoperative response of platelet count in these patients.

There was no operative mortality. Two patients who had recovered completely from operation died 3 months after operation, one of generalized sepsis and the second of multiple pulmonary emboli. The operative morbidity rate was 8%, consisting of three patients with subphrenic abscesses (one requiring drainage), one case of upper gastrointestinal bleeding that stopped after the saline lavage, two cases of multiple pulmonary emboli, and one case each of generalized sepsis and perirectal herpes simplex. Both patients with intracranial bleeding recovered completely.

Accessory Splenectomy for Persistent or Recurrent ITP

Of the 29 patients classified as nonresponders, 25 patients had a total of 30 radionuclide imaging studies. Six patients had only a technitium 99m sulfur colloid scan, which identified accessory spleens in three patients. Fourteen patients had only an indium 111-labeled platelet scan, revealing accessory spleens in eight patients. Both types of imaging were used in five patients. The presence of an accessory spleen was questioned on the Tc 99m scan in one patient but was very clearly imaged by the indium 111 scan. A second patient who had an accessory spleen identified by technitium 99m sulfur colloid scan was operated on but had persistent thrombocytopenia after excision of the accessory spleen. An indium 111 scan was performed that identified a second accessory spleen. The patient's ITP remitted completely after the second accessory splenectomy.

Accessory splenectomy for recurrent (5 patients) or persistent (4 patients) ITP was done in nine patients (Table 3). The average interval between primary and accessory splenectomy was 168 months (range: 1–504 months). The accessory splenic tissue was localized during operation using the isotope detector probe in six patients. The accessory spleens ranged in size from 0.5–7 cm in largest dimension. Six of the nine patients (66%) who had accessory splenectomy had complete remission of ITP and are no longer receiving steroids. No mortality was associated with accessory splenectomy but significant morbidity occurred in one patient in whom a left subdiaphragmatic hematoma developed that required surgical drainage.

Discussion

In this study, 58% of patients achieved platelet counts in excess of 150,000/μL within 1 week of operation and were weaned off steroids by the end of the third postop-

TABLE 3. *Accessory Splenectomy: Summary of Cases, Duke University 1975–1985*

	Primary Splenectomy		Accessory Spleen

9	7/F	360	444	7.0	Good

* Excellent = platelet count >100,000/μL; no steroids. Good = platelet count >100,000/μL; steroids for limited period. Fair = platelet count >100,000/μL; receiving steroids.

erative week. This immediate response rate increased to 71% as some patients who had an initial poor response to splenectomy remitted during follow-up on steroid therapy or responded to accessory splenectomy. This pattern of response is similar to the average complete response rate of 72% reported by others (Table 4). However, patient selection among these series was not uniform. Although none of the patients received steroid therapy before 1951,[3,14–16] most patients who had splenectomy after that date had failed immunosuppressive therapy. In the current series all patients failed intensive immunosuppressive therapy except for the three patients who had urgent splenectomy.

Does presplenectomy response to steroid therapy predict platelet response to splenectomy? Mintz et al.[22] observed a postsplenectomy remission rate of 92% in patients who had responded to steroids before operation and only a 68% response rate in those who had not shown response to preoperative steroids. However, the complete remission rate reported by others among patients who showed preoperative response to steroids ranged from 67–82%[23–25] and was not different from the overall response rate of 56–85% (Table 4). In the current study none of the 75 patients who had a sustained response to immunosuppression and who could tolerate steroids needed splenectomy (Fig. 1).

Although some previous reports suggest that a long duration of medical therapy before splenectomy is associated with poor response,[22,26–28] the current data suggest that the longer duration of medical therapy among the nonresponders reflects a selection bias on the part of primary physicians who were reluctant to refer older patients for surgical therapy. Age was an important predictor of response in the current study as the nonresponders were significantly older than the responders (Fig. 4). These observations concerning the predictive value of age are similar to those previously reported by Coon[21] and DiFino et al.[24] However, age did not appear to be a significant predictor of response in the series reported by Charlesworth and Torrance[29] and by Burger et al.[30]

The selection of patients with immune thrombocytopenic purpura for splenectomy on the basis of the form of disease was recognized very early. Splenectomy was

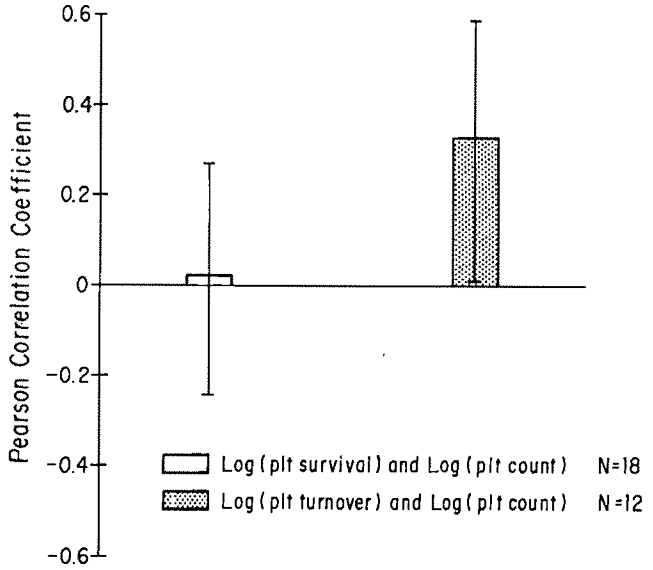

FIG. 5. Pearson correlation coefficients and relationship of preoperative indium 111 platelet survival and turnover to postoperative platelet count. No significant correlation exists between either presplenectomy log (platelet survival) and postsplenectomy log (platelet count) ($p = 0.9$) or presplenectomy (platelet turnover) and postsplenectomy log (platelet count) ($p = 0.3$).

advocated in the chronic form of ITP[2,31] and contraindicated in the acute form.[32] The acute form of the disease is seen most commonly in children and occurs 2–3 weeks after a virus infection. It often remits within 3 or 4 weeks and almost always within 6 months. Sixteen of our patients (6%) with a mean age of 9 years (range: 0.5–65 years) represented this group. The chronic form occurs most frequently in adults. The onset is insidious and is preceded by no infection or prodromes. Although some of our patients who had splenectomy were younger than 15 years of age and had had viral infections, their courses became more of the chronic type, with failure to remit after an average follow-up period of 15 months (range: 5–22 months). On the other hand, some of our adult patients had typical signs of viral illness.

The three patients who had urgent splenectomy deserve comment. Although we were reluctant to subject these difficult patients to urgent operation, their subsequently benign courses are a tribute to modern anesthetic and postoperative management. These early results encourage a continuing cautiously aggressive approach to patients in these desperate circumstances.

Platelet antibody titers failed to predict response to splenectomy as evidenced by almost similar regression lines before and after splenectomy for both responders and nonresponders (Figs. 2A and 2B). These observations confirm the earlier report of Kayser et al.[33] The strong inverse relationship between platelet count and platelet antibody titer in both responders and nonresponders, before and after splenectomy, confirmed the utility of the antibody titer as an adjunct in the diagnosis of ITP.

A correlation between the level of platelet associated IgG and the platelet count in ITP could not be confirmed by Kernoff and Malan[34] and by Kelton et al.[35]

We observed that among the responders the partial correlation coefficient between log platelet count and log antibody titer was significantly lowered by splenectomy. The coefficient among the nonresponders was unchanged by operation and was similar to that of the responders after operation (Fig. 3). An attractive hypothesis is that there is a difference in the rate of extent of clearance of platelets, initiated by the adherence of IgG-coated platelets to the surface Fc (IgG) receptors on tissue macrophages.[36] These receptors may be higher in number or may be better expressed in the spleens of responders. The number of receptors may not be as great and/or as well expressed in the spleen of nonresponders. Splenectomy would thus have little impact in this group of patients.

In newly diagnosed patients with ITP, Kernoff and Malan[34] described a significant correlation between the amount of platelet-bound antibody and the rate of platelet destruction. However, Mueller-Eckhardt et al.[37] could not correlate platelet-bound antibody with platelet survival. Although this relationship could not be examined in our patients, it is well established from our studies and others[38,39] that patients with ITP have low platelet survival. However, our study failed to confirm the value of presplenectomy platelet survival in predicting platelet response to splenectomy (Fig. 5). Moreover, platelet turnover, which reflects thrombopoiesis, ranged from subnormal to high in our patients and also failed to predict response to splenectomy (Fig. 5). Previous work by MacMillan et al.[40] has shown that cultured splenic cells in patients with ITP will synthesize IgG, which binds specifically to megakaryocytes. Other authors have also suggested that impaired thrombopoiesis plays a role in the pathogenesis of ITP.[41,42] This view might be supported by the subnormal range of turnover in some of our patients but is not true in the other patients with high turnovers. Our investigation also confirms that the pattern of presplenectomy platelet sequestration did not predict the outcome of splenectomy. This observation is in agreement with previously published chromium 51 and indium 111 studies, which show no association between the pattern of platelet destruction and platelet counts obtained after splenectomy.[39,43,44]

Although the labeling of platelets with indium 111 oxine has many advantages over the chromium 51 label for the study of platelet kinetics,[45,46] the superior gamma emitting properties of indium 111 allows more accurate

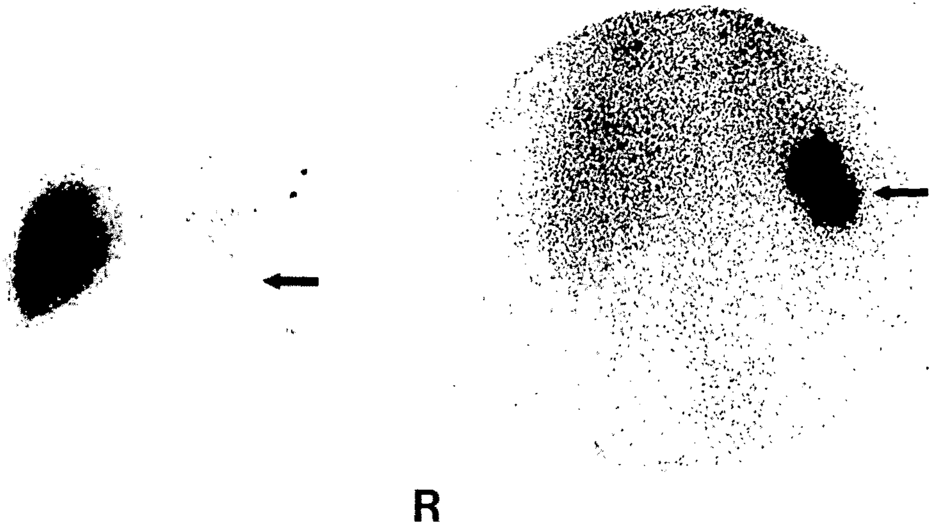

FIG. 6. Technitium 99m sulfur colloid scan (*left*) barely shows uptake in left upper quadrant accessory spleen in this previously splenectomized patient. The indium 111-labeled platelet scan (*right*) of the same patient clearly images the large accessory spleen confirmed at operation.

quantitation of absolute levels of activity within organs by quantitative scanning with the gamma camera.[47,48] This makes indium 111 an invaluable tool in the detection of accessory spleens (Fig. 6). Since the implication of an accessory spleen in the recurrence of ITP was suggested by Finkelstein[49] and the first evidence of its involvement in recurrent ITP by Morrison et al. in 1928,[50] various techniques have been used in its detection, including exploratory laparotomy,[51] thorium dioxide scans,[52] technitium sulfur colloid scans,[53] abdominal ultrasonography,[54] CT scan of the abdomen,[55] labeled RBC,[56] and indium 111-labeled platelet scan.[57] Although each modality enabled the detection of accessory spleens, there are not enough cases to compare one method with another except in one series where Tc 99m sulfur colloid was found to be inferior to CT scan and radiolabeled RBC opsonized with anti-D IgG.[58] We believe that the indium 111-labeled platelet scan offers the advantage of increased sensitivity and the possibility of studying platelet kinetics.

Re-exploration of the abdomen, especially of the left upper abdominal quadrant after initial splenectomy, may be difficult since the accessory spleen may be concealed by fat, adjacent organs, or scar tissue. Even though the location of the accessory spleen is suggested by a preoperative scan, this gives information only about the general location of the tissue. The use of a hand-held isotope detector probe during operation for this purpose was recently introduced by Wallace et al.[59] who used Tc 99-labeled RBC. We could detect accessory spleens as small as 0.5 cm using indium 111-labeled platelet scan and the intraoperative probe, and found another accessory spleen during a second operation in a patient using this method that was previously missed by a technitium 99 sulfur colloid scan.

The high incidence of accessory spleens found in the current study (18%) at the time of primary splenectomy, especially in the younger patients, should encourage a thorough search for accessory spleens and an aggressive approach looking for them in patients who do not respond to primary splenectomy. We are more enthusiastic about this approach because of the successful results in six (67%) of our nine patients and by the good results published by others in a total of 56 patients[51-66] and in whom the response was excellent in 41 patients (73%)[51,53,55,61,63-66] and moderate in the others (27%).[51,52,54,58,62,64-66]

However, an accessory spleen is not the cause of a relapse or poor response in the majority of patients. Although our nonresponders continued to be free of other diseases during their follow-up period, the association of ITP and other diseases should be kept in mind. Nonresponders should be continuously screened. Seventy-four of our patients (28%) (Fig. 1) had secondary ITP. Twenty-four had splenectomy before the primary disease was manifested. Connective tissue disorders and hematologic malignancies accounted for more than half of these cases of secondary ITP. Dameshek found that eight of 51 patients followed after primary splenectomy had definite SLE and two more had probable examples of that disorder.[67] Other reports have indicated the association of ITP with hematologic malignancies,[68-71] pregnancy,[72] hemolytic anemias,[7] and homosexuality,[73] as well as during infections.[74] The induction of thrombocytopenia by drugs such as quinidine has been said to be self-limited after discontinuation of the drug.[75] However, 10 of our patients who received diazide or quinidine progressed to chronic ITP requiring splenectomy.

Although the platelet antibody measured in the different states of secondary ITP may not be the same,[76] these observations tend to suggest that ITP is part of a more complex immune disorder. Transfusion of these patients with platelets and blood products may help in the development of isoantibodies to platelets and makes preparation for splenectomy with corticosteroids an attractive option in responsive patients. Our preliminary success with intravenously administered gamma globulin in the preparation of some of our patients for operation offers yet another option that, although currently limited by its great expense, deserves further study.

Conclusions

Although it is currently offered only to those patients in whom ITP is refractory to immunosuppressive therapy or in whom complications of steroid therapy develop, splenectomy continues to be efficacious in inducing remission of ITP in the majority of patients. Because older patients with ITP are less responsive to splenectomy, the notion that nonresponders are treated medically for longer periods before splenectomy probably reflects the selection bias of primary physicians who are reluctant to refer older patients for surgical therapy.

Although platelet antibody titer and platelet survival and turnover studies using autologous indium 111-labeled platelets were important adjuncts in the diagnosis of ITP, these tests did not predict platelet response to splenectomy in the current study. However, patients who relapse or have persistent ITP after primary splenectomy should be scanned for accessory spleens using indium 111-labeled platelets. These accessory spleens are easily localized during operation by a hand-help isotope detector probe.

DISCUSSION

DR. A. AUFSES (New York, New York): Dr. Akwari and his colleagues are to be congratulated for presenting a beautifully documented series of 100 patients operated on for idiopathic thrombocytopenic purpura (ITP) over a 10-year period.

The manuscript that I was privileged to review is replete with extensive, prospectively derived hematologic observations and the discussion section is most complete and superbly written. I recommend its reading to all of you.

I would like to limit my remarks and questions to only one aspect of this very complete review. That is, the role of the accessory spleen in the failure of response to primary splenectomy.

Autopsy studies have shown about a 10% incidence of accessory splenic tissue. In 1969, Olsen and Beaudoin reported a large series of splenectomies performed in Ann Arbor. At operation for nonhematologic causes, the incidence of accessory splenic tissue was 4%. This incidence rose to 25% when operation was performed for either ITP or autoimmune hemolytic anemia. In that paper the authors cautiously point out that bias may have entered the picture since a more diligent search for accessory spleens was probably carried out in those patients operated on for hematologic disease.

In 1984, we reported a consecutive series of 69 patients operated on for ITP. Of 60 initial complete responders, three relapsed at 1, 2, and 5 years after operation. Nine patients were either partial or nonresponders. All 12 patients had technetium scanning and no accessory tissue was identified. We do, however, have one patient who had the primary splenectomy performed elsewhere and then relapsed after a number of years. An accessory spleen was identified by scan. This was removed by Dr. Isadore Kreel of our faculty and the patient has had a complete and sustained response.

Returning to Dr. Akwari's most interesting data, 18 accessory spleens were found at primary splenectomy in the 100 patients. Fifty-eight patients had an immediate excellent response. Of 13 patients with a poor response, five required accessory splenectomy, not recognized at the first operation, and scanning of 29 nonresponders identified seven more patients with accessory spleens of whom four were operated on. These were also not recognized at the first operation.

This gives us at least 30% of the original group of 100 patients with accessory splenic tissue, a very high percentage indeed. Might not it have been even higher?

It has been shown that it is possible in ITP to have a prolonged good response to splenectomy and still have occasional splenic tissue present. In fact, in the Duke series, four of the nine patients who had accessory splenic tissue removed at a second operation had had a response to primary splenectomy that lasted from 2 to 10 years.

My questions to the authors then are: (1) Is it not possible that some of the patients in this series as well as ours and others might still have splenic tissue remaining and be doing well? (2) Is there any explanation as to why some patients with accessory spleens will do well for prolonged periods after primary splenectomy for ITP and others do not? (3) Is it possible that some of the "accessory spleens" found at subsequent surgery were not present originally, but might represent nodules of splenic tissue developed after a fragment of spleen is spilled at the primary operation? In other words, a form of localized splenosis. Seeing the movie just now, it is hard to believe that those two lesions could have been missed at the primary operation. The first one was in the original hilum of the spleen, the second was 7 cm in diameter. Could this development of localized splenosis be the responsible agent for the late relapses? (4) Since indium-11 appears to be a more sensitive scanning isotope than technetium, should all patients who have surgery for ITP have a preoperative scan?

With a high incidence of accessory spleens, scanning might be cost effective when compared with the cost of a second operation. Certainly there is nothing more frustrating for a surgeon than to perform a splenectomy for ITP, not get the platelet response hoped for, and then worry whether an accessory spleen was left behind, or whether the patient does, in fact, have a different diagnosis?

DR. WILLIAM W. COON (Ann Arbor, Michigan): Dr. Akwari asked me yesterday to make a few brief comments concerning his manuscript. We have few differences of opinion. The immediate and sustained response rate in our recently reported series is almost identical with Dr. Akwari's. I believe one of the major points that Dr. Akwari has made, and we would certainly agree with, is that there currently is no way in a given individual to predict whether he or she will respond to splenectomy. We know some statistical bases that can help in predicting response; for example, age, as Dr. Akwari pointed out. Another observation we made is that the response rate, as you might expect, is higher in patients who respond to a burst of high-dose steroids, particularly if the platelet count goes above 100,000/mm^3. On the other hand, about half of the patients who do not get a response above 50,000/mm^3 with steroid bursts still get a response of splenectomy. Although the odds go up, there is no certainty as far as that is concerned.

We also have been unimpressed with the predictive value of platelet antibody studies. There has been no correlation in our hands between platelet antibody titers and whether the patient is going to respond to splenectomy.

One difference of opinion that we have is that we seldom believe that we need to give platelet transfusions to our ITP patients unless the platelet count at the time of operation is 20,000/mm^3 or below. In our big hematologic center we have a greater need for platelets than the supply at any given time. The ITP patient, compared with patients with other hematologic problems, has young, very hyperfunctional platelets that are circulating, and we have not encountered any bleeding problems in recent years in greatly restricting the use of platelet transfusions.

As Dr. Aufses implied, we also have been somewhat skeptical about the value of accessory splenectomy in patients who are nonresponders. Certainly there is every reason to scan a patient who responds initially to splenectomy and then relapses later. I believe there is some correlation between the size of the accessory spleen that one may encounter and the predictability of response to accessory splenectomy, and in the scan that Dr. Akwari showed, certainly with that huge splenic remnant, there would be a good chance for response, but we have performed accessory splenectomy on a number of patients without seeing any response in their recurrent thrombocytopenia.

Another observation that we have made is that, of our nonresponding patients, less than 20% are on any long-term ancillary therapy for their thrombocytopenia. Many patients will function very well with platelet counts between 50,000/mm^3 or even 30,000/mm^3 and 150,000/mm^3 without needing any subsequent treatment. The majority of those who are on any therapy are on a relatively low-dose chronic prednisone treatment.

I believe we can limit the use of cyclophosphamide or vincristine with all their potential toxic effects because even the nonresponders seldom need it.

DR. CHARLES L. WITTE (Tucson, Arizona): I congratulate the authors on their remarkable series and on an ingenious method to detect these spleens at operation. On the other hand, as some of the other discussants implied, I also interject a word of caution about the real implications of these accessory spleens. Some years ago Crosby suggested (N Engl J Med 1972; 286:1252–1254) that small remnants play little or no role in ITP, which displays great clinical variability in terms of platelet response as well as need for prolonged follow-up to ensure that these small remnants or their removal truly exert an impact on the peripheral platelet count. We are all familiar with the improved response of children over adults to splenectomy. When an IgM protein coats the peripheral platelets, as in adults, both the liver and the spleen prematurely extract platelets from the blood circulation, whereas when platelets are coated by IgG alone, as in children, splenectomy is usually highly effective.

I would like to describe three patients with ITP from my experience whose findings cast doubt on the importance of small accessory spleens in influencing the peripheral platelet count. Although I would not recommend the first approach, it nonetheless is noteworthy that one of my colleagues, a pediatric surgeon in Tucson, some years ago in a 5-year-old boy with a very low peripheral platelet count opted to do a splenectomy, which was entirely appropriate, and then placed small autoremnants into the anterior abdominal wall as an implant, presumably to protect against overwhelming sepsis. A technetium sulfur colloid scan at 2 months failed to reveal remnant tissue, and the peripheral platelet count was normal. About 2 years later, the mother returned and inquired about a palpable nodule in the boy's abdominal wall. A radionuclide heat-damaged red cell scintiscan was then obtained (slide), and on the lateral view right beneath the skin a splenic remnant is clearly visible. The child's platelet count was still 350,000/mm^3, and 4 years thereafter the platelet count remained normal despite persistence of the splenic nodule. Unfortunately over the past 1.5 years he has disappeared from follow-up.

A second patient was a 5-year-old girl (slide) in whom I tried some years ago to regulate splenic function by ligating the splenic artery close to the hilum. Subsequently I have learned that because of a rich peripancreatic and gastric collateral circulation, the effectiveness of this procedure is only temporary. Nontheless, her peripheral platelet count, which had been less than 20,000/mm^3 for over 1 year, rose promptly after operation but thereafter fluctuated widely. Four months after splenic artery ligation she demonstrated a normal splenic image on radionuclide scintiscan and her blood platelet count 12 years later is now 300,000/mm^3. She menstruates without excessive bleeding.

The final patient is a young man with Evans syndrome, which is both an autoimmune hemolytic anemia and thrombocytopenic purpura. He initially did well after splenectomy, but returned 15 years later with recurrence of thrombocytopenia, and a prominent splenic remnant was detected. This splenic fragment was removed and again he had a prompt rise in the blood platelet count. Within 6 months, however, the peripheral platelet count again dropped to 22,000/mm^3 despite lack of a residual spleen.

These patients with ITP highlight the variable nature of peripheral platelet count with and without remnant spleens and suggest that we should exert extreme caution in ascribing the clinical outcome to small residual splenic fragments after splenectomy. They also emphazise again the need for prolonged follow-up given the wide fluctuation in platelet count and even spontaneous remissions that may occur in ITP.

DR. ONYE E. AKWARI (Closing discussion): I am most grateful to the discussants. The points raised are all most interesting and reveal our ignorance in this disease.

One can say that ITP, an immune disorder, is not primarily a surgical disease, and requires close collaboration between the surgeon and the hematologist for optimum management. We continue to learn a lot from this team approach.

Dr. Aufses, I believe that splenosis is well documented in the literature, and as I remarked in my presentation, we do exercise great care not to spill any splenic tissue because of that eventuality, and the possibility of iatrogenic splenosis. I do not know, however, that there is proof that splenosis *per se* relates to recurrence of this disease. I know of no specific evidence that splenosis tissue is immunologically viable or can lead to the phenomena that are observed in this disease.

It is true that a large number of the patients have relatively large accessory spleens, but in some of these patients we found accessory spleens less than 1 cm in greatest diameter. Still when the splenic tissue was removed, the patients had a sustained response, with normal platelet counts during several years of observation. All we can conclude is that the accessory spleen must have had something to do with the disease in these patients, but the exact mechanism of its function remains to be fully elucidated.

The 30% incidence of recurrent ITP observed in this series is high. I believe it is because we search unusually meticulously for accessory spleens. I have no further explanation for that.

Dr. Coon raised many good points, and I would agree with him that currently we do not have any way of predicting response in any one patient, but therein, I believe, lies a challenge for the future.

I enjoyed seeing the transplanted splenic tissue in the abdominal wall, and was pleased to learn that the patient is doing well. I would agree with you that one would not advise doing that on a routine basis. I believe, however, that our data would suggest that the patient in question merits close observation.

Recurrence of ITP after previous accessory splenectomy occurred in one of our patients, and this was before we established our current techniques of intraoperative localization. In that patient, I believe it was patient No. 5 in our series, we identified additional accessory splenic tissue on a subsequent scan and performed repeat accessory splenectomy. The patient now enjoys a total response. One would have to conclude, cautiously, that in cases of initial failure, re-examination and repeat accessory splenectomy may be helpful in those selected cases in whom unequivocal evidence of additional splenic tissue is found.

Management of Infected Pancreatic Necrosis by Open Drainage

EDWARD L. BRADLEY III, M.D.

From the Department of Surgery, Emory University, Atlanta, Georgia

Twenty-eight consecutive patients with infected pancreatic necrosis were managed by extensive unroofing of the superior retroperitoneum, blunt pancreatic sequestrectomy, laparotomy pad packing of the lesser sac over a layer of Adaptic® gauze, and scheduled re-explorations at intervals of 2–3 days (open drainage). Wounds were permitted to heal by secondary intention. All patients were maintained on intravenous hyperalimentation. Three of the 28 patients died (11%); none died of sepsis. Procedure-specific complications included: pancreatic fistula (10 patients), incisional hernia (8 patients), persistent functional gastric outlet obstruction (2 patients), retroperitoneal venous hemorrhage (2 patients), and intestinal fistula (1 patient). Limited initial experience with dynamic pancreatography and serial monitoring of acute phase reactants as indicators of pancreatic necrosis is promising. Compared with historic controls, open drainage of infected pancreatic necrosis represents a significant advance over more conventional surgical approaches. Controlled studies and more widespread experience are necessary for further evaluation of this procedure.

DESPITE SIGNIFICANT recent advances in supportive therapy and intensive care, the mortality rate from acute pancreatitis has remained constant for more than 40 years.[1-3] Today, few patients die of the well-recognized consequences of hypovolemia induced by acute pancreatitis. Rather, the development of sepsis has emerged as the principal determinant for survival in patient with acute pancreatitis surviving longer than 7 days.[2-4] In this regard, it would seem that our previous efforts to reduce mortality in acute pancreatitis have served to change the mode of death from fluid deficit to septicemia.

Pancreatic abscess is a particular case in point. In 1963, Altemeier and Alexander recommended anterior celiotomy, identification and debridement of necrosis, and closed drainage for patients with pancreatic abscess.[5] In the 25 years that this conventional surgical approach to pancreatic sepsis has been used, mortality rates have remained unacceptably high, ranging from 30–60%.[6-11] Furthermore, as many as three fourths of the deaths *after* conventional surgical debridement and drainage for pancreatic abscess have been due to sepsis.[12] These observations cast serious doubt on the efficacy of the conventional surgical approach to the management of these patients. It is becoming increasingly clear that if we are to reduce mortality in acute pancreatitis, additional approaches to the various forms of pancreatic sepsis must be sought.

Recently, infected pancreatic necrosis has become recognized as the most severe form of pancreatic sepsis, with surgical mortality rates greater than twice those of classical pancreatic abscess.[13] The current report details a 10-year personal experience using an alternative surgical procedure (open drainage) in the management of these difficult patients with infected pancreatic necrosis.

Patients and Methods

The patient population consists of 28 consecutive patients with surgically proved infected pancreatic necrosis who were seen at Grady Memorial Hospital and the Atlanta Veterans Administration Hospital during 1976–1986. Previous communications have described our earlier experiences with these patients.[14,15] Each patient had an antecedent episode of *severe* acute pancreatitis as stratified by two independent clinical classification systems (Table 1). The anticipated overall mortality rate for acute pancreatitis of this severity exceeds 50% in both systems.[9,16]

Presented at the 107th Annual Meeting of The American Surgical Association, Palm Beach, Florida, April 21–23, 1987.

Reprint requests and correspondence: E. L. Bradley III, M.D., Department of Surgery, 1968 Peachtree Rd., N.W., Atlanta, GA 30309.

Submitted for publication: April 24, 1987.

The cause of the acute pancreatitis was believed to be alcohol in 19 patients, gallstones in three patients, Type IV hyperlipidemia in two patients, hyperparathyroidism in one patient, and three cases of acute pancreatitis were classified as idiopathic. There were 20 men and eight women with an average age of 46.1 years (range: 36–85 years).

In the initial phase of the study, the diagnosis of infected pancreatic necrosis was primarily one of suspicion; *i.e.*, progressive deterioration in a septic patient with antecedent pancreatitis. Later, computed tomography (CT) became of considerable assistance to the clinical diagnosis. Most recently, bolus contrast enhanced CT scans (dynamic pancreatography), guided needle aspiration bacteriology, and serial serum monitoring of acute phase reactants have materially assisted the clinical diagnosis of infected pancreatic necrosis. Bolus contrast enhanced CT scans were performed by the administration of iodine contrast material (400 mg/kg) by pressure injection through a large central vein catheter over 10–20 seconds. Serum levels of C-reactive protein, α-1 antitrypsin, and α-2 macroglobulin were monitored every other day in the last four patients.

Surgical exploration was begun in each patient by a left subcostal incision. Pancreatic necrosis was considered to be present when the typical grey-black necrotic material of putty-like consistency with surrounding turbid fluid was found in the lesser sac. Considerable effort was spent in determining whether the necrotic material was pancreatic or peripancreatic tissue. It was estimated at the operative table that pancreatic necrosis exceeded 30% of the gland in each of these 28 patients. Exposure of the splenic or superior mesenteric veins after debridement of the necrotic tissue greatly assisted this determination. When pancreatic necrosis was established as being present, the incision was extended and extensive unroofing of the retroperitoneum, sequestrectomy, and open packing of the lesser sac over Adaptic® gauze was carried out as previously described.[15] Pancreatic necrosis was considered infected only when smears or cultures of the necrotic material were positive for bacteria. After operation, additional debridement was carried out and dressings were changed in the operating room under light inhalation anesthesia at 2–3-day intervals. After three to five such re-explorations, dressing changes were done at the bedside. Wounds were permitted to heal by secondary intention. All patients were managed by intravenous hyperalimentation until oral feedings were resumed. Needle catheter jejunostomy for enteral feeding access has been added in recent patients.

The duration of hospitalization in these 28 patients ranged from 31 to 96 days (mean: 46 days). This time is not appreciably different from the 50–70 days required for drainage by the conventional surgical approach.[7,17,18]

TABLE 1. *Stratification of Severity in 28 Patients with Infected Pancreatic Necrosis*

Staging System	Average # Criteria (Range)	Expected Surgical Mortality Rate
Ranson and Spencer[9]	5.3 (3–8)	65%
Bank et al.[16]	1.6 (1–4)	56%

In the 10 most recent patients who had open drainage, the average length of postoperative recovery was 39 days.

Results

Twenty-five of 28 patients treated by open drainage survived (11%). A 75-year-old woman died of autopsy-proved myocardial infarction 21 days after surgery. Massive aspiration after attempts at enteral feeding for persistent gastric outlet obstruction was responsible for the death of a 65-year-old man 87 days after surgery. Sudden death in a 47-year-old man 60 days after surgery was attributed to air embolism from a disconnected hyperalimentation catheter. In none of the three deaths was persistent or recurrent sepsis a factor.

Particularly impressive was the amount of additional necrotic and infected material that was found at the scheduled re-explorations. Reaccumulation of such materials, and the discovery of additional pockets of infected necrosis at scheduled dressing changes, occurred in each patient in this series. In general, the discovery of additional necrosis became less frequent in the individual patients as granulation tissue began to appear in the base of the lesser sac. In some patients, granulation tissue began to occur as early as the third dressing change. The predominant bacteria cultured from the necrotic tissue are shown in Table 2. Anaerobic bacteria (principally bacteroides) were also cultured in seven of these patients.

Despite favorable mortality, considerable morbidity attended the hospital courses of these patients. In addition to the known pulmonary, renal, metabolic, hematologic, and regional consequences of severe acute pancreatitis, a number of complications seemingly specific

Persistent	2	
Retroperitoneal hemorrhage	2	7
Intestinal fistula	1	4

for open drainage occurred (Table 3). Pancreatic fistula occurred in 10 patients but could be managed by conservative means in each patient. Somewhat surprisingly, incisional hernia developed in only eight patients, despite extension of the initial left subcostal incision to a bilateral subcostal incision in 26 of 28 patients. Gastric outlet obstruction was noted in six patients, and was persistent in two patients. Unfortunately, both of the latter patients died as a direct result of attempts to find alternate methods of nutrition. Two additional patients had major retroperitoneal venous hemorrhage from the portal system (one splenic vein and one superior mesenteric vein). These episodes were controlled with great difficulty by a combination of pressure and clotting agents. Early in our experience, we attempted to accelerate wound healing by sewing synthetic mesh to the abdominal wall. In one of the two patients in whom this technique was used, a jejunal fistula developed from contact with the mesh. This approach is no longer used and wounds now are permitted to heal entirely by second intention.

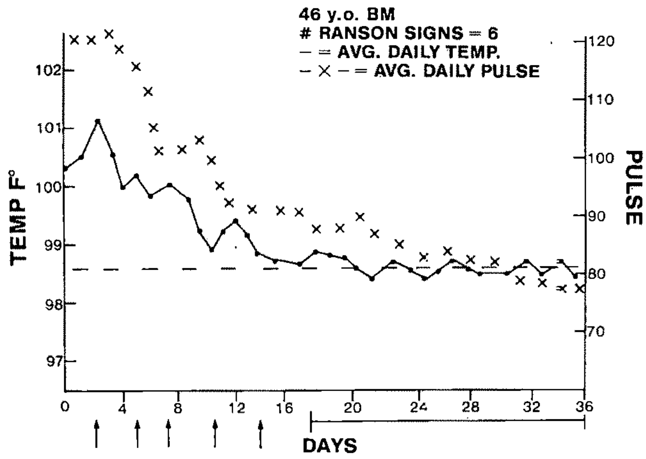

FIG. 1. Hospital course of a recent patient with infected pancreatic necrosis treated by open drainage. Arrows represent re-exploration in operating room; daily dressing changes on ward are shown by solid line.

Most importantly, none of the 28 patients subjected to open packing and scheduled re-exploration had persistent or recurrent sepsis. A representative hospital course from a recent patient is seen in Figure 1.

Dynamic CT pancreatography was correctly predictive of pancreatic necrosis in the four patients in whom it was used (Figs. 2 and 3).

Severely elevated serum levels of C-reactive protein (205 ± 30 mg/L SEM; NL < 40 mg/L) and α-1 antitrypsin (6.1 + 1.8 g/L SEM; NL 1.5–3 g/L) along with depressed valves for α-2 macroglobulin (1.5 ± 0.6 g/L SEM; NL 2.3–2.7 g/L) were found before operation in the last four patients with infected pancreatic necrosis. Values tended to normalize as the necrotic process was controlled.

Discussion

In recent years, the clinical course of patients with severe acute pancreatitis has changed. Formerly, the majority of deaths occurred early in the course of the disease, and were principally due to the consequences of hypovolemia.[1–2] More recently, however, advances in resuscitative and supportive management have all but eliminated dehydration as a mechanism of death in these patients. As a consequence of an increase in the length of patient survival, the later complications of severe acute pancreatitis (*i.e.*, necrosis and infection) are being recognized with increasing frequency. Sepsis has now become the most common cause of death in patients with acute pancreatitis who survive the first week of illness.[2–4] However, since the *overall* mortality rate in acute pancreatitis has not changed during this same period,[1–3] it seems clear that we must shift our attention to the management of sepsis if we are to make further progress in reducing mortality.

After the original morphologic classification of "hemorrhagic, suppurative, and gangrenous pancreatitis" by Fitz in 1889,[19] over 30 years passed before Moynihan recommended anterior celiotomy, debridement, and external drainage for patients with pancreatic abscess.[20] However, it was not until the landmark report of Altemeier and Alexander in 1963,[5] that these principles were widely adopted. In the 25 years that this conventional approach has been followed, operative mortality rates have remained in the range of 30–60%.[6–11] Periodic dissatisfaction with such results seemed to have been centered around the number and the types of drains used; the majority opinion being that sump suction was superior to other forms of drainage.[6,7,9,21] However, three of the largest surgical series of pancreatic abscess using the conventional approach failed to demonstrate any difference in survival regardless of the type or number of drains used.[8,10,22]

Why should the results of surgical drainage in pancreatic abscess be so greatly inferior to abscesses of other tissues? It has been claimed that 40% of patients who have conventional surgical drainage for pancreatic abscess will require re-exploration for persistent or recurrent abscesses.[23] Other workers have also noted a disturbingly high incidence of recurrent postoperative sepsis.[6,7,10,22,24,25] In an extensive review of the reported cases of pancreatic abscess in which the cause of death could be determined, we found that 76% of the postoperative deaths after conventional surgical drainage were due to sepsis.[12] These observations are sufficient to indict the conventional surgical approach. Fry and coworkers have also concluded that ineffective surgical drainage is primarily responsible for postoperative mortality in patients with intra-abdominal abscess.[26]

Why should the rate of persistent or recurrent sepsis be so high after conventional surgical drainage for pancreatic abscess? In addition to the observations that the retroperitoneum has few anatomic limitations to extensive tracking, and seems limited in its protective mechanisms against infection,[27] necrosis is a predominate feature of pancreatic abscess, and such particulate material cannot be drained by small caliber drains.[10,15,22,28] Recognition of pancreatic necrosis as a significant feature of pancreatic abscess has important clinical implications. Patients with infected pancreatic necrosis have a significantly higher mortality rate, more severe pancreatitis, increased renal insufficiency, and more profound metabolic aberrations than do patients with the more classical purulent forms of pancreatic abscess.[13] In view of these observations, a precise morphologic definition of any septic retroperitoneal process is clearly required.

Survival figures for "pancreatic abscess" may therefore be influenced either favorably (by inclusion of infected pseudocysts, suppurative peripancreatic abscess, and possibly even nonpancreatic lesser sac abscesses) or unfavorably (by including infected pancreatic necrosis). Many examples of such favorable definitions appear in the literature. In a recent review of 112 articles dealing with pancreatic abscess, we found that *only ten* authors even offered operational definitions of pancreatic abscess.[29] No two definitions were the same, and only two groups defined "pancreatic abscess" as necrosis. In view of the significantly greater mortality and morbidity of infected pancreatic necrosis, it is important that future reports distinguish between these conditions and recognize infected pancreatic necrosis as a separate clinical entity.

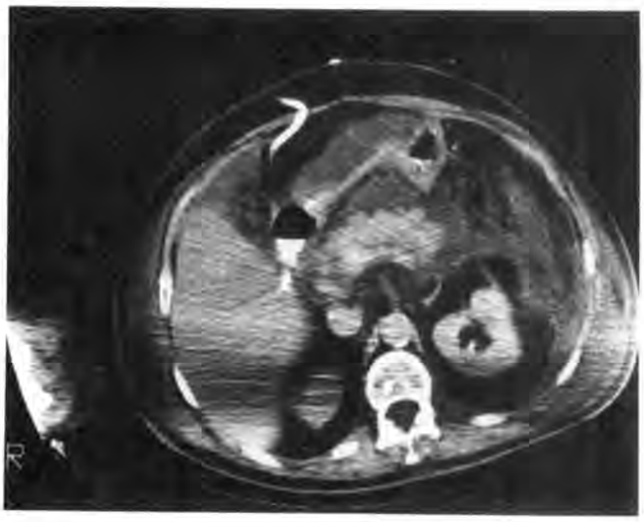

FIG. 2. Dynamic pancreatogram depicting absence of pancreatic parenchymal opacification in tail of pancreas. Necrosis of the tail of the pancreas was confirmed at surgery. Pancreatitis developed after common duct exploration (note T-tube).

The low mortality rate in the current series of patients with infected pancreatic necrosis treated by open drain-

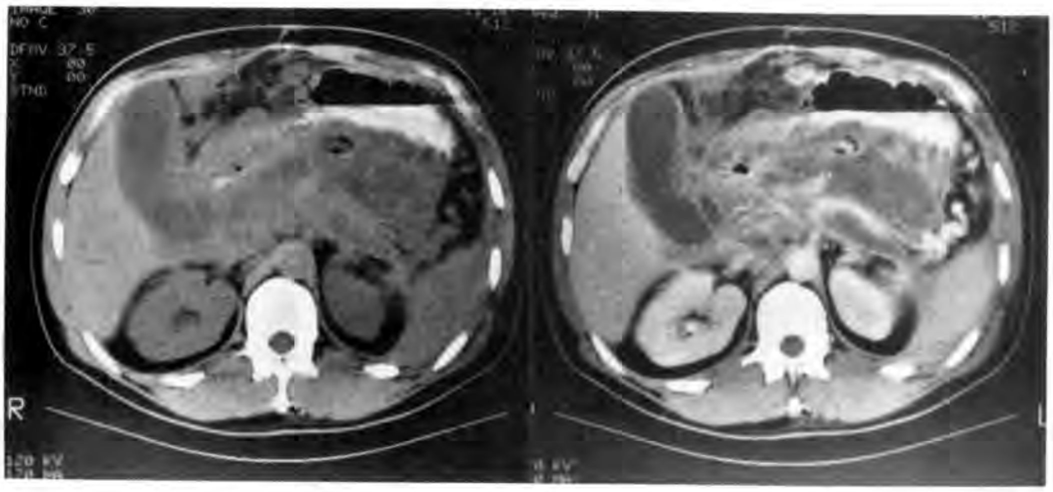

FIG. 3. Differential diagnosis of pancreatic necrosis by dynamic pancreatography. Process shown by conventional CT on left could represent either phlegmon or necrosis. After intravenous bolus of contrast material (note contrast in aorta), no pancreatic tissue could be opacified. Surgical exploration revealed extensive pancreatic necrosis.

age compares favorably with the 30–60% mortality rates from previous reports of "pancreatic abscess" using conventional drainage.[6–11] The comparison becomes even more favorable when it is appreciated that in many of the previous series pancreatic abscess was not defined as adversely as in the current report.

Dismayed by a 55% surgical mortality rate for patients with infected pancreatic necrosis treated by conventional surgical drainage in our own institution, in 1976, we devised the concept of open drainage to combat the problem of continuing necrosis and reaccumulation of purulent material after conventional drainage.[14] At that time we were unaware of previous efforts in the use of this principle. In 1928, Schmeiden and Sebening recommended that after exploration for pancreatic necrosis, "the incision should be kept wide open for many weeks because of the persistent wound and pancreatic enzyme secretion and also because of the extremely long time required for the discharge of the gland sequestra."[30] In 1968, Bolooki and co-workers reported suturing the wall of pancreatic abscesses to the abdominal skin (marsupialization) with successful results.[28] The current technique of open drainage differs from these historic precedents by extensive unroofing of the retroperitoneum, the use of nonadherent Adaptic® gauze, and scheduled re-explorations with additional debridement and dressing changes.

Favorable experiences with open drainage are also being accumulated by other workers. Pemberton and his colleagues reported a 20-year longitudinal comparison of open drainage (17 patients) with conventional closed drainage (64 patients) in which they found a significant decrease in mortality rate when open drainage was used (18% *vs.* 44%; $p < 0.05$).[31] Wertheimer and Norris salvaged 8 of 10 deteriorating patients with necrotizing pancreatitis and persistent sepsis after conventional surgical drainage by converting each case to open drainage.[32] Vogel and his associates have successfully managed 11 consecutive patients with infected pancreatic necrosis by open drainage (Vogel S, personal communication, 1987). Waclawiczek et al. reduced their surgical mortality rate in infected pancreatic necrosis from 70% using conventional surgical drainage to 17% in a group of 17 patients treated by open drainage.[33] Each of these workers have also attributed the reduction in mortality rate with open drainage to the removal of reaccumulated necrotic and infected material by the continued debridement of scheduled re-exploration and dressing changes. We continue to believe that reaccumulation of necrosis and infection accounts for the high incidence of postoperative sepsis after conventional debridement and drainage, and ultimately results in increased mortality.[14]

Warshaw and Jin have taken issue with the necessity for open drainage in patients with pancreatic sepsis, citing a 5% mortality rate for conventional closed drainage in 45 patients with "pancreatic abscess."[34] Compared with previous studies using similar conventional surgical drainage, they attribute their greatly improved survival rates to earlier diagnosis and surgical intervention, extensive debridement and drainage, and improved postoperative care. Unfortunately, they did not define "pancreatic abscess" as adversely as infected pancreatic necrosis, nor did they stratify the severity of the underlying pancreatitis. Each of these factors is known to significantly affect mortality rate.[2,13] Furthermore, Pemberton and co-workers separated their data on 81 patients with pancreatic abscess into three time periods and could not demonstrate any recent increase in survival, which if present, might have been attributable to earlier diagnosis by computed tomography or to recent improvements in intensive care.[31] These observations suggest that apples and oranges remain incomparable.

Three complications of open drainage that could be considered procedure-specific require further comment. In the Mayo Clinic series, an enteric fistula developed in 31% of patients, presumably resulting from the frequent dressing changes.[31] We have continually advocated placing a porous nonadherent petrolatum gauze (Adaptic®) next to the intestine to prevent inadvertent intestinal debridement during frequent dressing changes,[14] an important step omitted in the Rochester series. Using this approach, only one of our 28 patients had an enteric fistula. Similarly, it is recommended that Adaptic® be used to cover any major veins exposed by the process of debridement to limit the frequency of major venous hemorrhage. Less major hemorrhage is easily controlled by the packing process. Finally, functional gastric outlet obstruction has been seen in six of our 28 patients. In each of the six patients, barium studies failed to demonstrate a mechanical cause. Since prolonged delays in gastric emptying have also been noted after conventional closed drainage,[6,8] it is possible that the observed functional obstruction in our patients represents a defect in gastric or duodenal motility caused by severe pancreatitis, rather than being due to the technique of open drainage. Nevertheless, since gastric emptying did not improve in two of the six patients despite intense medical management, and ultimately led to the death of both patients, needle catheter jejunostomy for subsequent enteral feeding is now placed in an uninvolved segment of jejunum at the original exploration.

Recognition of infected pancreatic necrosis can be difficult even using currently available diagnostic modalities. Bolus contrast enhanced CT scanning (dynamic pancreatography) appears to be particularly attractive in its ability to distinguish pancreatic necrosis from the less severe edematous pancreatitis. Kivisaari and his associates described significantly decreased contrast enhancement after a rapid bolus injection of contrast material (dynamic pancreatography) in a group of nine patients who had surgery for pancreatic necrosis.[35] In a prospective study using dynamic pancreatography, Block et al. correctly predicted the presence of pancreatic necrosis in 50 of 59 patients.[36] In the four patients in the current study in whom dynamic pancreatography was used, it was of material value in both the diagnosis of pancreatic necrosis and the timing of surgery.

Favorable experiences with serum monitoring of the acute phase reactants C-reactive protein, α-1 antitrypsin, and α-2 macroglobulin to indicate the presence of pancreatic necrosis are being accumulated by several groups.[37,38] Overall detection rates have been as high as 85–90% in small groups of patients. If these serum tests maintain similar accuracy in controls and larger groups of patients with acute pancreatitis, they will represent a significant diagnostic addition. We are continuing to collect data on these tests.

In agreement with others[39–41] it has been our experience that CT-guided fine needle aspiration for smear and culture can be a valuable adjunct in determining whether a given pancreatic process is sterile or infected. This technique may prove to be particularly helpful in evaluating whether pancreatic necrosis indicated by dynamic pancreatography or serum acute phase reactants has become infected.

Open drainage of infected pancreatic necrosis appears to represent a significant advance over previous conventional techniques. Although it is likely that the final form of open drainage has not yet been described,[42] the principles of management described in this report continue to be promising and merit further study.

Acknowledgments

The author expresses his sincere appreciation to the surgical housestaff and the nurses of the intensive care units without whose dedication and attention to detail such a study would not have been possible.

Discussion

Dr. Charles F. Frey (Sacramento, California): Dr. Bradley a number of years ago brought to our attention the open packing method of treating patients with infected necrosis of the pancreas and peripancreatic tissues. He has now accumulated a large experience and has achieved the lowest mortality reported for this otherwise lethal complication of pancreatitis. I believe Dr. Bradley's technique of dealing with infected necrosis represents a significant advance.

It is important to emphasize one semantic point that bears on this. That is, a well-loculated walled-off collection, whether it is called an abscess or an infected pseudocyst, is a different entity from infected pancreatic necrosis. Reports lumping the two together are mixing apples and oranges. Infected pancreatic necrosis occurs earlier after the onset of symptoms than an abscess. It consists of large segments of intact or infected particulate matter involving the pancreas and/or pancreatic tissues. It is usually associated with signs of gram-negative sepsis and can only be effectively managed by debridement or excision of particulate matter, and as Dr. Bradley is teaching us, by open packing and repeated debridement. The latter is made necessary by the fact that the combination of bacteria and enzymatic destruction of the pancreas and peripancreatic tissue continues after the initial debridement, creating new areas of necrosis. Abscesses, on the other hand, are easily managed by operative or percutaneous drainage as no new necrosis occurs after drainage.

I support the use of the open packing technique, which we use in our patients, as we believe it reduces the mortality and the length of hospitalization.

I would like to show two slides, and I would like comments from Dr. Bradley, which are little variations in technique.

Before we put in the open packing technique, we use a large Davol drainage catheter from one side of the abdomen to the other for irrigation purposes. (Slide) Then we place the adaptic gauze and packed over it.

The other thing I would like to ask Dr. Bradley about is that we have encountered patients in whom there has been hemorrhage at the time of the debridement with extension of infection into the spleen. We have found splenectomy should be performed under these circumstances to avoid further bleeding.

I would also like to ask the question of Dr. Bradley as to whether he has follow-up information on his patients after they have been discharged from the hospital. Dr. Braasch, a number of years ago, pointed out that many of the patients who had recovered from their pancreatic infections returned with complications of chronic pancreatitis.

Finally, I do not believe we can attribute all of the reductions in mortality to the open packing technique. The importance of other factors such as improved surgical intensive unit care, including monitoring, ventilator care, fluids and electrolytes, antibiotics and TPN, cannot be discounted and are, in my opinion, significant contributors to the reduction in mortality we are seeing in this disease.

Dr. Andrew L. Warshaw (Boston, Massachusetts): I rise in admiration of Dr. Bradley's continuing efforts to deal with these very ill patients, but I must say that I have to disagree with him on a number of points.

He and Dr. Frey have made the point that infected necrosis is different from an abscess. There is an element of difference in that some of these patients are more ill than others, but I submit that infection is not the primary difference, but whether or not there is ongoing necrotizing pancreatitis.

The infected necrosis patients do present earlier, at an average of about 10 days. The so-called pure pus collections are several weeks later, and they are often less ill but not always. At the time of operation the difference between infected necrosis and noninfected necrosis may be absolutely indistinguishable to the naked eye. It, therefore, may make little difference in terms of the treatment.

In terms of toxicity, Beger, whom Dr. Bradley quoted, has shown that the hemodynamic changes of necrotic tissue, whether or not infected, are virtually identical, and therefore, the toxic effects on the organism as a whole may be indistinguishable.

On the contrary, the patient with infected necrosis may be completely nontoxic. Percutaneous needle aspiration studies have shown in fact that a patient may have no signs of toxicity: no fever, leucocytosis or hemodynamic instability, and yet have bacteria present in the pancreatic necrosis. I remind you that Ranson's criteria are prognostic signs developed in the first 2 days of illness. They are not signs of what goes on 2 weeks later at the time of pancreatic abscess or infected necrosis.

The infection can set in as early as the fourth or fifth day, much earlier than we had previously suspected. This indicates that there may be a long indolent phase before it is clinically apparent. It would seem that the effects of infection and the ongoing enzymatic and necrotizing effects of pancreatitis combine early in some patients to generate a particularly fulminant course.

I find it difficult as well to accept the bland statement of how much of the pancreas is involved. Much of the lucent areas seen in these CAT scans is not pancreatic but peripancreatic fat. Since the tissue that is debrided is unidentifiable necrotic debris, I find it difficult to know how much of the pancreas is involved no matter how big the glob of swamp muck you pick out. In fact, as Bradley's figures show, few of these patients turn out to be diabetic in the long run. Although up to 80 or 90% has to be lost before producing diabetes, long-term studies do not show much pancreatic insufficiency after severe necrotizing pancreatitis.

The use of contrast-enhanced CT scanning is being suggested. This is a bandwagon that many are jumping on now. As far as I am aware, it has yet not been validated in any long-term study in Europe or here.

Finally, the statement that this is the best series in terms of reduction of mortality from this very difficult problem is a slight overstatement. Beger's own large study is reported as achieving about a 5% mortality rate with closed debridement and drainage. Although he does add local lavage catheters into the pancreatic bed, it is closed drainage, not packing. In our own series presented before this society 2 years ago, now up to 60 patients, the mortality over the past 7 years, and about 40 patients is also 5%. Our historical controls like Dr. Bradley's had a 40% mortality rate in the previous 5 years.

Therefore, what we are seeing in a number of different centers is a much improved survival rate resulting from a variety of different techniques: open packing, closed debridement and drainage (which is what we use), and Beger's closed debridement and drainage with addition of local lavage. Since all are accomplishing the same thing, it is probable that the common element is adequate debridement. Whatever else you do is probably less important and camouflages the basic issue.

I would like to ask Dr. Bradley at what point would he use needle aspiration techniques to determine whether or not there is infection, and would he use that information once he had it to decide whether or not to debride a patient who had extensive necrotic tissue? Do we really know the natural history of that dead gangrenous material well enough to sit back on any of them? Perhaps when the amount is small, but with large areas I am doubtful.

Dr. John M. Howard (Toledo, Ohio): I recently summarized 30 patients with massive pancreatic necrosis treated by external (closed) drainage. Debridement is the thing that I should like to emphasize as did Dr. Bradley. Repeated debridement was often required.

I would like to say that of the 30 patients, there was one death, a mortality rate of 3%. I should like to challenge my colleagues by saying that I believe in 1987, the mortality rate of acute pancreatitis should approach that of acute appendicitis. The mortality rate of pancreatic abscess should approach that of appendiceal abscess. The figures quoted in the past no longer are acceptable.

Could I show you a slide? (Slide) I would like to ask Dr. Bradley if this is a pancreatic abscess. Here is a woman 2 months into her illness. She has been receiving hyperalimentation, and is off and on antibiotics. She has been on a ventilator off and on for 2 months. The indication for operation was failure to thrive and delayed gastric emptying. Her temperature was 99–102 F over 2 months.

The lesser cavity is approached by laparotomy. A needle is inserted, and you see the pus exuding from the retroperitoneal tissue. The culture is negative. The gram stain is negative. There are many polymorphonuclear cells present.

The debridement continued with the hemostat inserted along the needle track and the massive retroperitoneal adipose tissue removed.

It is my belief that this may or may not be an abscess. The consistency and color suggests liquefying retroperitoneal adipose tissue. Perhaps we are looking at liquifaction of adipose tissue more than an exudate of infection.

I would like to show one other slide, (Slide) a patient who was operated on 11 months after the acute attack. The retroperitoneal tissue was debrided, and you see that over 11 months, this tissue had not liquefied.

It is my impression that the retroperitoneal tissue constitutes the majority of the necrotic tissue and that liquefaction in this relatively ischemic, more or less encapsulated space, proceeds very slowly.

Dr. John H. C. Ranson (New York, New York): I also would like to congratulate Dr. Bradley on the results he has achieved with this difficult problem using open drainage. Like the previous discussants, I agree that patients with infected necrosis require radical surgical debridement and that a readiness to reoperate and redebride necrotic tissue is an essential feature of their management. However, in evaluating the results reported today, it is critical to remember that major advances in diagnosis and supportive care have occurred in recent years and that the 40–60% mortality rate that Dr. Bradley ascribes to closed drainage is from an earlier era.

The report this morning prompted me to review our own experience with 29 consecutive patients managed over the past 4 years by debridement and wide, but closed section, drainage. The overall mortality rate in this group of patients was 17%, which, although not as good as that reported this morning, is much better than we had heard ascribed to this type of treatment. Among the patients who died, two deaths were cardiac without any residual sepsis, two deaths were related to hepatic failure in patients with associated cirrhosis, and one death was due to pulmonary embolism, in the only patient who died with uncontrolled sepsis. One third of the surviving patients required reoperation and redebridement, but two thirds required only one operative procedure for control of sepsis. In short, I believe that open packing may be a valuable approach for selected patients, but it is not needed for most patients.

Dr. Bradley reported in his abstract that his patients had more than 30% glandular necrosis, and like Dr. Warshaw, I would like to ask him how this was quantified. Certainly, contrast-enhanced computed tomography may not reliably differentiate, I believe, fluid from necrotic tissue, and certainly was not available, as Dr. Bradley said, for the whole period of his study. Measurement of weight of debrided tissue may be a valuable index of the extent of necrosis but cannot, I believe, reliably differentiate pancreatic from peripancreatic tissue necrosis.

If we did use this last criterion, our one death with uncontrolled sepsis would have been classified as having 100% necrosis, and, in this particular patient, this was combined with duodenal and colonic necrosis, which brings up my last question for Dr. Bradley.

Three, or about 10%, of our recent group of patients, have had necrosis of a portion of the duodenum in addition to their other infected necrosis. I would like to ask him if he has observed this problem, and if so, how does he approach it in his patients managed by open packing?

Dr. J. Pemberton (Rochester, Minnesota): Thank you for allowing me to read the manuscript and for extending an invitation to discuss this fine paper.

You are to be congratulated for achieving such an enviable mortality rate for one of the most devastating complications facing patients with pancreatitis.

I would like to lend support from our institution to you and to others who are attempting to define precisely the pathologic process of pancreatic abscess. Your term "infected pancreatic necrosis" is a good one, aptly descriptive and accurate. Such a term qualitatively describes a group of patients with pancreatic abscess who have the most aggressive form of this lethal complication.

Further understanding of this particularly difficult problem will be helpful in classifying such patients in the future. Moreover, you have nicely documented the severity of the predisposing episode of pancreatitis. The severity scores in your patients were high and consistent with an expected mortality of greater than 50%.

That the surgical procedure used achieved the desired goal is illustrated by the fact that no patient in your series had sepsis after operation. At Mayo, the persistent sepsis rate after operation was 47%, even after open drainage. We defined sepsis, however, based on both laboratory and clinical parameters, and I wonder if your definition and ours were the same? Nevertheless, we need to do better.

Your technique for open drainage deserves comment. As you might remember, in commenting on our report in 1985, you suggested protecting the base of the lesser sac and the abdominal viscera with Adaptic® gauze and/or Silastic® sheeting to decrease fistula and rebleeding rates. Indeed, the incidence of enteric fistula reported today is commendably low. I and others at our institution have heeded your advice, and in addition, in some cases have used a heavy plastic zipper, described by Stone, to prevent drying of those packs and subsequent debridement of the viscera.

Your report stimulated us to update the Mayo series of 81 consecutive patients with this problem. Eight additional patients were identified between 1985 and 1986. Of the five patients treated by controlled open drainage, one patient, or 20%, died. Of the three patients treated by closed drainage, all died. These most recent results, therefore, continue to support the use of open drainage in most patients with severe pancreatic abscess and necrosis.

I have two brief additional questions. Do you ever use a zipper?

Your 28 patients had 28 organisms cultured. Apparently no patient, therefore, had a polymicrobial infection. Typically, between 10 and 66% of such patients will have multiple organisms cultured from the retroperitoneum. Such polymicrobial infections may be more difficult to treat than monomicrobial infections. Although your patients had severe pancreatitis and therefore were at high risk of death, were they less difficult to manage because most of their infections were monomicrobial?

Dr. David A. Dreiling (New York, New York): I have three brief questions: (1) How long was the follow-up? (2) How many of the patients treated stopped drinking because this leads to the third question? (3) Have you observed any patients who were diabetic who lost their diabetes, and have you observed any patients who showed a malabsorption who lost that dysfunction? Many of these patients do regenerate, and I have had a patient whose total pancreas was necrotic and I could see the duodenal curve, etc., and within 18 months, his pancreatic function returned to normal. I am very interested in the possibility of pancreatic regeneration even in these severely ill patients.

Dr. George H. A. Clowes, Jr. (Boston, Massachusetts): I want to make a brief report on a carefully studied series of pancreatic necroses in which we looked at the protein metabolism in 10 patients. Two of these patients, who were cirrhotic, died. On the other hand, we had a number of patients who had liver failure associated with the presence of pancreatic septic process. You have heard me talk about the "central plasma clearance rate" of amino acids. I simply want to report that those who survived had an average value of 195 mL/m^2/min, and that those who died were in the range of 100 mL/m^2/min, which is significantly lower.

The importance of this is that Dr. Bradley is applying a real surgical principle of removing the stimulus that causes the trouble throughout the rest of the body, and I would just ask him to tell us whether with his procedure, he did not see a fairly rapid improvement in other systems. Did the patients get off the ventilator promptly? Did their liver function improve by whatever method of assessment you used?

DR. EDWARD L. BRADLEY, III (Closing discussion): I am most grateful to the discussants not only for their perceptive but also stimulating questions. I wish, indeed, I had all the answers for you this morning. Surgery in acute pancreatitis is still in its infancy. I believe over the next 10–15 years we will improve our indications and procedures. Having said that, let me address the specific questions.

Dr. Frey, thank you very much for your kind words. We do not use catheters as part of our open drainage technique. We had significant trouble when we were using the large-bore closed drainage catheters with erosion into blood vessels and into various pieces of intestine.

Dr. Frey also asked about whether we have seen hemorrhage; yes, we have. We have seen if from the splenic vein and from the superior mesenteric vein, and it certainly got our attention on both occasions. However, it does respond well to packing, part and parcel of our technique. However, we do recommend that you place Adaptic® gauze over any exposed vessels.

Dr. Frey asked for follow-up information. We have an average 5-year follow-up for this group. Within that period we did not see any of the typical changes of chronic pancreatitis.

Dr. Howard, you are to be congratulated for your low mortality rate with closed drainage in patients with pancreatic abscess. With regard to the slide you showed us, we could consider that to be liquified fat necrosis, possibly in a patient who had peripancreatic necrosis.

Dr. Ranson also has experienced low morbidity and mortality from his patients with closed drainage, and has suggested that recent changes in intensive care may have accounted for a significant portion of that result. I have no doubt that we are much smarter than we used to be in this regard, and certainly I believe patients are being better taken care of in our institution than they were 5–10 years ago. However, if you look at this particular question from a more critical viewpoint, such as the people from Mayo Clinic did when they reported their experience with open drainage in 1984, you may reach a different conclusion. They divided their data into three periods. The most recent period included all of the recent modalities such as CT scans, ICU support, and needle aspirations, and they did not find any change in mortality that they could attribute to earlier diagnosis or improved survival through better care in the intensive care unit. Accordingly, the question of why we are achieving these low mortality rates with this technique is open for further study. It is our belief that we are achieving these results because of the repetitive removal of persistent or recurrent infected necrosis.

Dr. Ranson has questioned whether we need to do open drainage if we are prepared to reoperate. In the abstract, the answer is no. However, as I told you, three quarters of the deaths in *postoperative* patients with infected pancreatic necrosis have been from sepsis. Clearly, that means that there has been reluctance to re-explore these patients in the past. Today, if one wishes to debride and close a patient with infected necrosis, one must observe these patients much closer than they have been observed in the past, and be willing to reoperate at a relatively frequent level.

Dr. Pemberton, thank you for updating the Mayo Clinic series. I am pleased that you are continuing your good results. We have not used the zipper and have not found it necessary.

The particular bacterial floral was predominantly monomicrobial, although we did have anaerobic bacteria in some of the patients along with the aerobic bacteria.

Dr. Dreiling, our follow-up, as mentioned, is 5 years. We have seen malabsorption in these patients, which probably reflects the degree of pancreatic necrosis.

Several of the questioners asked how we could tell whether the necrosis was pancreatic or peripancreatic. It is not always easy. In situations where one can visualize the splenic vein or the superior mesenteric vein, after you have done the debridement, I believe you can be reasonably certain that the pancreas is missing. Furthermore, we have had the opportunity to do ERCP on nine of these patients after operation, and in eight of the nine, at least half of the pancreatic duct was not visualized. I believe we can be sure in the that group of patients that we certainly have pancreatic necrosis.

Dr. Warshaw, has asked a series of stimulating questions. He specifically asked about necrosis *versus* infected necrosis, and, whether in fact, they are different. The only data that I know that bear on this question are the data from Dr. Beger's study. Mortality rate for noninfected necrosis was 8%, and was 32% for infected necrosis. This is a significant clinical difference.

He asked us about our classification system and reminded us that Dr. Ranson's classification is one that is done in the first 48 hours. We also classified these patients with Banks' criteria, which, of course, are continuing criteria. In both classification systems, the mortality rate should have exceeded 50%.

We agree that dynamic pancreatography is not yet validated, and we are currently conducting a prospective study to investigate whether it is going to be useful in the management of the timing of operation in these patients.

We use needle aspiration only when we see an avascular area on our dynamic pancreatogram. We do not advocate doing needle aspirations in every patient with acute pancreatitis, but only if the patient shows evidence of what we consider to be focal necrosis and clinical sepsis.

Your results in patients with pancreatic abscess, like those of Dr. Ranson's and Dr. Howard's, are to be commended because they are equally low. However, patients with infected pancreatic necrosis have a higher mortality rate and a greater incidence of multiorgan failure than do patients with pancreatic abscess. In our opinion, infected necrosis requires open drainage.

(Slide) This, ladies and gentlemen, is an apple. (Slide) And that is an orange.

Announcing . . .
FOUR NEW CLINICAL SERIES
from an Innovative New Publisher:

QMP

QUALITY MEDICAL PUBLISHING, INC

PERSPECTIVES IN PLASTIC SURGERY and
PLASTIC SURGERY OUTLOOK
Beginning July 1987

EDITORIAL BOARD
Fritz Barton, Jr., M.D.
John Bostwick III, M.D.
Joel Feldman, M.D.
Ian Jackson, M.D.
Stephen Mathes, M.D.
Thomas Rees, M.D.
Jack Sheen, M.D.

PERSPECTIVES IN VASCULAR SURGERY and
VASCULAR SURGERY OUTLOOK
Beginning January 1988

EDITORIAL BOARD
Jerry Goldstone, M.D., Editor
David Brewster, M.D.
David J. Effeney, M.D.

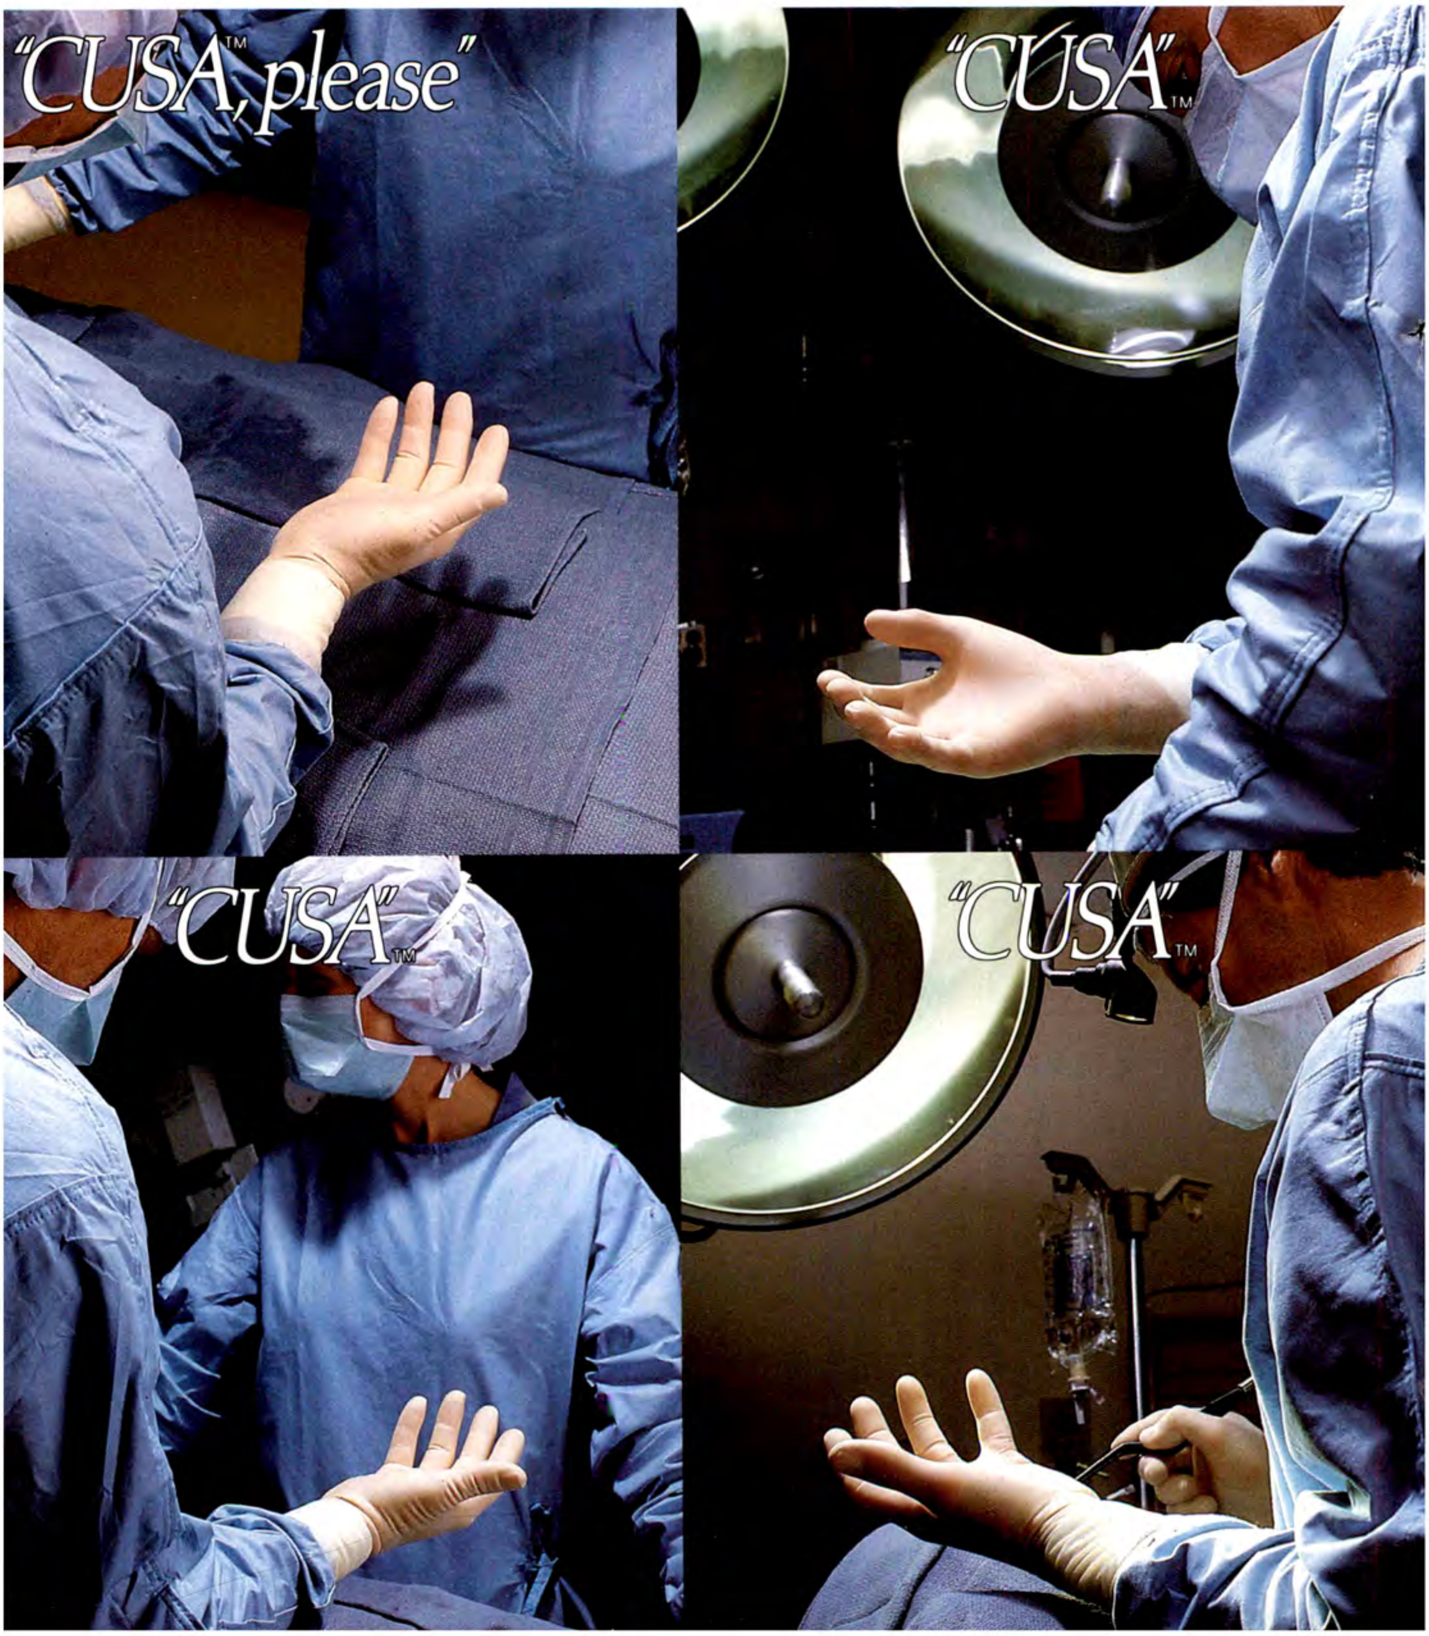
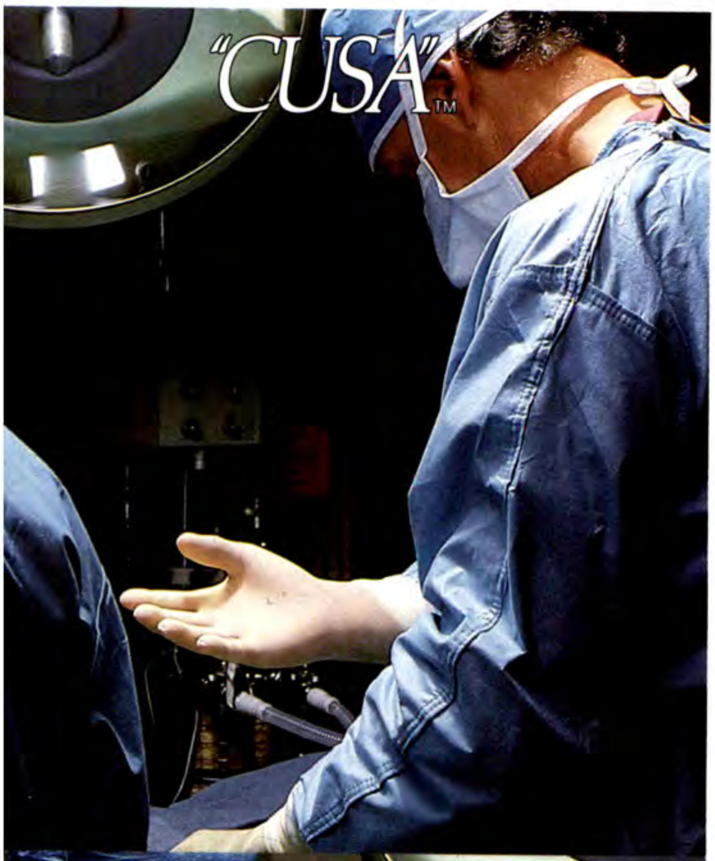
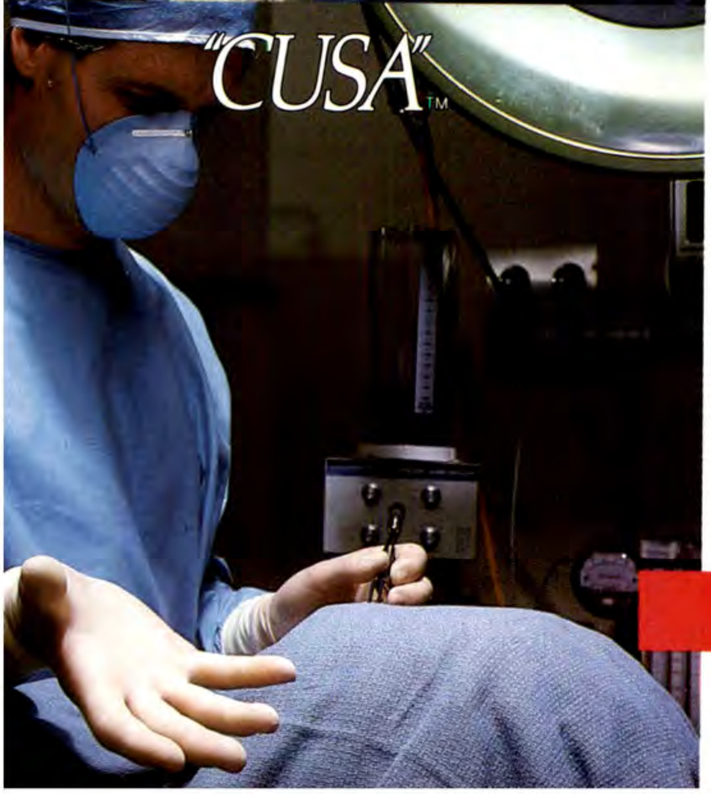
In ultrasonic surgery,



one name is a given.





In thousands of operating rooms around the world, the Cavitron Ultrasonic Surgical Aspirator–CUSA™–is synonymous with ultrasonic surgery. Already well-established in neurosurgery for rapid, efficient tumor removal, the CUSA™ is now proving itself indispensable as an ultrasonic scalpel in general surgery for liver, colorectal, and oncologic procedures.

Indeed, an overwhelming number of CUSA™ users–97% in a recent survey*–have expressed their high level of satisfaction with this system.

There is only one CUSA,™ and only Cavitron can support it with almost 40 years of experience as the world leader in ultrasonic surgical technology. It is no wonder, then, that surgeons have called for the CUSA™ in over 100,000 successful procedures.

CHANGE THE FACE OF PAIN

The following is a brief summary only. Before prescribing, see complete prescribing information in TYLOX® (oxycodone and acetaminophen) labeling.

CONTRAINDICATIONS: TYLOX (oxycodone and acetaminophen) capsules should not be administered to patients who have previously exhibited hypersensitivity to any component.
WARNINGS: Contains sodium metabisulfite, a sulfite that may cause allergic-type reactions including anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people. The overall prevalence of sulfite sensitivity in the general population is unknown and probably low. Sulfite sensitivity is seen more frequently in asthmatic than in nonasthmatic people.

PRECAUTIONS: General: *Head Injury and Increased Intracranial Pressure:* The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions, or a pre-existing increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.
Acute Abdominal Conditions: The administration of TYLOX (oxycodone and acetaminophen) capsules or other narcotics may obscure the diagnosis or clinical course in patients with acute abdominal conditions.
Special Risk Patients: TYLOX capsules should be given with caution to certain patients such as the elderly or debilitated, and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, and prostatic hypertrophy or urethral stricture.

Information for Patients: Oxycodone may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. The patient using TYLOX capsules should be cautioned accordingly.
Drug Interactions: Patients receiving other narcotic analgesics, antipsychotics, anti-anxiety agents, or other CNS depressants, including alcohol, concomitantly with TYLOX capsules, may exhibit additive CNS depression due to the oxycodone component. When such combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with oxycodone preparations may increase the effect of either the antidepressant or oxycodone. The concurrent use of anticholinergics with oxycodone may produce paralytic ileus.

GENERAL or THORACIC SURGEON

A RARE OPPORTUNITY

BOSLEY MEDICAL GROUP IS OFFERING AN EXCEPTIONAL OPPORTUNITY TO MARKEDLY IMPROVE YOUR MEDICAL CAREER BOTH FINANCIALLY AND PROFESSIONALLY. OUR HIGHLY RESPECTED GROUP SPECIALIZES IN HAIR RESTORATION PROCEDURES FOR MALE PATTERN BALDNESS.

BENEFITS OF AFFILIATION WITH BMG INCLUDE:

- Opportunity to travel
- High level monthly compensation—directly related to your skills and efforts
- Superb training in hair restoration—no prior experience necessary or even desirable
- Regular daytime hours—enjoy a normal life and work schedule
- No night calls, no Sunday calls, no holiday calls, no emergencies "at any time of day or night", etc.
- No third party payers—only fee for service paid directly by patients
- No accounts receivable or billing problems—fees paid in advance of services
- Happy and appreciative patients are the great majority
- One million dollar financial security plan

THE PREFERRED APPLICANT WILL BE:

- Board certified in General or Thoracic Surgery
- Experienced in successful private practice
- A team-player who wants to join a select group

If this sounds like the opportunity you have been looking for, we'd like to hear from you!

Write: L. Lee Bosley, M.D., Director

TO THE FACE OF RELIEF

TYLOX® Ⓒ**II** capsules
(OXYCODONE &
ACETAMINOPHEN)

THE POTENCY OF PERCODAN®*
WITHOUT ASPIRIN

*Percodan is a registered trademark of DuPont Pharmaceuticals.

Usage in Pregnancy: Pregnancy Category C. Animal reproductive studies have not been conducted with TYLOX. It is also not known whether TYLOX can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. TYLOX should not be given to a pregnant woman unless in the judgement of the physician, the potential benefits outweigh the possible hazards.
Nonteratogenic Effects: Use of narcotics during pregnancy may produce physical dependence in the neonate.
Labor and Delivery: As with all narcotics, administration of TYLOX to the mother shortly before delivery may result in some degree of respiratory depression in the newborn and the mother, especially if higher doses are used.
Nursing Mothers: It is not known whether the components of this drug are excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TYLOX is administered to a nursing woman.
Pediatric Use: TYLOX capsules should not be administered to children.
ADVERSE REACTIONS: The most frequently observed adverse reactions include lightheadedness, dizziness, sedation, nausea, and vomiting. These effects seem to be more prominent in ambulatory patients than in non-ambulatory patients, and some of these adverse reactions may be alleviated if the patient lies down. Other adverse reactions include allergic reactions, euphoria, dysphoria, constipation, skin rash, and pruritus. At higher doses oxycodone has most of the disadvantages of morphine including respiratory depression.
DRUG ABUSE AND DEPENDENCE: TYLOX (oxycodone and acetaminophen) capsules are a Schedule II controlled substance. Oxycodone can produce drug dependence of the morphine type and, therefore, has the potential for being abused. Psychic dependence, physical dependence, and tolerance may develop upon repeated administration of TYLOX capsules and they should be prescribed and administered with the same degree of caution appropriate to the use of other oral narcotic-containing medications.

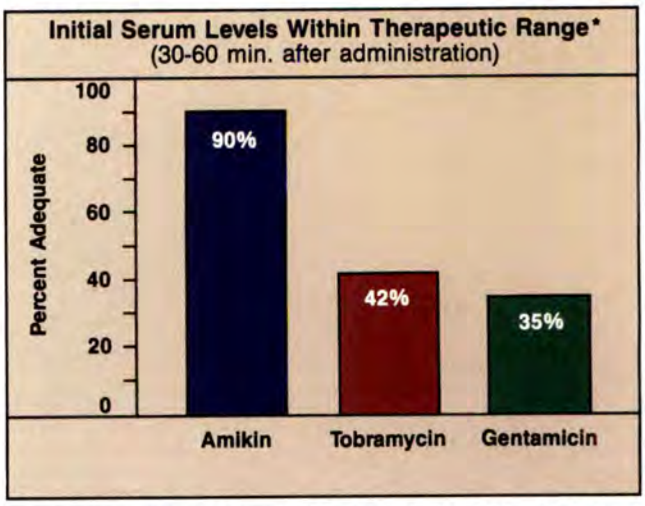
IN EMPIRIC THERAPY OF NOSOCOMIAL INFECTIONS

Peace of mind. Right from the start.

When infection develops in the hospitalized patient, there's no time to be wrong. Amikin® (amikacin sulfate) delivers the aggressive First-Dose therapy that can save lives.

First-Dose Predictability.
After the first dose, Amikin produces therapeutic blood levels that are more predictable than those of the other aminoglycosides.[1]

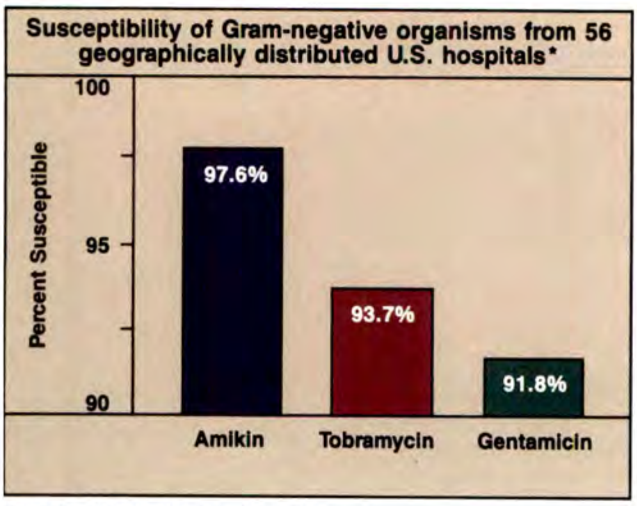


*Adapted from Holloway WJ: Management of sepsis in the elderly. *Am J Med* 80 (suppl 6B): 143-148, 1986.

BRISTOL®
NDC 0015-3020-20
Amikin®
AMIKACIN SULFATE
INJECTION For I.M. or I.V. Use
EQUIVALENT TO
500 mg AMIKACIN Per 2 ml
CAUTION: Federal law prohibits dispensing without prescription.
30
40

First-Dose Antimicrobial Activity.

Amikin has the broadest spectrum of any aminoglycoside.[2]



Total Amikin isolates = 247,503

In vitro data may not be directly correlated to clinical effectiveness. Data on file, Bristol Laboratories.

First-Dose Synergy.

In combination with antipseudomonal penicillins and latest generation cephalosporins, Amikin is overall the most synergistic of the aminoglycosides.[3,4]

First-Dose Economy.

The least expensive aminoglycoside is not necessarily the one with the lowest acquisition cost. It's the one *not* requiring replacement with a more effective agent.[5]

AMIKIN®
AMIKACIN SULFATE

BRIEF SUMMARY OF PRESCRIBING INFORMATION (1) 10/83
For complete prescribing information, please consult product literature.

WARNINGS

Patients treated with aminoglycosides should be under close clinical observation because of the potential ototoxicity and nephrotoxicity associated with their use.

Ototoxicity, both auditory and vestibular, can occur in patients treated at higher doses or for periods longer than those recommended. The risk of amikacin-induced ototoxicity is greater in patients with renal damage. High frequency deafness usually occurs first and can be detected only by audiometric testing. Vertigo may occur and may be evidence of vestibular injury.

The ototoxicity potential of amikacin in infants is not known. Until more safety reports become available, amikacin should be used in infants only in those specific circumstances when susceptibility testing indicates that other aminoglycosides cannot be used or are otherwise contraindicated, and when the infant can be observed closely for evidence of toxicity.

Aminoglycosides are potentially nephrotoxic. Renal and eighth-nerve function should be closely monitored in patients with known or suspected renal impairment and also in those whose renal function is initially normal but who develop signs of renal dysfunction during therapy. Such impairment may be characterized by decreased creatinine clearance, the presence of cells or casts, oliguria, proteinuria, decreased urine specific gravity or evidence of increasing nitrogen retention (increasing BUN or creatinine).

Evidence of impairment in renal, vestibular or auditory function requires discontinuation of the drug or dosage adjustment.

Serum concentrations should be monitored when feasible, and prolonged peak concentrations above 35 mcg/ml should be avoided. Urine should be examined for increased excretion of protein, the presence of cells and casts, and decreased specific gravity.

Concurrent and/or sequential use of topically or systemically neurotoxic or nephrotoxic antibiotics, particularly kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin should be avoided.

AMIKIN should not be given concurrently with potent diuretics (ethacrynic acid, furosemide, meralluride sodium, sodium mercaptomerin or mannitol). Some diuretics themselves cause ototoxicity, and intravenously administered diuretics enhance aminoglycoside toxicity by altering antibiotic concentrations in serum and tissue.

CONTRAINDICATIONS

A history of hypersensitivity to amikacin is a contraindication for its use.

WARNINGS

See "Warning" box above.

PRECAUTIONS

AMIKIN is potentially nephrotoxic, ototoxic, and neurotoxic. The concurrent or serial use of other ototoxic or nephrotoxic agents should be avoided either systemically or topically because of the potential for additive effects. Such agents include antibacterial drugs such as kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin as well as certain diuretic agents such as ethacrynic acid or furosemide.

Ototoxicity — See "Warning" box.

Nephrotoxicity — Since AMIKIN is present in high concentrations in the renal excretory system, patients should be well hydrated to minimize chemical irritation of the renal tubules. Kidney function should be assessed by the usual methods prior to starting therapy and daily during the course of treatment.

If signs of renal irritation appear (casts, white or red cells or albumin), hydration should be increased. A reduction in dosage (see "Dosage and Administration") may be desirable if other evidence of renal dysfunction occurs such as decreased creatinine clearance, decreased urine specific gravity, increased BUN, creatinine or oliguria. If azotemia increases or if a progressive decrease in urinary output occurs, treatment should be stopped.

Note: When patients are well hydrated and kidney function is normal the risk of nephrotoxic reactions with amikacin is low if the dosage recommendations (see "Dosage and Administration") are not exceeded.

Neurotoxicity — Neuromuscular blockade and muscular paralysis have been demonstrated in the cat with high doses of amikacin (188 mg/Kg). The possibility of neuromuscular blockade and respiratory paralysis should be considered when amikacin is administered concomitantly with anesthetic or neuromuscular blocking drugs. If blockade occurs, calcium salts may reverse this phenomenon.

Other — Cross-allergenicity among aminoglycosides has been demonstrated. As with other antibiotics the use of amikacin may result in overgrowth of nonsusceptible organisms. If this occurs, appropriate therapy should be instituted.

Pregnancy — Reproduction studies have been performed in rats and mice and have revealed no evidence of impaired fertility or harm to the fetus due to amikacin. There are no well-controlled studies in pregnant women but investigational experience does not include any positive evidence of adverse effects on the fetus. Although there is no clearly defined risk, such experience cannot exclude the possibility of infrequent or subtle damage to the fetus. AMIKIN should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

ADVERSE REACTIONS

Ototoxicity — See "Warning" box.

Nephrotoxicity — Albuminuria, presence of red and white cells, casts, azotemia and oliguria have been reported.

Other — In addition to those described above, other adverse reactions which have been reported on rare occasions are skin rash, drug fever, headache, paresthesia, tremor, nausea and vomiting, eosinophilia, arthralgia, anemia, hypotension.

Overdosage — In the event of overdosage or toxic reaction, peritoneal dialysis or hemodialysis will aid in the removal of amikacin from the blood.

Book Reviews

William P. Longmire, Jr., M.D.
Advisor for Editorial Board
Los Angeles, California

H. Kim Lyerly, M.D.
Advisor for Residents in Surgery
Durham, North Carolina

The Impact of Illness on World Leaders. Bert Edward Park. 377 pp. Philadelphia: University of Pennsylvania Press. 1986. $24.95.

PATHOGRAPHY, the role of illness in a person's life story, has long been a theme of interest. Major illness, of course, may play any number of roles in the lives of the sufferers, but it becomes especially fascinating when a serious study of its effects on artistic creativity or on leadership abilities is done. In this continuously engaging book, Dr. Bert Park, a practicing neuro-surgeon, guides us through the devastating effects of the aging process and neurologic disorders in the leaders of the western world during much of the twentieth century.

Beginning with the American president during the years of World War I, Dr. Park, in an extensive review of the case of Woodrow Wilson, concludes that he suffered from lacunar infarcts from a series of small strokes brought on by severe and prolonged hypertension. Some of the most critical decisions of the Paris Peace Conference were made by an impaired leader, and his battle for American participation on the League of Nations is retold here in light of Wilson's increasing inabilities. The extreme effects of the aging process on Paul von Hindenburg, the German leader who handed the reins of government to Adolf Hitler, the British prime minister Ramsey MacDonald, and the Polish leader Josef Pilsudski are examined in light of future events. Alzheimer's disease in MacDonald's case played a role in his relationship to both England's friends and potential foes.

The literature about Adolf Hitler is sizeable, but much of the pathography has turned on psychiatric questions. In a well-argued chapter, Park makes an excellent case for an organic brain disease, especially temporal lobe epilepsy and Parkinsonism, accompanied by chronic cholecystitis and flagrant over-medication or the syndrome of polypharmacy. This and the Wilson chapters are the longest, yet they are so well written that any reader, especially one with medical knowledge, will be pulled from page to page by the great drama.

Franklin D. Roosevelt's chronic obstructive pulmonary disease, congestive heart failure, and severe hypertension all took their toll, especially by the end of the third term. Park argues that despite his increasing incapacities, Roosevelt gave up little at Yalta. Finally, the British leadership was seriously compromised by strokes suffered by the aging Winston Churchill and amphetamine addiction of Anthony Eden.

Space does not allow fuller discussion of the many implications of this superb book. But surely the role of the presidential physicians and the public's need and right to know the facts have changed, but the question the author raises is whether we have learned enough from past experiences of compromised leadership?

GERT H. BRIEGER, M.D.
Baltimore, Maryland

Current Therapy in Vascular Surgery. Calvin B. Ernst, James C. Stanley. 469 pp. Philadelphia: B. C. Decker Inc. 1987 $68.50.

THIS BOOK consists of a series of short presentations by a large number of experts. The major thrust is a focused discussion of most of the many topics of interest in vascular surgery presented as contemporary thought on the topics by an individual author rather than being an exhaustive review of the subject. The editors have asked the authors to reflect his or her own personal views and experiences and no references to the literature are cited.

The editors have been very successful in their effort to evaluate *current* therapy. In the preface they say they wanted to provide a book that is not out of date before it is read. This book is very much up to date. They wanted to provide a book of use to medical students and residents, as well as experts in the field, and they have achieved that too. They also have picked topics that span the simple type problems such as ulcers in the diabetic foot or varicose veins, to the esoteric such as carotid body tumors or celiac artery entrapment. Controversy is not avoided, *e.g.*, nonresectional therapy of aneurysm or surgery for carotid artery kinks. Nonsurgical approaches are aired such as that for carotid artery stenosis and thrombolytic therapy.

The text is thorough, topical, well written, and readable. The first section I read (retroperitoneal approach to the aorta) was as interesting as was the last, thoracofemoral bypass. I enjoyed the whole book very much and will refer to it myself, I am sure, often. I would highly recommend it as being similarily enjoyable and useful to others.

WILLIAM M. ABBOTT, M.D.
Boston, Massachusetts

Rob & Smith's Operative Surgery: Thoracic Surgery, 4th Edition. Hugh Dudley, David Carter (General Editors), John W. Jackson, D. K. C. Cooper (Consultant Editors). 380 pp. St. Louis: Mosby/Butterworths. 1986. $99.95.

IN THIS FOURTH EDITION of *Rob & Smith's Operative Surgery*, the editors have acknowledged the trend toward specialization into either cardiac or thoracic surgery by publishing the volume on general thoracic surgery separately, in contrast to previous editions. Thirty-seven authors have contributed 42 chapters covering virtually the entire list of thoracic operations: chest wall, mediastinal, pulmonary, and esophageal (*oesophageal* in this text). Though the authors are predominantly British, there are several from Canada, the United States, South Africa, Yugoslavia, and Germany, thus providing an international flavor.

In each topic, the operative procedure is presented in step-by-step fashion with numerous illustrations. Primary emphasis is on the technical procedure and is given in detail; the preoperative and postoperative management, complications, and results are generally discussed in summary form.

The numerous authors and artists provide variability to the style of the presentations. They also evidence the wide range of choice among surgeons individually and geographically for the type of incision, suture material, use of the stapler, prosthetic material for chest wall reconstruction, anesthesia, etc. Thus, the reader is provided excellent descriptions of operative techniques, and simultaneously notes the option of individual choice about some parts of the procedure.

Descriptions of the various muscle and omental flap procedures used for chest wall, pleural, and sternal operations and mention of newer anesthetic techniques (unilateral intubation, high frequency ventilation, and epidural analgesia) would enhance the volume and make it more complete. Also noted is the omission of operations for Zenker's diverticulum. However, these are insignificant detractions from the book's overall value.

The book is a compendium/atlas of thoracic operations and provides an easily understandable and comprehensive review of "general thoracic" surgical operations. It will be of great benefit to general and thoracic surgeons alike.

C. FREDERICK KITTLE, M.D.
Chicago, Illinois

Oxygen Transport in the Critically Ill. James V. Snyder, Michael R. Pinsky. 554 pp. Chicago: Year Book Medical Publishers. 1987. $74.95.

THE PROMISE OF THE TITLE is well fulfilled in this excellent textbook. As critical care practice has become divided into organ-specific interests, the idea of a unifying focus for patient management has been forgotten. This text reinforces the importance of the maintenance of oxygen metabolism as the core of organ system preservation in critical illness. A major difference between this and other similar works is the attention placed on basic principles within the framework of clinical care. The authors divide the book into six basic areas that deal with the areas of oxygen supply and demand, regulation of oxygen transport, cellular oxygenation, clinical evaluation of oxygen transport, ventilatory support, and circulatory support, respectively. Where appropriate, as in the section on mechanical ventilatory support, the authors discuss the physiologic basis for support techniques and continue to describe their clinical application. This logical approach works well and is stimulating for the reader. Indeed, the text may well serve as a basis for further reading in many areas because the reference sections in each chapter are well researched and up to date.

In the preface, the authors hope to "present the physiologic and therapeutic paradigms that incorporate recent insights and prepare the reader for the anticipated increasing focus on regional pathophysiology and treatment." To accomplish this goal, the editors have assembled 37 contributing authors, each of whom follows the theme and begins by detailing the physiology that underlies his/her contribution. At no point is the clinical contribution to patient management forgotten, but the importance of laboratory assessment as an indispensable adjunct to sophisticated management techniques is highlighted. It is interesting to note that increased interest is being placed on oxygen metabolism, especially with the clinical use of multiple sophisticated monitoring devices. In fact, the technology is reinforcing the importance of basic physiology in the management of critical illness. The Society of Critical Care Medicine has published a textbook devoted to the subject of oxygen metabolism, and the subject is both timely and fundamental to patient care.

In summary, this textbook should enjoy wide popularity. It is well written, informative, and up to date. This is not a simple restatement of the shunt equation or another discussion of mechanical ventilation or the Starling curve revisited. Rather, it is an attempt to integrate the practical aspects of oxygen transport with the physiologic requirements of the organism. In this regard it is highly successful, and it will remind each reader of the intellectual inadequacies of daily practice. Perhaps its greatest success will be in the stimulation of the critical care practitioner to initiate new discussions on forgotten subjects and to investigate the vagaries of tissue metabolism. It is unlikely that any reader will remain immune to this challenge.

PHILIP D. LUMB, M.B., B.S.
Durham, North Carolina

Trauma: Clinical Care and Pathophysiology. J. David Richardson, Hiram C. Polk, Jr., Lewis M. Flint. 597 pp. Chicago: Year Book Medical Publishers. 1987. $65.00.

IN THE PREFACE, the editors state that this book is intended "to describe in detail methods of treating various injuries encountered in clinical practice" and "to provide insights into the basic pathophysiology that is operative in a variety of injured states." To accomplish this they have assembled a group of 40 contributors, 27 of whom are from the University of Louisville.

After introductory chapters on epidemiology and organization of trauma care, there are seven chapters dealing with the pathophysiology of problems common to the trauma patient, including shock, infection, organ failure, hemostasis, catabolism, and wound healing. Each chapter is concise and well written, and most chapters have extensive and current references. Especially well done are the chapters on host defense and organ failure (222 references), burn pathophysiology, respiratory pathophysiology, and wound repair (215 references).

The subsequent 11 chapters deal with the clinical evaluation and management of specific injuries, including facial trauma, thoracic and abdominal injuries, neck trauma, and pediatric trauma. Subjects are treated regionally rather than systemically, *i.e.*, the chapter on neck trauma covers vascular and aerodigestive injuries in the cervical region, whereas the chapter on thoracic trauma covers similar subjects in the chest. For the most part, these chapters are authored by the Louisville faculty drawing on their vast clinical experience. The editors emphasize this in the preface, pointing out the extensive contributions Louisville surgeons have made to trauma care for the past 75 years. Although the Louisville experience is evident, the recommendations regarding diagnosis and treatment are not parochial. The chapters on abdominal trauma and thoracic injuries are especially comprehensive with 131 and 94 references, respectively. The chapter on urologic trauma contains a section on injuries to the external genitalia, a subject treated poorly or not at all in previous texts. The final chapter on ethical, moral, and legal issues in trauma care contains useful information for the surgeon practicing in today's litigious society.

This book is written in clear and practical terms. Major points are printed in boldface type for emphasis and quick review. The text is well illustrated and the algorithms in the chapters on pathophysiology are easy to understand. The only deficiencies are minor. There is no overview chapter on initial management, evaluation, and injury priority. The chapter on epidemiology is too superficial and the chapter on trauma systems lacks information on triage, trauma registries, cost, and outcome analysis.

This is a substantial contribution to the trauma literature because it amalgamates the pathophysiology of injury with sound recommendations for clinical management. It has broad appeal and is recommended for the surgical resident and the practicing surgeon alike. Clearly, the editors have accomplished their purpose.

STEVEN R. SHACKFORD, M.D.
San Diego, California

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

- Title page
- Abstract and key words
- Text
- Acknowledgments
- References
- Tables: each table, complete with title and footnotes, on a separate page
- Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

Announcing the new definitive reference on

TRAUMA

edited by Kenneth L. Mattox, M.D., Ernest Eugene Moore, M.D. and David V. Feliciano, M.D.

Three of the nation's leading trauma surgeons have gathered the top specialists in trauma care to write in their areas of expertise creating this comprehensive volume on the care of the victim of traumatic injury. Destined to become *the* classic reference in the field, the book covers all aspects of trauma, emphasizing current approaches to the care of the trauma patient.

The complete contents listed here shows that this is the text-reference anyone involved in the growing field of trauma care should own.

Oct. 1987, 960 pp. (approx.),
A9004-1, $125.00 (tentative price)

If the movement needs improvement...
Colace® or Peri-Colace®

Recommend the time-tested anticonstipants that relieve gently and reliably. Colace (docusate sodium) softens the stool and helps prevent straining...especially important for patients with anorectal disorders.

When laxative action is also needed, Peri-Colace (casanthranol and docusate sodium) both softens stools and stimulates peristalsis to correct constipation, usually overnight.

Colace and Peri-Colace offer you the flexibility of 50 mg and 100 mg capsules, syrup, or liquid. Recommend them with confidence for virtually all your adult and pediatric patients.

Gentle relief you've relied on for over 25 years

COLACE®
(stool softener)

PERI·COLACE®
(laxative plus stool softener)

Wilmington, Delaware 19897

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.†

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of

CEFOTAN® (cefotetan disodium)

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

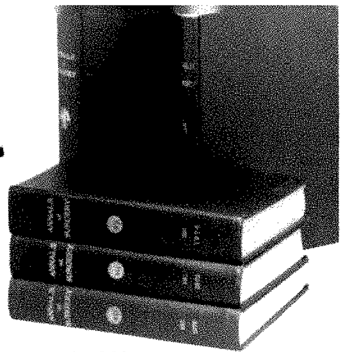
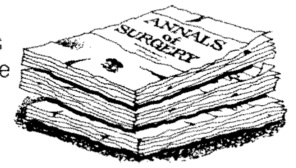
New for 1987



For your professional library

Bound volumes of

Annals of Surgery



Long after your personal copies of ANNALS OF SURGERY have been read, shared with your office staff, used up and worn out, you can have instant access to the unique and valuable information in back issues of this distinguished journal by ordering bound volumes.

Your bound volumes give you a permanent and comprehensive reference for changes and advances in your specialty—a source that will grow and increase in usefulness over the years. Each volume features:

- *all text pages of every issue, including the complete author and title indexes*
- *no advertising—only professional, clinically pertinent material (a space-saver on your bookshelves)*
- *handsome, durable bindings in maroon buckram, with the journal name, year, and volume number imprinted in gold on the spine*

No need to return your personal copies to us, or to go to the trouble and expense of having them bound locally. We over-run copies of each issue in order to have sufficient quantities on hand. But we must tell our printer how many we need, so please let us know right away.

You must be a current subscriber to take advantage of this bound volume offer.

Use the convenient coupon to order your 1987 volumes today. They will be on their way to you shortly after the publication of the final volume issue.

Yes! Please send me the 1987 bound volumes of ANNALS OF SURGERY (65-98635/65-98643) for $49.00 U.S. ($59.00 elsewhere).

vicodin

hydrocodone bitartrate 5 mg (Warning: May be habit forming.) with acetaminophen 500 mg

INDICATIONS AND USAGE: For the relief of moderate to moderately severe pain.

CONTRAINDICATIONS: Hypersensitivity to acetaminophen or hydrocodone.

WARNINGS

Drug Abuse and Dependence: VICODIN is subject to the Federal Controlled Substances Act (Schedule III). Psychic dependence, physical dependence and tolerance may develop upon repeated administration of narcotics; therefore, VICODIN should be prescribed and administered with the same caution appropriate to the use of other oral-narcotic-containing medications.

Respiratory Depression: At high doses or in sensitive patients, hydrocodone may produce dose-related respiratory depression by acting directly on brain stem respiratory centers. Hydrocodone also affects centers that control respiratory rhythm, and may produce irregular and periodic breathing.

Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.

Acute Abdominal Conditions: The administration of narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions.

PRECAUTIONS

Special Risk Patients: VICODIN should be used with caution in elderly or debilitated patients and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture.

Information for Patients: VICODIN, like all narcotics, may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery; patients should be cautioned accordingly.

Cough Reflex: Hydrocodone suppresses the cough reflex; caution should be exercised when VICODIN is used postoperatively and in patients with pulmonary disease.

Drug Interactions: The CNS-depressant effects of VICODIN may be additive with that of other CNS depressants. When combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with hydrocodone preparations may increase the effect of either the antidepressant or hydrocodone. The concurrent use of anticholinergics with hydrocodone may produce paralytic ileus.

Usage in Pregnancy: Pregnancy Category C. Hydrocodone has been shown to be teratogenic in hamsters when given in doses 700 times the human dose. There are no adequate and well-controlled studies in pregnant women. VICODIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nonteratogenic Effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The intensity of the syndrome does not always correlate with the duration of maternal opioid use or dose.

Labor and Delivery: Administration of VICODIN to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.

Nursing Mothers: It is not known whether this drug is excreted in human milk; therefore, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Central Nervous System: Sedation, drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, dizziness, psychic dependence, mood changes.

Gastrointestinal System: Nausea and vomiting may occur; they are more frequent in ambulatory than in recumbent patients. Prolonged administration of VICODIN may produce constipation.

Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.

Respiratory Depression: (See WARNINGS.)

DOSAGE AND ADMINISTRATION: Dosage should be adjusted according to the severity of the pain and the response of the patient. However, tolerance to hydrocodone can develop with continued use, and the incidence of untoward effects is dose related. The usual dose is one tablet every six hours as needed for pain (if necessary, this dose may be repeated at four-hour intervals.) In cases of more severe pain, two tablets every six hours (up to eight tablets in 24 hours) may be required.

Problems in General Surgery

Lloyd M. Nyhus, M.D., Editor.

This series of hardbound volumes features a symposium on a specific topic in general surgery in each issue. It serves as an outlet for the publication of original articles aimed at defining and suggesting solutions to difficult problems encountered in practice. Clinical problems are emphasized, with concentration on difficulties and complications. Leading authorities, chosen for their expert knowledge in their assigned topics, contribute articles on specific subjects, pooling the expertise of specialists for the benefit of generalists.

Published quarterly. Individual rate $59.00 per year (U.S.), $68.00 (elsewhere). Residents $39.00 (U.S. only).

Annals of Surgery

Official Publication of The American Surgical Association, The Southern Surgical Association, Philadelphia Academy of Surgery, and the New York Surgical Society

David C. Sabiston, Jr., M.D., Chairman of Editorial and Advisory Board.

Annals of Surgery—the world's oldest exclusively surgical journal—has provided the medical community with reports on significant contributions to the advancement of surgical science and practice for over 100 years. Its 20,000 subscribers find it a practical way to keep up to date with important developments in surgery.

Published monthly. Individual rate $53.00 per year (U.S.), $70.00 (elsewhere). Residents $35.00 (U.S.), $52.00 (Canada).

The American Surgeon

Official Publication of the Southeastern Surgical Congress, the Midwest Surgical Association, the Association of Clinical Anatomists, and the Society of American Gastrointestinal Endoscopic Surgeons (SAGES)

Arlie R. Mansberger, Jr., M.D., Editor-in-Chief.

An authoritative forum for the publication of original papers contributing to the advancement of surgery. Each issue contains information on the clinical application of new methods used in the management of patients; review articles with continuing education questions; condensed reviews of unusual case reports; "How I Do It" articles emphasizing the technical aspects of surgery.

Published monthly. Individual rate $49.00 per year (U.S.), $60.00 (elsewhere). Residents $32.00 (U.S. only).

Current Surgery

The Official Journal of the Association of Program Directors in Surgery

Lloyd M. Nyhus, M.D., Editor.

An internationally renowned editorial board prepares abstracts from every dependable source of surgical information throughout the world. Drawing on their own clinical experience and that of other recognized authorities, the members of the board provide commentary to further amplify and illuminate the material contained in each abstract. Also included are editorials, reports of new discoveries, residents' corner, and book reviews.

Published bimonthly. Individual rate $40.00 per year (U.S.), $46.00 (elsewhere). Residents $26.00 (U.S.), $32.00 (Canada).

Diseases of the Colon and Rectum

Official Journal of the American Society of Colon and Rectal Surgeons and the International Society of University Colon and Rectal Surgeons

Robert W. Beart, Jr., M.D., Editor-in-Chief.

This journal publishes reports on contemporary practice in the diagnosis and management of proctologic diseases and surgery. International in scope, it includes articles from physicians worldwide who share their important discoveries that offer new insights into basic research in metabolism, pathology, virology, radiology, and the clinical practice of medicine and surgery.

Published monthly. Individual rate $74.00 per year (U.S.), $89.00 (elsewhere). Residents $44.00 (U.S.), $59.00 (Canada).

Journal of Cardiovascular Surgery

Official Journal of the International Society for Cardiovascular Surgery

J. E. Connolly and S. S. Rose, Co-chief Editors.

The Journal is devoted to disease of the heart and the entire vascular system. It presents concise, informative coverage of the most significant work being done in diagnostic, experimental, and clinical surgery of the heart and blood vessels.

Published bimonthly. Individual rate $80.00 per year (North America only).

SPRAY ON HEMOSTASIS

THROMBOSTAT™ (THROMBIN, USP), a trusted hemostatic aid, is now available in a pump spray form—permitting flexible and easy application. With the new THROMBOSTAT pump, you can achieve hemostasis in seconds over large body surface areas. Each depression of the pump offers an even distribution of THROMBOSTAT solution—allowing uniform hemostasis of the total area. The THROMBOSTAT pump is available in a convenient sterile kit that features a 20,000-unit vial of THROMBOSTAT (a practical size for procedures involving capillary bleeding), an appropriate measure of diluent, and a pump sprayer cap. The kit offers sterile packaging—permitting the entire contents to be brought directly into the sterile field. With the new THROMBOSTAT kit, it has never been simpler to control capillary bleeding.

Please see next page for brief summary of prescribing information.

THROMBOSTAT™ (THROMBIN, USP) (Bovine Origin)
Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE: Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS: Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING: Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS: General: Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated-sponge procedure.

Pregnancy—Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: An allergic type reaction following the use of Thrombostat for treatment of epistaxis has been reported. Febrile reactions have also been observed following the use of Thrombostat in certain surgical procedures but no cause-effect relationship has been established.

DOSAGE AND ADMINISTRATION: General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc. solutions containing approximately 100 units per ml are frequently used. For this, 10 ml of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per ml may be required. For this the 5000 unit vial dissolved in 5 ml or 2.5 ml respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate volume of diluent. In many situations, it may be advantageous to use Thrombostat (Thrombin, USP) in dry form on oozing surfaces.

Caution: Solutions should be used the day they are prepared. The solution may be used for up to 6 hours when stored at room temperature; up to 24 hours when stored under refrigeration, and, if necessary, up to 48 hours when stored frozen.

The following techniques are suggested for the topical application of Thrombostat.

1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:

1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Thrombostat Kit: Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The Kit may be used as follows:

1. Remove the Tyvek blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

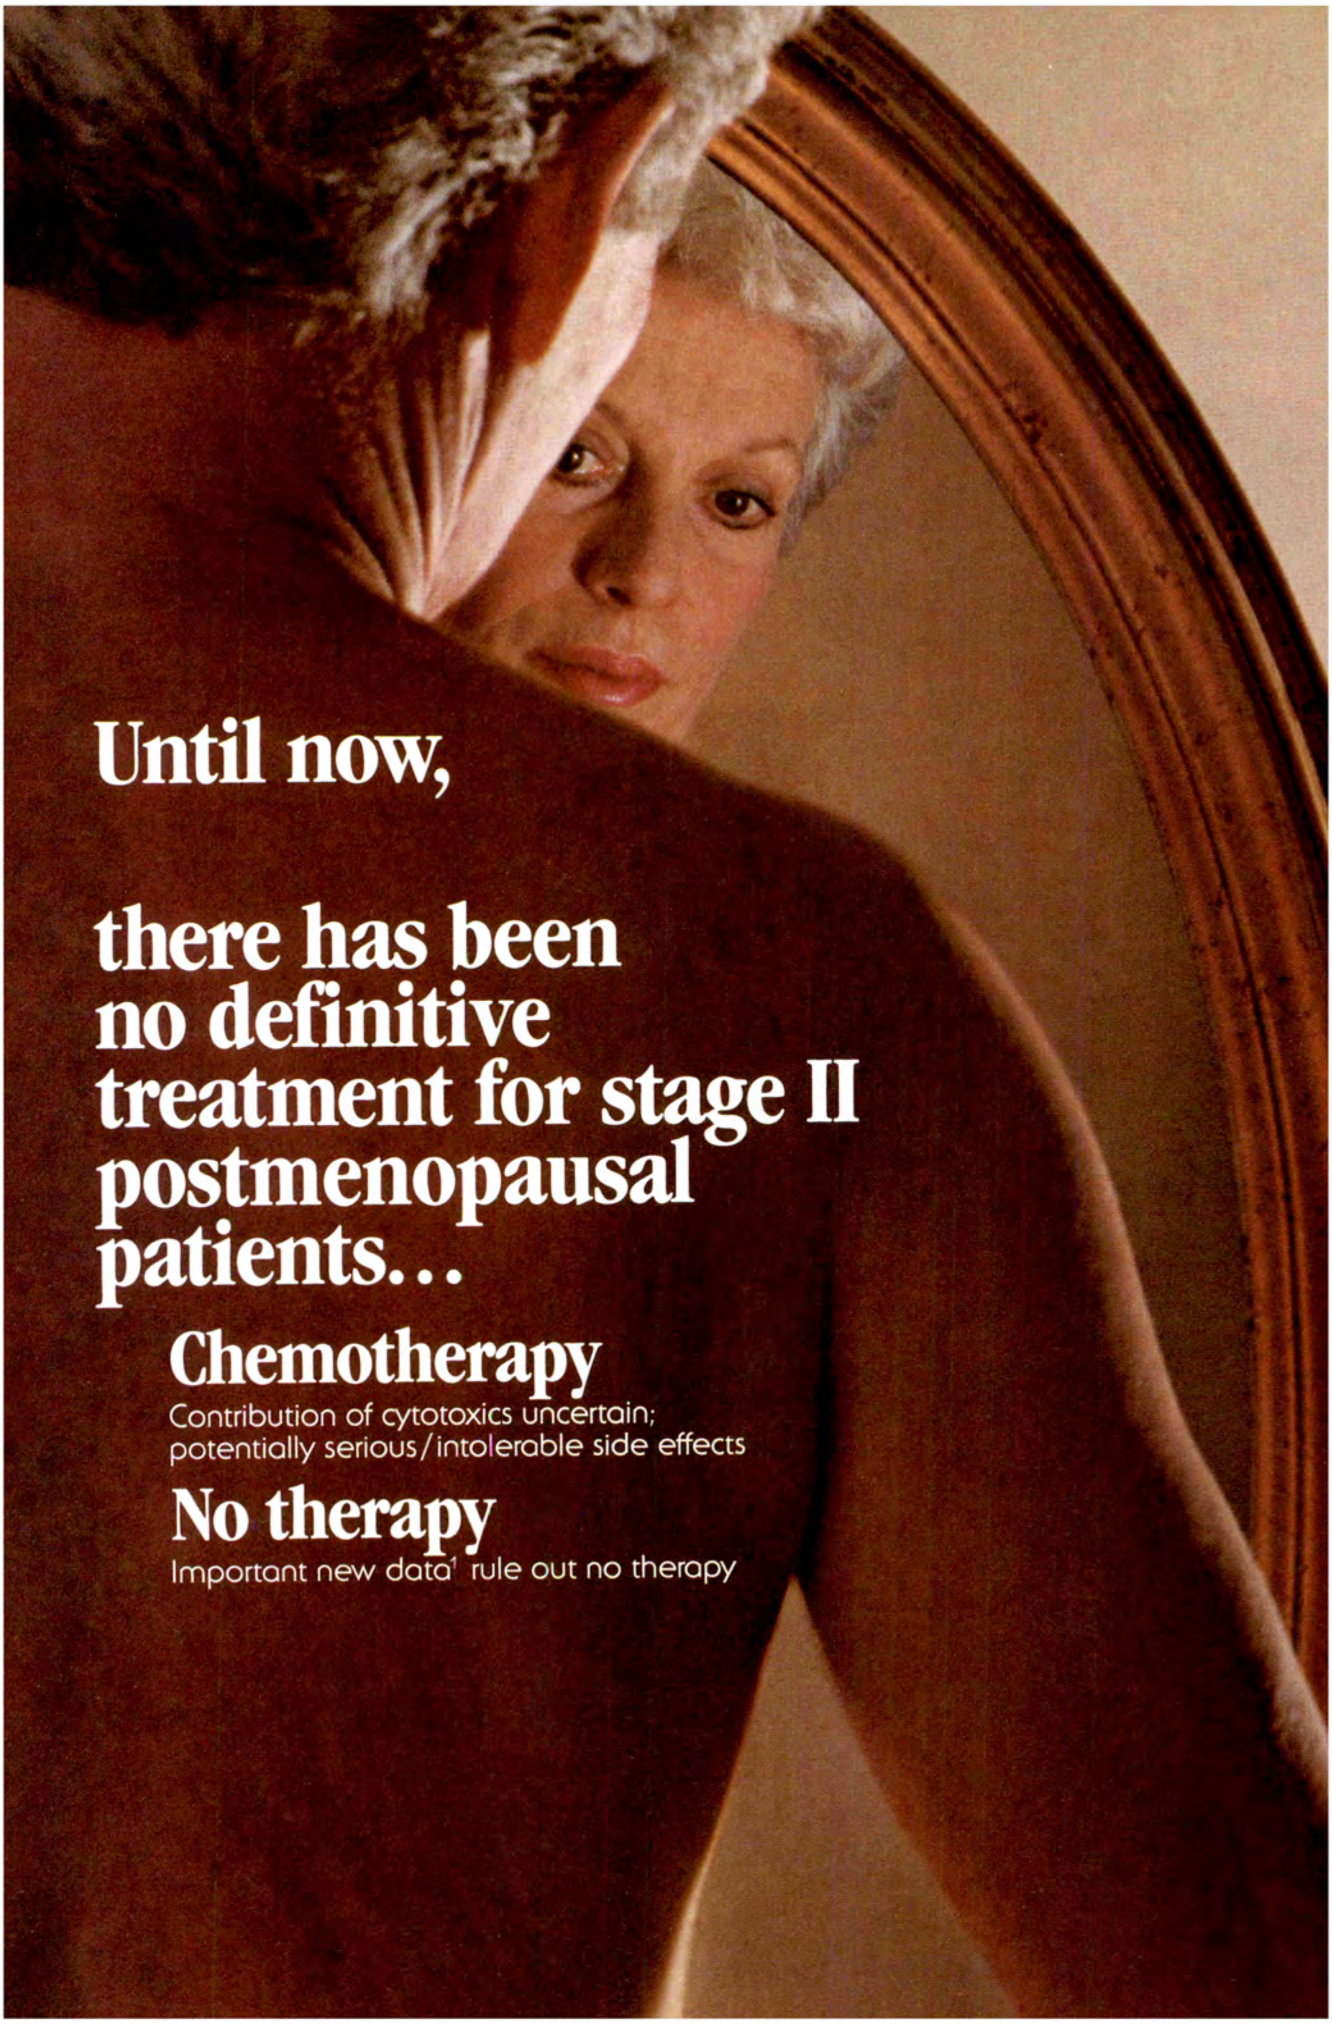
following
surgery
for primary
breast cancer.
What
next?



Until now,
there has been no definitive treatment for stage II postmenopausal patients…
Chemotherapy
Contribution of cytotoxics uncertain; potentially serious/intolerable side effects
No therapy
Important new data[1] rule out no therapy

Today there is.

Nolvadex® 10 MG TABLETS

TAMOXIFEN CITRATE

Adjuvant Monotherapy

Now, the treatment of choice

A recent National Institutes of Health consensus report states that following surgery, "Tamoxifen [NOLVADEX] should now be regarded as standard therapy for postmenopausal patients with positive axillary lymph nodes and positive hormone receptor status."[1]

NOLVADEX increases disease-free time[2-5] by delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer ($T_{1\text{-}3}$, N_1, M_0). Moreover, NOLVADEX improves overall survival, with a 34% reduction in risk of mortality, as observed in the NOLVADEX Adjuvant Trial Organization (NATO) study.[4] This treatment is extremely well tolerated by patients[2-5]; in fact, one double-blind, placebo-controlled study demonstrated a NOLVADEX side effects profile similar to placebo.[2] And, since NOLVADEX has a mild side effects profile and is easy to administer, patients are afforded a better quality of life. NOLVADEX—today's promising breast cancer therapy for the postmenopausal woman—in the adjuvant setting and in metastatic disease.

Please see next page for brief summary of prescribing information.

Nolvadex®

10 MG TABLETS

TAMOXIFEN CITRATE

BRIEF SUMMARY

INDICATIONS AND USAGE: NOLVADEX is effective in the treatment of metastatic breast cancer in postmenopausal women. Available evidence indicates that patients whose tumors are estrogen receptor positive are more likely to benefit from NOLVADEX therapy.

NOLVADEX is effective in delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T1-3, N1, M0). The estrogen and progesterone receptor values may help to predict whether NOLVADEX therapy is likely to be beneficial. In some NOLVADEX adjuvant studies, most of the benefit to date has been in the subgroup with 4 or more positive axillary nodes.

CONTRAINDICATIONS: None known.

WARNINGS: Pregnancy Category D: NOLVADEX may cause fetal harm when administered to a pregnant woman. Individuals should not become pregnant while taking NOLVADEX. Effects on reproductive functions are expected from the antiestrogenic properties of the drug. In reproductive studies in rats at dose levels equal to or below the human dose, nonteratogenic developmental skeletal changes were seen and were found to be reversible. In addition, in fertility studies in rats and in teratology studies in rabbits using doses at or below those used in humans, a lower incidence of embryo implantation and a higher incidence of fetal death or retarded in utero growth were observed, with slower learning behavior in some rat pups. The impairment of learning behavior did not achieve statistical significance in one study, and, in another study where significance was reported, this was by comparing dosed animals with controls of another study. Several pregnant marmosets were dosed during organogenesis or in the last half of pregnancy. No deformations were seen and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. There are no adequate and well controlled studies in pregnant women. There have been reports of spontaneous abortions, birth defects, fetal deaths, and vaginal bleeding. If this drug is used during pregnancy or the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Ocular changes have been reported in a few patients who, as part of a clinical trial, were treated for periods greater than one year with NOLVADEX at doses at least four times the highest recommended daily dose of 40 mg. The ocular changes consist of retinopathy and, in some patients, there are also corneal changes and a decrease in visual acuity.

In addition, a few cases of ocular changes including visual disturbance, corneal changes, and/or retinopathy have been reported in patients treated with NOLVADEX at recommended doses. It is uncertain if these effects are due to NOLVADEX.

As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastases within a few weeks of starting treatment with NOLVADEX. If hypercalcemia does occur, appropriate measures should be taken and, if severe, NOLVADEX should be discontinued.

PRECAUTIONS: General: NOLVADEX should be used cautiously in patients with existing leukopenia or thrombocytopenia. Observations of leukopenia and thrombocytopenia occasionally have been made, but it is uncertain if these effects are due to NOLVADEX therapy. Transient decreases in platelet counts, usually to 50,000-100,000/cu mm, infrequently lower, have been occasionally reported in patients taking NOLVADEX for breast cancer. No hemorrhagic tendency has been recorded and the platelet counts returned to normal levels even though treatment with NOLVADEX continued.

Laboratory Tests: Periodic complete blood counts, including platelet counts, may be appropriate.

Carcinogenesis: While no conventional bioassay has been conducted, endocrine changes in immature and mature mice were investigated in a 13-month study. Granulosa cell ovarian tumors and interstitial cell testicular tumors were found in mice receiving NOLVADEX, but not in the controls.

Mutagenesis: No genotoxic potential has been found in a battery of in vivo and in vitro tests with pro- and eukaryotic test systems with drug metabolizing systems present.

Impairment of Fertility: Fertility in female rats was decreased following administration of 0.04 mg/kg for 2 weeks prior to mating through day 7 of pregnancy. There was a decreased number of implantations, and all fetuses were found dead.

Following administration to rats of 0.16 mg/kg from days 7-17 of pregnancy, there were increased numbers of fetal deaths. Administration of 0.125 mg/kg to rabbits during days 6-18 of pregnancy resulted in abortion or premature delivery. Fetal deaths occurred at higher doses. There were no teratogenic changes in either rat or rabbit segment II studies. Several pregnant marmosets were dosed with 10 mg/kg/day either during organogenesis or in the last half of pregnancy. No deformations were seen, and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. Rats given 0.16 mg/kg from day 17 of pregnancy to 1 day before weaning demonstrated increased numbers of dead pups at parturition. It was reported that some rat pups showed slower learning behavior, but this did not achieve statistical significance in one study, and in another study where significance was reported, this was by comparing dosed animals with controls of another study.

The recommended daily human dose of 20-40 mg corresponds to 0.4-0.8 mg/kg for an average 50 kg woman.

Pregnancy Category D: See WARNINGS.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from NOLVADEX, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

ADVERSE REACTIONS: The most frequent adverse reactions to NOLVADEX are hot flashes, nausea and vomiting. These may occur in up to one fourth of patients, but are rarely severe enough to require discontinuation of treatment.

Less frequently reported adverse reactions are vaginal bleeding, vaginal discharge, menstrual irregularities and skin rash. Usually these have not been of sufficient severity to require dosage reduction or discontinuation of treatment.

Increased bone and tumor pain and, also, local disease flare have occurred, which are sometimes associated with a good tumor response. Patients with increased bone pain may require additional analgesics. Patients with soft tissue disease may have sudden increases in the size of preexisting lesions, sometimes associated with marked erythema within and surrounding the lesions and/or the development of new lesions. When they occur, the bone pain or disease flare are seen shortly after starting NOLVADEX and generally subside rapidly.

Other adverse reactions which are seen infrequently are hypercalcemia, peripheral edema, distaste for food, pruritus vulvae, depression, dizziness, light-headedness and headache. There have been infrequent reports of thromboembolic events occurring during NOLVADEX therapy. Since for cancer patients in general an increased incidence of thromboembolic events is known to occur, a causal relationship to NOLVADEX remains conjectural. An increased incidence has been reported when cytotoxins are combined with NOLVADEX.

If adverse reactions are severe, it is sometimes possible to control them by a simple reduction of dosage without loss of control of the disease.

OVERDOSAGE: Acute overdosage in humans has not been reported. Signs observed at the highest doses following studies to determine LD_{50} in animals were respiratory difficulties and convulsions. No specific treatment for overdosage is known; treatment must be symptomatic.

DOSAGE AND ADMINISTRATION: One or two 10 mg tablets twice a day (morning and evening). In the three single agent adjuvant NOLVADEX studies noted above (See Clinical Pharmacology), NOLVADEX was administered for two years. The optimal duration of adjuvant therapy is not known.

HOW SUPPLIED: Tablets containing tamoxifen as the citrate in an amount equivalent to 10 mg of tamoxifen (round, biconvex, uncoated, white tablet identified with NOLVADEX 600 debossed on one side and a cameo debossed on the other side) are supplied in bottles of 60 tablets and 250 tablets. Protect from heat and light.

WE HAVE ONLY GOOD THINGS TO SAY ABOUT CANCER OF THE COLON.

If detected early, the cure rate for colorectal cancer is very high. It can be as high as 75%.

Because we now know how to detect it early. And we know how to fight it once we detect it.

There are three simple checkup guidelines for men and women without symptoms.

One, get a digital exam every year. This is recommended for everyone over 40.

Two, get a stool blood test every year if you are over 50.

Three, after two initial negative tests one year apart, get a procto exam every three to five years if you are over 50.

These guidelines are the best protection against colorectal cancer you can have.

If you're not over 50, please give this information to friends and loved ones who are.

In any case, please help spread the word.

Good news doesn't always travel fast.

AMERICAN CANCER SOCIETY®

Get a checkup. Life is worth it.

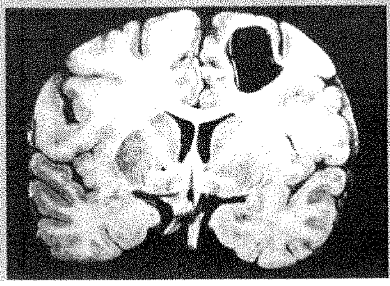
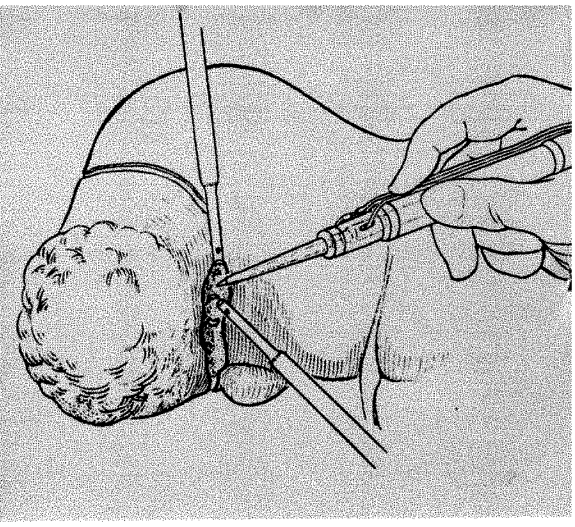
Letters to the Editor

Now...the new book that shows you the role of surgical resection in the curative treatment of metastatic cancer



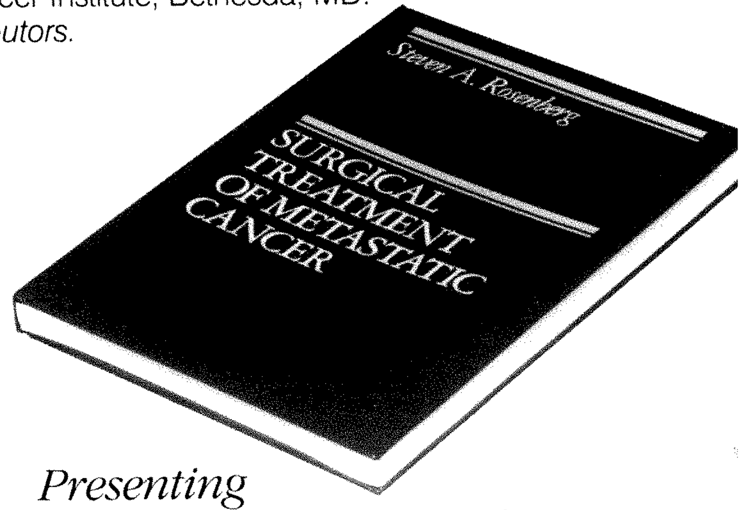


SURGICAL TREATMENT of METASTATIC CANCER

Edited by Steven A. Rosenberg, M.D., Ph.D.

Chief of Surgery, National Cancer Institute, Bethesda, MD.
9 contributors.

> *For many patients with isolated visceral metastases from solid tumors, surgical resection of those metastatic deposits represents the best opportunity for cure. For patients with solitary pulmonary and hepatic metastases, up to 30% of patients may experience prolonged disease-free survival after metastasectomy. Only a small subset of patients with metastatic cancer are likely to benefit from surgical resection and identification of these patients is an important part of the application of this treatment.*
>
> **—from the *Preface***



Taking a bold approach to treatment

Now, for the first time, here is an in-depth resource that describes the role of surgical resection in the treatment of metastatic cancer. Editor Dr. Steven A. Rosenberg, Chief of Surgery at the National Cancer Institute, and a leading figure in cancer research and treatment, poses the premise that the role of surgical resection in treating metastatic cancer has indeed been underappreciated. He and a distinguished group of contributors have designed this book to present the essential information oncologists and surgeons need to understand the value of this treatment.

Presenting a highly significant option

Detailed information is presented concerning:

- the modern understanding of the biology of the metastatic process
- up-to-date techniques for the diagnosis of lung, liver, and brain metastases
- indications for and results of the surgical resection of lung, liver, and brain metastases
- the indications for lymph node dissection in the treatment of cancer.

286 pages. 120 illustrations. 68 tables. 1987. $59.50

NUBAIN IM IV SC
nalbuphine HCl

Brief Summary of Prescribing Information

INDICATIONS For the relief of moderate to severe pain. NUBAIN can also be used for preoperative analgesia, as a supplement to surgical anesthesia, and for obstetrical analgesia during labor.

CONTRAINDICATIONS NUBAIN should not be administered to patients who are hypersensitive to it.

WARNINGS Drug Dependence NUBAIN has been shown to have a low abuse potential which is approximate to that of pentazocine. When compared with drugs which are not mixed agonist-antagonists, it has been reported that nalbuphine's potential for abuse would be less than that of codeine and propoxyphene. Psychological and physical dependence and tolerance may follow the abuse or misuse of nalbuphine. Therefore, caution should be observed in prescribing it for emotionally unstable patients, or for individuals with a history of narcotic abuse. Such patients should be closely supervised when long-term therapy is contemplated. Care should be taken to avoid increases in dosage or frequency of administration which in susceptible individuals might result in physical dependence. Abrupt discontinuation of NUBAIN following prolonged use has been followed by symptoms of narcotic withdrawal, i.e., abdominal cramps, nausea and vomiting, rhinorrhea, lacrimation, restlessness, anxiety, elevated temperature and piloerection. **Use in Ambulatory Patients** NUBAIN may impair the mental or physical abilities required for the performance of potentially dangerous tasks such as driving a car or operating machinery. Therefore, NUBAIN should be administered with caution to ambulatory patients who should be warned to avoid such hazards. **Use in Emergency Procedures** Maintain patient under observation until recovered from NUBAIN effects that would affect driving or other potentially dangerous tasks. **Use in Children** Clinical experience to support administration to patients under 18 years is not available at present. **Use in Pregnancy (other than labor)** Safe use of NUBAIN in pregnancy has not been established. Although animal reproductive studies have not revealed teratogenic or embryotoxic effects, nalbuphine should only be administered to pregnant women when, in the judgement of the physician, the potential benefits outweigh the possible hazards. **Use During Labor and Delivery** NUBAIN can produce respiratory depression in the neonate. It should be used with caution in women delivering premature infants. **Head Injury and Increased Intracranial Pressure** The possible respiratory depressant effects and the potential of potent analgesics to elevate cerebrospinal fluid pressure (resulting from vasodilation following CO_2 retention) may be markedly exaggerated in the presence of head injury, intracranial lesions or a pre-existing increase in intracranial pressure. Furthermore, potent analgesics can produce effects which may obscure the clinical course of patients with head injuries. Therefore, NUBAIN should be used in these circumstances only when essential, and then should be administered with extreme caution. **Interaction With Other Central Nervous System Depressants** Although NUBAIN possesses narcotic antagonist activity, there is evidence that in nondependent patients it will not antagonize a narcotic analgesic administered just before, concurrently, or just after an injection of NUBAIN. Therefore, patients receiving a narcotic analgesic, general anesthetics, phenothiazines, or other tranquilizers, sedatives, hypnotics, or other CNS depressants (including alcohol) concomitantly with NUBAIN may exhibit an additive effect. When such combined therapy is contemplated, the dose of one or both agents should be reduced. **Sulfites Sensitivity** NUBAIN contains sodium metabisulfite, a sulfite that may cause allergic-type reactions (e.g., hives, itching, wheezing, anaphylaxis) in certain susceptible persons. Although the overall prevalence of sulfite sensitivity in the general population is probably low, it is seen more frequently in asthmatics or in atopic nonasthmatic persons.

PRECAUTIONS Impaired Respiration At the usual adult dose of 10 mg/70 kg, NUBAIN causes some respiratory depression approximately equal to that produced by equal doses of morphine. However, in contrast to morphine, respiratory depression is not appreciably increased with higher doses of NUBAIN. Respiratory depression induced by NUBAIN can be reversed by NARCAN® (naloxone hydrochloride) when indicated. NUBAIN should be administered with caution at low doses to patients with impaired respiration (e.g., from other medication, uremia, bronchial asthma, severe infection, cyanosis or respiratory obstructions). **Impaired Renal or Hepatic Function** Because NUBAIN is metabolized in the liver and excreted by the kidneys, patients with renal or liver dysfunction may overreact to customary doses. Therefore, in these individuals, NUBAIN should be used with caution and administered in reduced amounts. **Myocardial Infarction** As with all potent analgesics, NUBAIN should be used with caution in patients with myocardial infarction who have nausea or vomiting. **Biliary Tract Surgery** As with all narcotic analgesics, NUBAIN should be used with caution in patients about to undergo surgery of the biliary tract since it may cause spasm of the sphincter of Oddi.

ADVERSE REACTIONS The most frequent adverse reaction in 1066 patients treated with NUBAIN is sedation 381 (36%). Less frequent reactions are sweaty/clammy 99 (9%); nausea/vomiting 68 (6%); dizziness/vertigo 58 (5%); dry mouth 44 (4%); and headache 27 (3%). Other adverse reactions which may occur (reported incidence of 1% or less) are: **CNS Effects** Nervousness, depression, restlessness, crying, euphoria, floating, hostility, unusual dreams, confusion, faintness, hallucinations, dysphoria, feeling of heaviness, numbness, tingling, unreality. The incidence of psychotomimetic effects, such as unreality, depersonalization, delusions, dysphoria and hallucinations has been shown to be less than that which occurs with pentazocine. **Cardiovascular** Hypertension, hypotension, bradycardia, tachycardia. **Gastrointestinal** Cramps, dyspepsia, bitter taste. **Respiration** Depression, dyspnea, asthma. **Dermatological** Itching, burning, urticaria. **Miscellaneous** Speech difficulty, urinary urgency, blurred vision, flushing and warmth. **Patients Dependent on Narcotics** Patients who have been taking narcotics chronically may experience withdrawal symptoms upon the administration of NUBAIN. If unduly troublesome, narcotic withdrawal symptoms can be controlled by the slow intravenous administration of small increments of morphine, until relief occurs. If the previous analgesic was morphine, meperidine, codeine, or other narcotic with similar duration of activity, one-fourth of the anticipated dose of NUBAIN can be administered initially and the patient observed for signs of withdrawal, i.e., abdominal cramps, nausea and vomiting, lacrimation, rhinorrhea, anxiety, restlessness, elevation of temperature or piloerection. If untoward symptoms do not occur, progressively larger doses may be tried at appropriate intervals until the desired level of analgesia is obtained with NUBAIN. **Management of Overdosage** The immediate intravenous administration of NARCAN® (naloxone hydrochloride) is a specific antidote. Oxygen, intravenous fluids, vasopressors and other supportive measures should be used as indicated. The administration of single doses of 72 mg of NUBAIN subcutaneously to eight normal subjects has been reported to have resulted primarily in symptoms of sleepiness and mild dysphoria.

Nutrition After Vertical Banded Gastroplasty

LLOYD D. MACLEAN, M.D., PH.D., BARBARA RHODE, P.DT., M.SC. (NUTR.), and HARRY M. SHIZGAL, M.D.

From the Departments of Surgery, Royal Victoria Hospital and McGill University, Montreal, Canada

The authors assessed the nutritional status of 60 morbidly obese patients by determining body composition, using multiple isotope dilution at 13.6 ± 0.4 months following operation. Body weight was followed for an additional 12.3 ± 0.8 months. Twenty-four patients lost more than 25% of their preoperative weight and were within 30% of ideal weight (a "good" result). At 1 year they had lost 41.4 ± 1.8% of preoperative weight and the body mass index (BMI) decreased from 46.7 ± 1.2 to 27.0 ± 0.6 kg/m^2. Despite rapid weight loss, malnutrition did not develop and their body composition became indistinguishable from that of normally nourished volunteers. Twenty-nine patients had a "satisfactory" result with more than 25% weight loss but were not within 30% of ideal. Their weight decreased by 34.8 ± 1.0% as their BMI decreased from 55.4 ± 1.2 to 36.0 ± 0.8 kg/m^2. Seven patients lost less than 25% of their preoperative weight (an "unsatisfactory" result). Malnutrition did not develop in any patient. In the authors' experience, in contrast to other weight reducing operations, vertical banded gastroplasty (VBG) results in rapid weight loss without the concomitant development of malnutrition even in patients who return to normal weight.

MALNUTRITION COMMONLY OCCURS in patients who have had significant weight loss following operations for morbid obesity.[1,2] The malnutrition that develops following jejunoileal bypass has been classified as kwashiorkor in type, as it is associated with hepatic dysfunction and is similar to what occurs with protein deprivation without carbohydrate restriction. These patients usually have a reduction in the plasma concentrations of essential amino acids, an elevation of plasma glycine, and a favorable therapeutic response either to intravenous amino acids or to restoration of intestinal continuity.[3,4]

In contrast, operations designed to limit intake result in a decreased intake of both calories and protein, and malnutrition more closely mimics marasmus, in which liver failure is rare but vitamin deficiencies are common.[1] Patients with malnutrition following intake-limiting procedures exhibit weakness, easy fatigue, a failure to return to their former occupation,[1] repeated infections and immunologic incompetence,[5] Wernicke-Korsakoff disease,[6] and vitamin B-12 and folic acid deficiencies. Nutritional studies of gastric limiting operations until now have been confined to gastric bypass or to horizontal gastroplasty. The malnutrition that develops following both jejunoileal bypass and gastric limiting operations is characterized by an abnormal contraction of the body cell mass (BCM) with an expansion of extracellular mass (ECM).[1,2]

Supported by a grant from the Medical Research Council of Canada.

Reprint requests and correspondence: Lloyd D. MacLean, M.D., Ph.D., Royal Victoria Hospital, 687 Pine Ave. West, Montreal Quebec, Canada, H3A 1A1.

Submitted for publication: March 13, 1987.

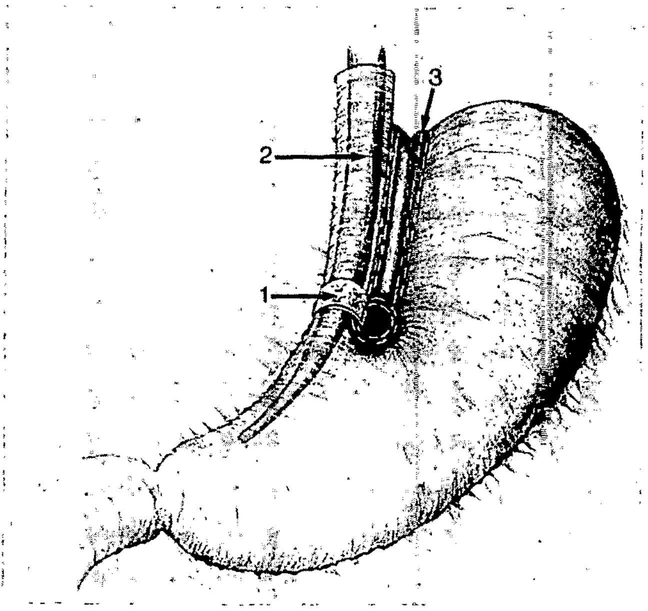

FIG. 1. Vertical banded gastroplasty (1) polypropylene band created an external circumference of outlet orifice of 55 mm in two patients, 50 mm in seven patients, and 41–45 mm in 51 patients; (2) 26 Fr bougie within new gastric pouch; and (3) vertical staple line.

In this study, we measured body composition by multiple isotope dilution in 60 patients 13.6 ± 0.4 months after vertical banded gastroplasty (VBG) to document the nutritional consequences of this popular operation for the control of morbid obesity. We followed the stability of weight loss by measuring weight change for an additional 12.3 ± 0.8 months following the measurement of body composition.

Materials and Methods

Patient Selection

All patients entered into the study were at least twice ideal weight, had a body mass index (BMI) of 50.7 ± 1.0 kg/m^2, and were considered capable of participating in an exacting postoperative follow-up program. After surgery all patients were seen weekly for 1 month, monthly for 1 year, and then bimonthly by a research dietitian, the surgical staff, and by a psychiatrist if necessary. Weight, height, and ideal weight[7] were recorded for each patient before and at the stated intervals after surgery.

Operative Procedure

We performed VBG on all 60 patients.[8] A single layer of polypropylene mesh was used to band the orifice of the proximal gastric pouch (Fig. 1). This material was cut 15 mm wide and 60–70 mm long and overlapped to create an external circumference of 55 mm in two patients, 50 mm in seven patients, and 41–45 mm in 51 patients. The material used for banding was sutured to itself and not to the gastric wall using 4 polypropylene sutures. A No. 26 Fr bougie was used as a guide to establish the size of the gastric pouch. We used two rows of 4.8 mm vertical staples in all patients.

Measurement of Body Composition

Body composition was determined by multiple isotope dilution[9] at a mean of 13.6 ± 0.4 months after surgery. These measurements involved the simultaneous intravenous injection of 8 μCi of sodium-22 and 500 μCi of tritiated water. The plasma isotope concentrations were determined at 4 and 24 hours following isotope injection. All of the urine and any extrarenal fluid lost during the 24-hour isotopic equilibration period were collected to correct for isotope loss. Total exchangeable sodium (Na_e) was determined from the equilibrated plasma sodium-22 specific activity at 24 hours. Total body water (TBW) was calculated from the equilibrated plasma tritium concentration at 24 hours. Total exchangeable potassium (K_e) was calculated from TBW, Na_e, and the ratio in whole blood of the sodium plus potassium content divided by its water content. Lean body mass (LBM), body fat, and BCM were calculated from equations previously published.[10] The Na_e/K_e ratio is a sensitive index of the nutritional state. In the normally nourished this ratio approximates unity with an upper 95% confidence limit of 1.22. Malnutrition is characterized by a loss of BCM, accompanied by an expansion of the ECM, and thus an increase in the Na_e/K_e ratio. Malnutrition was therefore defined by a Na_e/K_e ratio greater than 1.22.[9] Because many preoperative body composition measurements have been recorded in obese patients, only postoperative nutritional measurements were performed in this study. The postoperative body composition data were compared to similar data obtained in 25 normally nourished healthy volunteers and in 100 preoperative morbidly obese patients.

Evaluation

We performed endoscopy with an 11-mm endoscope at 6 weeks, 6 months, and 1 year following gastroplasty to determine stoma size and the continuity of the vertical staple line separating the new small stomach from the gastric fundus. An upper gastrointestinal x-ray series was also obtained to rule out staple line disruption at 1 year and repeated later if clinically indicated.

Patients were individually classified on the basis of weight loss as "good" (if the weight loss after operation exceeded 25% of preoperative weight and was within 30% of ideal weight), "satisfactory" (if weight loss exceeded 25% but the patient still exceeded 30% of ideal),

TABLE 1. *Nutritional Status Following Vertical Banded Gastroplasty (13.6 ± 0.4 Months)*

	Normal	Good	Satisfactory	Unsatisfactory
Controls				
Patients	25	24	29	7
Weight (Kg)	70.4 ± 2.5	72.4 ± 2.2*	96.5 ± 2.8	89.2 ± 5.3

Stoma (% <11 mm—with intact vertical staple line)		100	86	29

* $p < 0.05$ between good and both satisfactory and unsatisfactory.

and "unsatisfactory" (if the weight loss was less than 25% of preoperative weight). These patients were followed closely for weight change for an additional year (12.3 ± 0.8 months) following the body composition measurement. The patients also were classified at 13.6 ± 0.4 and 25.9 ± 0.8 months as excellent, good, fair, poor, or failure using the criteria of Reinhold.[11]

Assessment of Food Intake

Patients recorded their food intake over a 7-day period immediately prior to the measurement of body composition. Types and quantities of foods consumed were recorded using the diary method. A research dietitian reviewed the food intakes for accuracy and classified them as A (a solid diet consisting of all foods), B (a soft diet with complete variety), and C (purees and/or liquids only).

Biochemical Measurements

Fasting blood specimens were analyzed before surgery and at 6-month intervals for blood glucose, total serum cholesterol, alkaline phosphatase, serum aspartate amino transferase (AST), serum alanine amino transferase (ALT), and serum lactic dehydrogenase (LDH).

Blood samples for vitamin determinations were drawn from the 60 patients following an overnight fast at the time body composition was determined. Serum or whole blood samples were analyzed for vitamin B-12,[12] folic acid,[13,14] and iron.[15]

Statistical Analysis

We used analysis of variance to evaluate the significance of differences. A p value of less than 0.05 was considered to be significant. Means were calculated with the corresponding standard error of the mean (SEM).[16]

Results

Body Composition, Body Mass Index, Weight

Table 1 and Figure 2 summarize the body composition and clinical results at 13.6 ± 0.4 months following operation. The patients were divided into three groups on the basis of their postoperative weight loss. Twenty-four patients had a good result, a loss of more than 25% of preoperative weight and a final weight within 30% of ideal weight. Twenty-nine patients had a satisfactory result, a loss of more than 25% of preoperative weight but a final weight greater than 30% of ideal weight. The remaining seven patients had an unsatisfactory result. Body composition data of 100 preoperative morbidly obese subjects and 25 normally nourished healthy volunteers are included for comparison. The mean preoperative body weight for each group is also included in Figure 2.

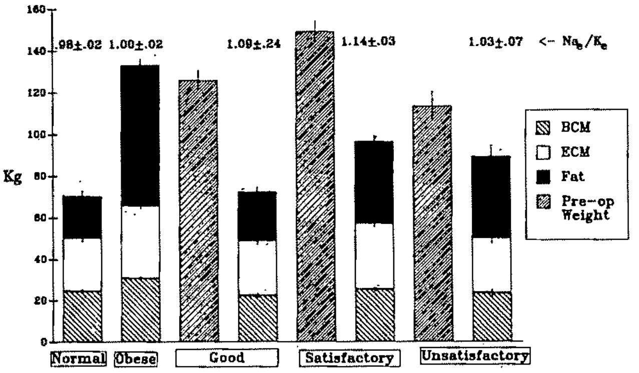

FIG. 2. Body composition of 25 normal controls (Normal); and of 100 obese patients prior to surgery (Obese); preoperative and postoperative weights and body composition at 13.6 ± 0.4 months after VBG are shown in 24 patients who achieved a good result, for 29 patients listed as satisfactory, and seven patients who achieved an unsatisfactory result. The Na_e/K_e ratio is shown for each group and controls. Malnutrition did not occur in any patient even though weight loss was rapid and great, especially in the good group. See text for definition of groups.

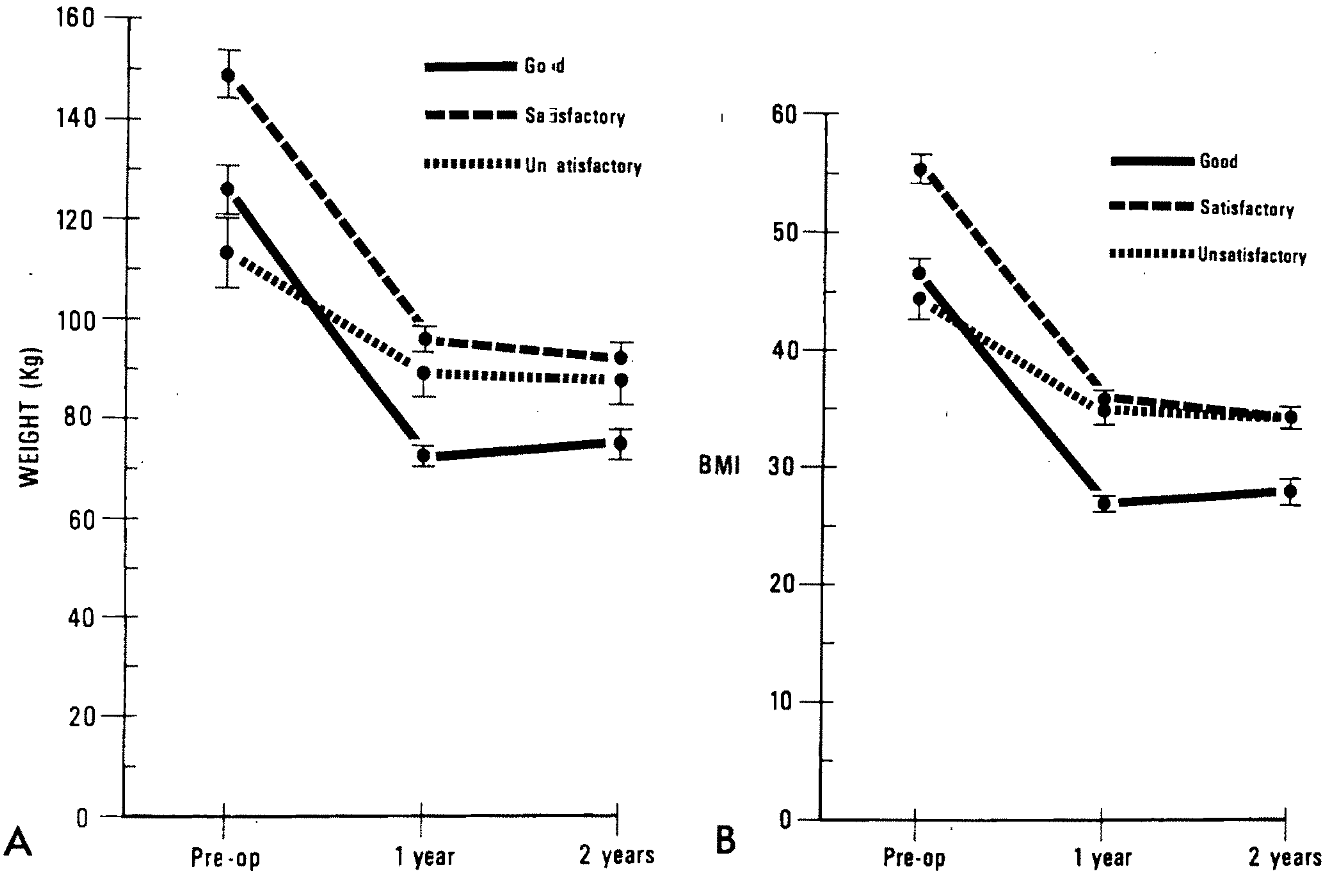

FIGS. 3A and B. Weight (*A*) and body mass index (*B*) changes 1 and 2 years after VBG in three groups of patients who achieved either a good, satisfactory, or unsatisfactory result. There was no significant weight change during the second year.

The mean body composition of the 24 patients with a good result at the time of evaluation was indistinguishable from normal. In spite of a mean weight loss of 41.4 ± 1.8% of preoperative weight, malnutrition did not develop. Body composition remained normal with a normal BCM and a normal Na_e/K_e ratio of 1.09 ± 0.04. The mean BMI decreased from 46.7 ± 1.2 to 27.0 ± 0.6 kg/m^2 ($p < 0.05$).

The mean weight loss in the 29 patients who achieved a satisfactory result was 34.8 ± 1.0%. However, they weighed significantly more prior to surgery than the good group ($p < 0.05$). Body composition also remained normal with a normal BCM and a normal Na_e/K_e ratio of 1.14 ± 0.03. The mean BMI decreased from 55.4 ± 1.2 to 36.0 ± 0.8 kg/m^2 ($p < 0.05$). In seven patients an unsatisfactory result occurred, with weight loss less than 25% of preoperative. Their nutritional status remained normal with a normal body composition.

The body fat of the good group returned to within normal limits. The postoperative body fat in this group was significantly ($p < 0.05$) less than the body fat in either the satisfactory or unsatisfactory groups. In all three groups no further weight loss occurred during the second postoperative year (Figs. 3A and B).

Early Surgical Follow-up

All patients with a good result and 86% of patients with a satisfactory result had an orifice of less than 11 mm in diameter at 1 year. At that time, staple line disruption had not occurred in any patient in either the good or satisfactory group.

In the unsatisfactory group a stoma size greater than 11 mm diameter was present in three patients and six of seven patients had developed a disruption in the vertical staple line.

Specific Nutritional Deficiencies

The percentage of patients with decreased serum concentrations of vitamin B-12, red blood cell folate, and serum iron are listed in Table 1. In all groups a significant number of patients had an abnormal reduction in

TABLE 2. *Diet Following Vertical Banded Gastroplasty*

Results	Total Patients	Consistency of Diet A	B	C
Good	24	9	8	7
Satisfactory	29	9	13	7
Unsatisfactory	7	3	4	0

the serum concentrations. However, a clinical deficiency state was not identified.

Dietary Habits

At 1 year 21 patients were eating a solid diet restricted only in quantity (an A result), 25 patients were ingesting a soft diet, and 14 patients were only able to take a pureed or a liquid diet. The distribution of these patients in reference to clinical result appears in Table 2. A good or satisfactory clinical result did not depend on intake of a low consistency diet. However, the majority of patients were ingesting a soft or pureed diet even a year after surgery.

Late Follow-up

All 60 patients were evaluated approximately 2 years (25.9 ± 0.8 months) after surgery, or 12.3 ± 0.8 months following the body composition measurement, to determine the stability of the weight loss (Tables 3 and 4). The method of Reinhold[11] is also included in Table 4 to evaluate weight loss as a percentage of excess weight. No patients have been lost to follow-up. Of the 24 patients with a good result at 1 year, one became satisfactory due to enlargement of the outflow banding because of migration of the polypropylene mesh into the gastric lumen. Three became unsatisfactory due to weight gain, the result of vertical staple line disruption (Table 3).

Of the 29 patients who had a satisfactory weight loss at 1 year, three patients became unsatisfactory due to disruption of the vertical staple line. However, two patients improved from satisfactory to good because of decreased caloric intake. Two patients converted from unsatisfactory to satisfactory due to slow but continued weight loss and one patient converted to good as a result of behavior modification and a decreased caloric intake. Seven patients were unsatisfactory after 1 year. After 2 years 11 had an unsatisfactory result, all due to either a staple line disruption or an outlet orifice that was too large (> 11 mm). An external band circumference that is made greater than 50 mm results in an outlet orifice as measured at endoscopy of > 11 mm.

TABLE 3. *Change in Results Between 1 and 2 Years Following Vertical Banded Gastroplasty*

24 Good	21	1	3
29 Satisfactory	2	23	3
7 Unsatisfactory	1	1	5
Total	24	25	11

Biochemical Results

An elevated fasting plasma glucose was present in 21 patients before surgery. The mean fasting plasma glucose was 151 ± 13 mg/dL. At the time of body composition studies the mean plasma glucose was 85 ± 3 mg/dL and was within normal limits in all but three patients. None of these patients required medication for hyperglycemia.

An elevated fasting serum cholesterol of greater than 280 mg/dL was found in only one patient. The value decreased from 286 to 237 mg/dL at 1 year. The mean cholesterol level for all patients before operation and at 1 year was 191 ± 5 mg/dL and 182 ± 5 mg/dL, respectively.

An elevated alkaline phosphatase was found before surgery in 30 patients. The mean of 142 ± 8 U/L declined to 86 ± 3 U/L at 1 year. Only four patients had a persistent elevation of serum alkaline phosphatase after operation.

Serum aspartate amino transferase was abnormally elevated before operation in eight patients to 61 ± 4

U/L. After surgery this returned to 18 ± 6 U/L. One patient remained abnormal after surgery. Serum alanine amino transferase was abnormally elevated before operation in 20 patients to 80 ± 12 U/L. After surgery this returned to 19 ± 3 U/L and all patients were within normal range.

Serum lactic dehydrogenase was abnormally elevated before operation in 25 patients to 279 ± 9 U/L, and in these patients it returned to 178 ± 6 U/L after operation. One patient continued to remain abnormal.

Discussion

The objective of our surgical approach to morbid obesity is to minimize the physical risks of obesity by restoring weight to within 30% of ideal without the induction of malnutrition. This was achieved in 24 of the 60 patients. At 1 year following VBG these patients had lost 41.4 ± 1.8% of their preoperative body weight. An additional 29 patients achieved a satisfactory result. In this group weight loss exceeded 25% of preoperative weight, but weight was not within 30% of ideal. At 1 year only seven patients had lost less than 25% of their preoperative weight. Their mean weight loss was 21.0 ± 0.9%.

In spite of the large weight loss at a relatively rapid rate, malnutrition did not develop in any patient. Except for excessive body fat, the body composition of all the patients at 1 year was normal with a normal BCM and a normal Na_e/K_e. The weight decrease was due to a loss of body fat without a loss of BCM. In similar studies of patients after jejunoileal bypass, horizontal gastroplasty, and gastric bypass, this degree of weight loss was associated with a significant incidence of malnutrition, which at times was life-threatening.[1,2]

The development of malnutrition following weight reduction surgery is generally not well appreciated. This is because in the studies that have monitored body composition following weight reduction surgery the LBM, not the BCM, was measured.[17,18] The LBM is not, however, a sensitive measure of the nutritional state. Malnutrition results in a loss of BCM accompanied by an expansion of the ECM and, as a result, the LBM does not change. In 75 severely malnourished individuals, there was a 41% reduction in the BCM with a concomitant 24% expansion of the ECM.[9] The LBM in these severely malnourished individuals was not significantly different from normally nourished individuals. Thus, to monitor the nutritional state following weight reducing surgery it is essential to measure the two components of the LBM: the BCM and the ECM.

We have previously reported the effect of jejunoileal bypass[2] on the nutritional status of 44 morbidly obese patients evaluated in a similar fashion. The operation involved anastomosing 15 inches of proximal jejunum, end-to-side, to 5 inches of distal ileum. Body composition remained normal after bypass in 33 patients, and at 1 year body weight had decreased by 24.4 ± 2.1%. This loss of body weight resulted entirely from a loss of body fat. Malnutrition developed in 25% or 11 patients. In these patients at 1 year the weight loss was 27.0 ± 3.0% while the BCM decreased by 22.6 ± 6.1%. Their body composition was characteristic of malnutrition with a contracted BCM, expanded ECM, and elevated Na_e/K_e. The metabolic complications associated with small bowel bypass occurred only in the patients who developed an abnormal body composition. Repeated hospital admissions were required because of these metabolic complications, which included malaise, anorexia, debilitating weakness, hypokalemia, and liver failure. Protein malnutrition was responsible for the observed abnormalities as the infusion of amino acids, without additional nonprotein calories, returned the body composition to normal and successfully corrected both the metabolic derangements and the abnormal liver function. Subsequently over several months, a high protein diet prevented the recurrence of symptoms and maintained a normal body composition. However, over several years bowel continuity was restored in almost all of the patients because of the difficulty they experienced in maintaining a high protein intake. Restoration of bowel continuity always restored both liver function and body composition to normal.

We have previously described the nutritional consequences of horizontal gastroplasty or gastric bypass[1] in 96 morbidly obese patients. In 49 patients, body composition remained normal at 24 months, with a 25.7% loss of body weight and a 36.2% loss of body fat. Malnutrition developed in 49% or 47 patients. In these patients weight loss was 25.9%, body fat decreased by 34.4%, and the BCM decreased by 29.4%. Malnutrition developed in patients with a small stoma and was associated with hair loss, lassitude, easy fatigue, and difficulty in attaining full employment. Liver failure did not occur. The body composition of all the malnourished patients eventually returned to normal. In 19 patients this occurred as the stoma enlarged spontaneously. Eight patients were successfully treated with dietary counseling. The orifice was enlarged by operation in 18 and by endoscopic dilatation in two patients.

All weight reducing operations are designed to reduce either the intake or absorption of food. To achieve adequate weight loss with jejunoileal bypass, a malabsorption state is created by limiting the length of functioning small bowel. However, if the length of small bowel remaining in circuit is too short, protein malnutrition develops. Furthermore, for the individual patient it is not possible to determine the appropriate length that must remain in circuit. The margin of error in measurement is small and hypertrophy of the remaining bowel in circuit is variable, adding to the unpredictability of this operation to produce adequate weight loss without inducing malnutrition.

The gastric weight reducing operations create a resistance to the movement of food out of the gastric pouch. With gastric bypass and horizontal gastroplasty, this is achieved by limiting both the reservoir capacity and the cross-sectional area of the outlet orifice. If the orifice is too small or eccentrically placed, vomiting and malnutrition can develop. If it is too large, weight loss is insufficient. Because the cross-sectional area is related to the $(\text{radius})^2$, small differences in the radius of the outlet orifice result in large differences in the cross-sectional area and thus to the resistance to the movement of food out of the stomach. Since narrowed orifice in the horizontal gastroplasty and gastric bypass as we performed it[1] is extremely short, it had to be constructed very small to limit flow and induce weight loss. This caused vomiting and malnutrition in a significant number of patients. This problem has been partially overcome with the VBG. With this operation, the resistance to the movement of stomach contents is not critically related to a very short but severe narrowing of the outflow tract. Vomiting is unusual after VBG for several reasons. The orifice is larger than that found effective after horizontal gastroplasty. The orifice is easily placed in the dependent position. The banding material very rarely migrates, which can cause narrowing of the orifice from the gastric pouch, and it is easier to make a smaller pouch in the vertical rather than in the horizontal position. Furthermore, by surrounding the dependent portion of the new pouch with nonelastic polypropylene mesh, the size of the orifice does not expand with time. It is not known presently how the gastric pouch changes in capacity with time. With this operation, 88% of the patients experienced a good or satisfactory result without the development of malnutrition in a single patient. This is in sharp contrast to the experience with the other weight reducing operations tested.

The operation performed in this study results in a smaller outflow tract of the new gastric pouch than the vertical banded gastroplasty described by Mason.[8] In the majority of patients the banded external circumference was 45 mm or less. The creation of an orifice of this size resulted in rapid weight loss, but was probably also responsible for the high rate of verticle staple line disruption herein reported.

At 2.2 ± 0.1 years after surgery, disruption of the staple line had developed in 14 of the 60 patients with an unsatisfactory weight loss in nine. Gastrointestinal x-ray examination and repeated endoscopy have both demonstrated that staple line disruptions enlarge with time. Most staple line perforations will probably result in an unsatisfactory result given enough time because of progressive enlargement of the communication between the new gastric pouch and the gastric fundus. This gives rise to an increased ability to eat and is associated with loss of the sense of satiety after eating small meals, which is so common in patients with intact gastric limiting operations. Loss of the feeling of satiety with small meals has prompted examination for staple line integrity in many patients and frequently has identified disruptions as the cause. Unless this complication is looked for very carefully, an inferior result can be attributed to the operation as designed.

Enlargement of the banded area of the gastroplasty occurred in only one patient in this series. This rare post-VBG complication was due to the migration of the polypropylene mesh into the lumen, with resulting enlargement of the orifice.[19] When supporting sutures, pledgets, or silicon rings are sutured to the stomach or placed near an anastomosis, migration of the material designed to maintain a constant orifice size occurs frequently.[1] All operations that depend on these materials sutured to the gastric wall or placed around or near an anastomosis are probably unacceptable. In contrast, polypropylene as used in the VBG has been dependable in maintaining orifice size with a very low incidence of migration.[19,20]

Staple line disruption occurs because the tissue between the anterior and posterior gastric walls does not heal together. In our study 4.8-mm staples were used. Lechner and Elliott[21] use 3.5-mm staples to ensure crushing and sealing between the anterior and posterior walls of the stomach. We have found that on dividing between vertical staple lines made with both 3.5- and 4.8-mm staples on the stomach, there is sufficient bleeding to require surgical hemostasis. If division between the staple lines is not done, the tissue at that site can remain viable and if the staples migrate a potential passage can develop between the new small pouch and the fundus of the stomach.

Vertical banded gastroplasty is capable of inducing impressive weight loss without malnutrition but fails in our experience, in many instances, because of staple line disruption. This complication has been previously reported.[20] For this reason we have for several months divided between the vertical staple lines in all patients undergoing VBG.

The inability to clear glucose adequately from the blood is common in obesity and may occur in the absence of clinically manifest diabetes mellitus. This was the case in 21 of the patients in this series with elevated fasting blood glucose. All but three had a complete and prompt decline in fasting blood glucose to normal with weight loss. An unsatisfactory weight loss occurred in one of the three. Several reports document the elimination of the requirement for insulin or other hypoglycemic agents in obese type II diabetics who lose weight after gastric surgery.[22,23,24]

Steatosis with abnormalities of liver function occurs commonly in obesity. In 45 of the 60 patients, one or more liver function tests were abnormally elevated before surgery. Approximately 1 year following surgery, liver function tests were normal in all but six of the 60 patients. The weight loss was good in one, satisfactory in three, and unsatisfactory in two of the six patients. In contrast, liver dysfunction is common after intestinal bypass and is especially severe in patients who develop malnutrition. Correction of the contracted BCM by intravenous amino acids or by surgical restoration of normal intestinal continuity promptly reverses even severe liver failure.[3]

All patients took a multivitamin preparation that contained 5 μg of vitamin B-12 and 0.1 mg of folic acid each day. Iron was not given routinely. No anemia developed during the 2 years of follow-up. However, serum and/or red blood cell deficiencies of vitamin B-12, folate, and iron did occur without clinical manifestation. This is in contrast to the report of Amaral et al.,[25] who described anemia in 37% of patients 20 months after gastric bypass, with a low serum iron concentration in 48.6% and a low serum vitamin B-12 concentration in 70%. These deficiency states might be expected to be lower with VBG, which does not bypass the duodenum and stomach. The final conclusion and recommendations for both operations is that careful and permanent follow-up for nutritional deficiencies be carried out.

In this study the 1983 Metropolitan height-weight tables[7] were used and the BMI[26] was calculated as (weight)/(height)^2(kg/m^2) to assess both the patients' preoperative status and the postoperative result. The BMI is a measure of the degree of obesity, with a high correlation with direct measures of body fat. It is simple to calculate and is more precise than skinfold measurements.[27]

A BMI in the range of 20–25, which was defined by Garrow[28] as Grade 0 obesity, is associated with minimal mortality and is equivalent to the insurance 'desirable weight' range. A BMI of 25–30 is Grade I obesity. The increase in mortality is minimal. Grade II obesity is a BMI of 30–40 and represents the transition from clinically trivial to crippling obesity. At the midpoint of this range, mortality is roughly double that found in the desirable weight range. Morbid obesity or Grade III obesity is a BMI over 40 and is usually incompatible with normal employment. Insurance statistics on mortality in Grade III obesity become unreliable because these individuals have difficulty obtaining insurance.[28] Patients in the upper ranges of Grade II obesity have an expected mortality three times that of individuals of normal weight in the same age group. The mortality ratio increases rapidly as BMI increases from 30 to 40.[27]

Drenick et al.[29] have reported a startling 12-fold increase in mortality in morbidly obese men between ages 25 and 34 when followed for a mean of 7.6 years. In the age group 35 to 44 years there was a six-fold excess mortality.

The effect on overall mortality resulting from a surgically induced weight loss is not easily measured at this time. While patients in the satisfactory group have lost a significant amount of weight with a decline in BMI from 55.5 ± 1.2 to 36.0 ± 0.8, it remains to be proven that this degree of weight loss will significantly decrease the physical risks associated with morbid obesity. It is likely that these patients remain at a two- to three-fold risk for mortality compared to controls of desirable weight even after surgically induced weight loss. Whether the patient has arrived at that point from a 12-fold or a four-fold increase in mortality over citizens of desirable weight is not yet clear. This type of reporting with estimates of physical risk and use of the BMI should be more widely used by surgeons assessing results in these patients.

Immature T Lymphocytes after Injury Characterized by Morphology and Phenotypic Markers

J. JEREMY WOOD, F.R.C.S. (Eng), JOHN B. O'MAHONY, F.R.C.S. (I), MARY L. RODRICK, Ph.D., and JOHN A. MANNICK, M.D.

From the Departments of Surgery, Brigham & Women's Hospital and Harvard Medical School, Boston, Massachusetts

Changes in the peripheral blood mononuclear cell (PBMC) population in patients following both thermal and nonthermal injury were defined by both morphological characteristics and surface phenotype with the monoclonal antibodies T6, OKT9, OKT10, and OKIa1, using a fluorescence activated flow cytometer with gating to separate small cells of the lymphocyte series from larger forms. Lymphocytes with surface antigens that bind T6, OKT9, and OKT10 are rarely found in the peripheral blood of adult patients, except in those with malignancies of the lymphoid system. In both burn and trauma patients the percentage of lymphocytes in the PBMC population after Ficoll-Hypaque separation was significantly reduced as compared with normal controls due to increases in the number of granulocytes, large granular lymphocytes (LGL), and monocytes, often present in immature forms. T6 cells were found in significantly greater numbers in both burn and nonthermal injury patients than in a control group using both small and wide gate settings on the fluorescence-activated flow cytometer. Significant increases in the number of $T9^+$ cells also were observed in both groups for a prolonged period following injury. Significantly increased numbers of the $T10^+$ and $Ia1^-$ cells were detected in burn patients. The response to injury, therefore, involves the appearance in the peripheral blood of immature cells that may express T6, T9, T10, and Ia1 surface antigens. These cells may be present in quantities otherwise seen only in malignant disease.

PATIENTS WHO SURVIVE the initial shock phase after major injury have an increased susceptibility to overwhelming sepsis that is frequently fatal.[1] This has been attributed to abnormalities of cell-mediated immunity. In burn patients, *in vivo* anergic responses to skin test antigens, decreased *in vitro* blastogenesis in response to T cell mitogens, reduced IL 2 production by lymphocytes, and suppressor cell activity in mixed lymphocyte culture have all been described.[2–4] Similar but less frequent findings have also been reported after major nonthermal injury.[5,6] Characterization of peripheral blood mononuclear cells (PBMC) obtained from patients after all types of trauma is therefore of considerable interest.

The development of an extensive repertoire of monoclonal antibodies (McA) that recognize antigens expressed on T cells both during development and in maturity has allowed the documentation of alterations in T cell subsets in disease states, and the delineation of thymocyte development. Using the OKT series, 70% of the total thymic cell population are $T4^+$, $T8^+$, $T6^+$, and $T10^+$, but on full maturation and export from the thymus T6 and T10 expressions are both lost.[7] As a result, PBMCs contain less than 1% $T6^+$ cells and very limited numbers of $T10^+$ cells.[7–9] The T9 antibody, which binds to both immature thymocytes and activated mature T cells, has been shown to recognize the transferrin receptor on these cells,[10,11] but normally less than 9% of PBMC are T9 positive.[8] OKIa1 also binds to activated T cells, B cells, and monocytes. In a variety of malignancies of the lymphoid system, circulating neoplastic cells that react with T6, T9, and T10 can occur in considerable numbers,[7,8,12] but otherwise cells of these phenotypes are rarely seen in the PBMC of adults.

In this study we have identified on morphologic grounds increased numbers of immature leukocytes in the cell population obtained after Ficoll-Hypaque separation of peripheral blood from both thermal and nonthermal injury patients. Examination of their T cell antigens revealed significantly increased numbers of cir-

culating T6, T9, and T10 positive cells among the burn patients' PBMCs, and increased numbers of T6 and T9 cells from trauma patients. This response to injury has not been previously reported, and its significance is discussed.

Methods

Subjects Studied

Three groups of subjects were studied. Thirteen burn patients (3 women, 10 men) aged 23–91 years (mean: 53.4) admitted to The Longwood Area Trauma Center at the Brigham & Women's Hospital with burns from 5 to 80% total body surface area (mean: 34%) comprised the first group. The second group consisted of nine patients (2 women, 7men) aged 16–42 years (mean: 22.4), who suffered a variety of moderate to severe nonthermal injuries, often multiple, ranged as assessed by the Injury Severity Score[13] from 9 to 40 (mean: 21.8). Both groups were studied weekly until discharge from the unit or death. Informed consent was obtained and the study approved by the Human Subjects Committee of the Brigham & Women's Hospital. These two groups were compared to a third group of 16 healthy volunteers (9 women, 7 men) aged 18 to 35 years (mean: 27.6), who comprised the controls.

The patients received conventional intensive care, including elective intubation for lung injuries, vigorous fluid replacement with close monitoring, and early excision and grafting or full thickness and deep partial thickness burns. Particular attention was paid to nutritional status and requirements. All patients were assessed shortly after admission and, if necessary, provided with full nutritional support by the intravenous route. Caloric requirements and nitrogen balance were continuously assessed and intake adjusted daily where needed.

Preparation of PBMCs

Peripheral blood was collected between 7:30 and 9:30 A.M. into heparinized 50 cc syringes. It was diluted 1:2 in phosphate-buffered saline (PBS), then placed over one-third this volume of Ficoll-Hypaque (Pharmacia, Piscataway, NJ) and centrifuged for 35 minutes at 400 g. The interface cells were collected, washed three times in minimal essential medium (MEM) (Eagle), and counted using trypan blue for assessment of viability, which was always more than 95%. The number of true mononuclear cells was estimated on a hemocytometer using a sample specimen in Turk's stain, other cell types being excluded from the count on morphological grounds. The mononuclear cells were then suspended at 5×10^6/ml in MEM with 2 mM-glutamine, 5% fetal calf serum (FCS, MA Bioproducts, Walkersville, MD), and 1% antibiotic/antimycotic solution containing 10,000 units penicillin/10,000 μg streptomycin/20 μg Fungizone per ml (Grand Island Biol. Co., NY).

Morphologic Assessment of PBMCs

PBMCs were diluted to 2×10^6/ml in MEM and an equal volume of 30% human albumin added. Two hundred microtiters of this suspension was centrifuged onto a slide using a Shandon-Cytospin (Shandon Southern Instruments, Inc., Sewickly, PA) at 900 rpm for 7 minutes, then stained with Wright-Giemsa. All the slides were examined by the same observer (MLR) using light microscopy at 1000× and classified by conventional hematological criteria into the following categories—granulocytes (PMN, bands, and less mature granulocytes), lymphocytes, atypical lymphocytes (including blasts), monocytes, and large granular lymphocytes (LGL). The observer was blind as to the origin of the cells being studied. High power fields were examined and the number of each cell type expressed as a percentage of the total counted.

Staining with Monoclonal Antibodies

An indirect technique was employed modified from the procedure recommended by the manufacturers of OKT3, OKT4, OKT8, OKT9, OKT10, and OKIa1 (Ortho Diagnostic Systems, Raritan, NJ). The T6 McA was a generous gift from Dr. Cox Terhorst of the Dana-Farber Cancer Institute, Boston, MA, and has been used extensively.[14] McA OKT3 recognizes cluster designation (CD) CD3, OKT4, CD4, and T6, CD1. Overnight incubation at 4 C of 100 μL of PBMC at 5×10^6/mL with 5 μL of McA produced good binding of McA to cell, and has been used throughout our work. Cells were then washed in PBS, and 100 μL of fluoresceinated goat anti-mouse Ig (Tago, Burlingame, CA) diluted 1:30 in MEM then added. After 45 minutes incubation at 4 C, the cells were washed twice in PBS and diluted with 1 cc of 1% paraformaldehyde in PBS and stored at 4 C prior to counting. Negative control cells were stained with fluoresceinated anti-mouse Ig (FITC) only. At least one control was assayed one each occasion patients were studied.

Modification of the monoclonal staining procedure made the timing more convenient and improved staining. This modification included overnight, rather than 2 hour, incubation of cells with the monoclonal antibody, followed the next day by washing and staining with the fluoresceinated anti-mouse Ig. Since this procedure differs from that currently recommended by the manufacturers of the monoclonal antibodies (Ortho Pharmaceuticals), experiments were done to compare overnight with the recommended 2-hour incubation period. In these experiments, nine normal controls were studied in nine different observations, and two thermal injury patients were studied for six observations. The results showed no significant differences with any monoclonal antibody tested, including OKT3, OKT4, T6, OKT8, OKT9, OKT10, and OKIa1 when compared by the Wilcoxon matched pairs analysis ($p = > 0.05$).[15] Early experiments done during this study with the assistance of Dr. Stuart Schlossman's laboratory (Dana Farber Cancer Institute, Boston, MA) had shown that there was no difference between background staining without the use of an irrelevant monoclonal mouse IgG, or with its use followed by fluorescent staining. However, these early experiments were only done with the three monoclonal antibodies OKT3, OKT4, and OKT8. We therefore carried out similar experiments with the remaining monoclonal antibodies used in this study (T6, OKT8, OKT9, OKT10, and Ia), and found no difference ($p = >0.05$) when cells were stained either with FITC alone or with irrelevant monoclonal Ig (MOPC-21, Litton Bionetics, Kensington, MD). No significant difference was observed between staining for either 2 hours or 24 hours with or without MOPC-21 as the control antibody ($p = >0.05$).

Flow Cytometry

Positive staining of PBMC by McA was determined by forward light scatter on a Becton-Dickinson Flow Cytometer (Becton-Dickinson, Mountain View, CA). Over 90% of the measurements were made by the same observer. After calibration of the cytometer with latex beads, a sample of OKT3-labelled cells from a control subject was used to adjust the cytometer gate to the size of normal mature T cells and measurement of control and patient OKT3 (CD3), OKT4 (CD4), and OKT8 (CD8) cells was performed. Assessment of positively staining cells of various sizes was important because we had observed that the patients' PBMC populations contained LGL, atypical lymphocytes, PMN, and blasts that had been shown on occasion to bind various McAs. Altering the gates permitted the exclusion of most of these cells, counting only those corresponding in size to the normal T cell population. This is of particular importance when mature cells are to be measured. As the T6, T9, and T10 markers can be found on immature cells that are morphologically larger than mature cells, two measurements were usually made—for "small" gates (*i.e.*, cells the size of control T3 cells) and for "wide" gates (this included any larger cells that might be present). The number of positive staining cells passing through each gate after subtraction of background staining was expressed as a percentage of total number of cells counted.

Statistical Analysis

Examination of the data suggested that its distribution was nonparametric, and this was confirmed using a normal probability plot. Some values are reported as means ± standard error of the mean (SEM) according to convention, but in order to depict more accurately the data, dot plots are presented. Statistical comparisons used the Mann-Whitney U Test and the level of significance was taken at $p = <0.05$. When comparison of staining methods were analyzed for significance, the Wilcoxon matched pairs analysis was used.

Results

Cellular Morphology of PBMC from Burn Patients (Table 1)

When smears of the PBMC populations were examined, obvious abnormalities were seen. Particularly striking was an increase in the number of cells showing features of immaturity (*e.g.*, banded nuclei, granular cytoplasm, and occasionally mitotic and multinucleate cells). Identification of such cells as being of a particular cell-type may be difficult, but when classified into the categories described above and compared to controls significant differences emerged. The controls showed that our technique of Ficoll-Hypaque separation was normally effective in removing almost all granulocytes and yielded a mean of 95% mononuclear cells. The main differences seen in the patients were an increase in granulocytes in particular, and sometimes also in monocytes, these occasionally occupying over 60% of the population. As a result, the percentage contribution of lymphocytes was reduced and a significant late increase in LGL was observed. Atypical lymphocytes were seen more frequently, but this apparent increase was never statistically significant at any time period.

Cellular Morphology of PBMC from Trauma Patients

Examination of the morphology of PBMC from patients after nonthermal injury revealed changes similar to those following burns. Overall there was a significant reduction in the number of lymphocytes (mean: 58.6%, SEM: 4.0, median: 62.5%, $p = 0.0002$), and a significant increase in the number of LGL (mean: 5.7%, SEM: 1.14, median: 4.0%, $p = 0.0006$). The number of lymphocytes was reduced for the periods 0–9, 10–19, and 20–29 days and then recovered. The number of monocytes was increased during days 10–19 (mean: 31.6%, SEM: 5.8, median: 27%, $p = 0.002$), whereas the increase in LGL was during the periods 20–29 and 30 days onward.

† Results from 14 different normal controls. Burn patients, 12 patients followed after injury during indicated days.

‡ NS = $p > 0.05$ by Mann Whitney Test.

Burn Patients—T6 Positive Cells (Fig. 1)

Using small gates, 21 measurements were made of the controls and failed to detect circulating $T6^+$ cells on 12 occasions. The mean value was 1.85% (SEM: 0.96) and median was 0. When larger cells were included using wide gates, more $T6^+$ cells were detected (mean: 3.08%, SEM: 1.03, median: 2.0%).

Burn patients were often found to have increased numbers of circulating $T6^+$ cells, and sometimes a sizeable population of these cells was present. When the total number of measurements on patients were compared to the controls a significant increase was observed. (Patients mean % $T6^+$ cells with small gates: 6.54%, SEM: 1.51, median: 4.0%—patients *vs.* controls, $p = 0.0081$). (Using wide gates, patients T6 positive cells —mean: 11.5%, SEM: 2.2, median: 9.0%—patients *vs.* controls, $p = 0.015$). For analysis of changes with time following injury, successive 10-day periods were considered, and each compared to controls. Significant increases in $T6^+$ cells ($p < 0.05$) occurred at days 0–10 and day 41 onward measuring small cells and using wide gates from 0 to 10 days, and from 11 to 30 days when two periods were combined.

Burn Patients—T9 Positive Cells (Fig. 2)

In 34 measurements of control PBMC using small gates, circulating $T9^+$ cells were absent or undetectable on 16 occasions. Overall the mean number of these cells was 1.82% (SEM: 0.47) and the median was 0. The corresponding values using wide gates were mean: 4.66, SEM: 1.28, and median: 3.5%.

The data analyzing small cells from burn patients re-

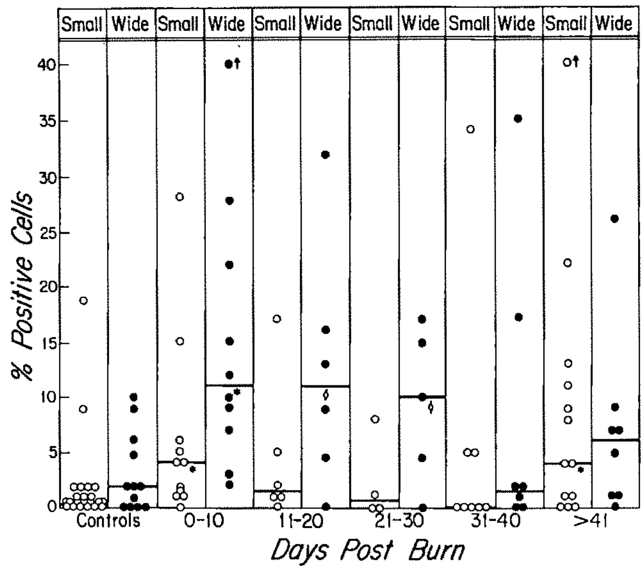

FIG. 1. *T6 positive cells following thermal injury.* Individual data points are shown using the small gate (O) and wide gate (●) setting on the FACS (see text), with the median value for each period indicated by the horizontal bar. More than 40% indicated by †. (*$p < 0.05$, patients *vs.* controls, and §$p < 0.05$ when the period 11–30 days considered.)

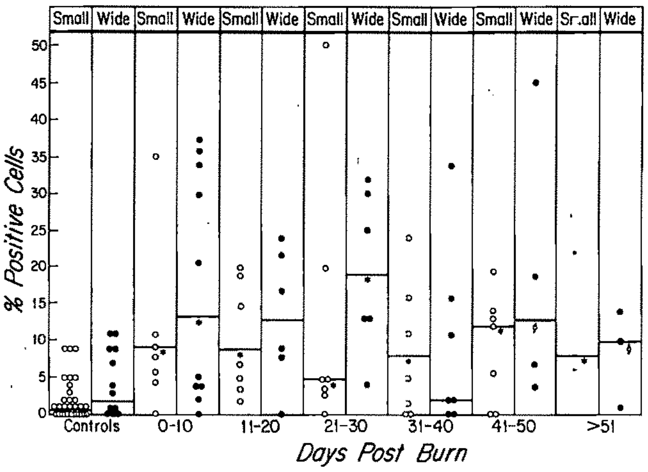

FIG. 2. *T9 positive cells following thermal injury.* Individual data points are shown for the small (○) and wide gate (●) setting on the FACS and the median value for each period indicated by the horizontal bar. (*p < 0.05, patients *vs.* controls, §p < 0.05, 41 days plus, patients *vs.* controls.)

vealed a consistent and statistically significant ($p < 0.05$) increase in the number of $T9^+$ PBMC throughout the study, in each 10-day period. In contrast to the controls, circulating $T9^+$ cells were undetectable in patients in only six occasions out of 42 measurements. Overall using wide gates, a significant increase in $T9^+$ cells was seen (median: 12.0%, $p = 0.007$). At all periods but one (31-40) there were increased numbers of T9 cells and this reached significance ($p < 0.05$) on days 0-10, 21-30, and when the periods 41-50 days and 51 plus days were combined).

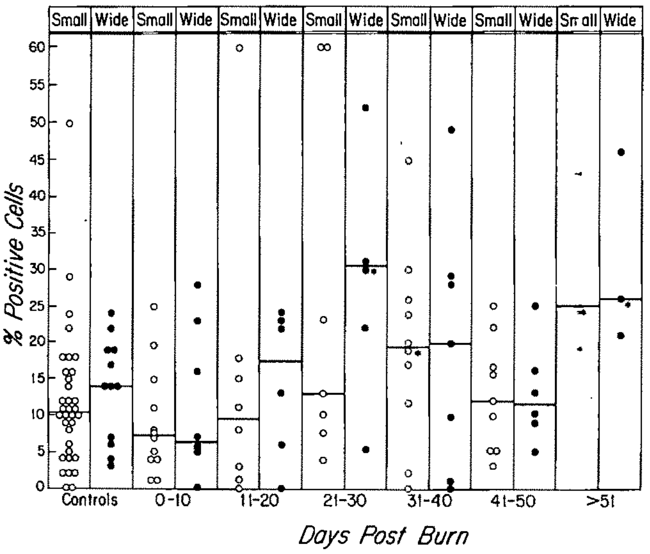

FIG. 3. *T10 positive cells following thermal injury.* Individual data points are shown for small (○) and wide gates (●) on the FACS and the median value for each period indicated by the horizontal bar. (*p < 0.05, patients *vs.* controls.)

Burn Patients—T10 Positive Cells (Fig. 3)

Thirty-four measurements of controls using small gates revealed a mean value of 11.8% (SEM: 9.6) and median of 10.5%. The patients overall had a slight increase in the number of $T10^+$ cells (mean: 17.3%, SEM: 2.5, median: 12.5%), but this failed to reach statistical significance ($p = 0.2$). When studied over time, however, significant increases were observed at 21-30 days and 51 plus days after injury ($p = 0.04$ and 0.015, respectively). On occasions it was possible to detect a population of $T10^+$ cells present in considerable numbers.

When the flow cytometer was set to use wide gates, the values obtained for controls were mean: 13.5%, SEM: 1.89, and median: 14%, and for the total burn group 18.3%, SEM: 2.3, and median: 18%. This difference was not significant ($p = 0.29$); however, significant increases were observed at 21-30 days following injury (median: 30.5, $p = 0.03$) and 51 plus days (median: 26, $p = 0.02$).

Burn Patients—Ia1 Positive Cells

Using small gates the mean per cent Ia1 positive cells in controls was 9.6%, SEM: 1.1, median: 8.75%. During the period 41 days onward, the number of $OKIa1^+$ cells was increased in burn patients (mean: 21.5, SEM: 4.7, median: 20.0, $p = 0.035$), but although increased at other times this failed to achieve statistical significance ($p > 0.05$).

When the gates were increased to include larger cells, however, an overall increase in $Ia1^+$ cells was observed (Controls' mean: 15.08%, SEM: 2.16, median: 15.0%; Patients' mean: 24.0%, SEM: 2.4, median: 22%; $p = 0.017$). Increased numbers of $OKIa1^+$ cells were observed during the 21-30 day period (mean: 40.6%, median: 35.3%, $p = 0.009$), during 31-40 days (mean: 22.7%, median: 23%, $p = 0.055$), and from 41 days onward (mean: 23.6%, median: 22%, $p = 0.04$).

Trauma Patients (Fig. 4)

Circulating $T6^+$ cells in the trauma patients were identified on 16 occasions out of 24 measurements using small gates, contrasting with only nine out of 21 measurements in the controls. Similarly using wide gates, we were only unable to detect T6 cells on two occasions from 15 patient assays. When all the data obtained using small gates were compared, a significant increase in the number of circulating $T6^+$ cells was noted (controls' mean: 1.86%, SEM: 0.96, median: 0; trauma patients' mean: 7.2%, SEM: 2.3, median: 3.0%, $p = 0.04$). Similarly, when the wide gate setting was employed an increased number of $T6^+$ cells was observed (controls' mean: 3.08%, SEM: 1.03, median: 2.0%; patients' mean: 15.1%, SEM: 4.6, median: 9.0% $p = 0.04$).

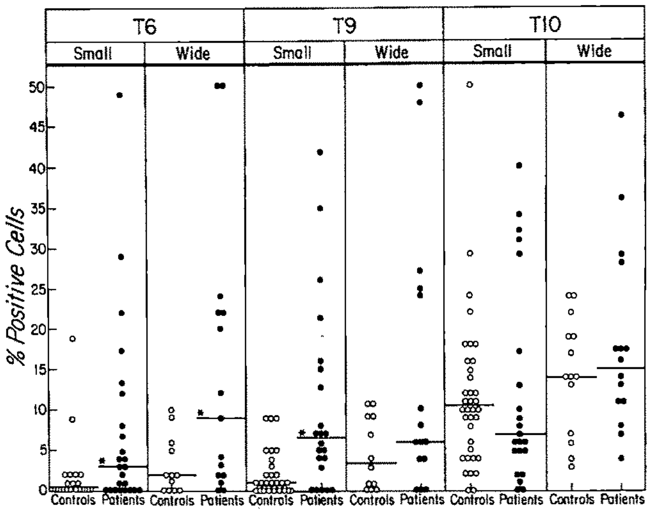

FIG. 4. T6, T9, and T10 positive cells after nonthermal injury. Individual data points are shown for controls (O) and patients (●) and the median values indicated by the horizontal bar. (*$p < 0.05$, patients *vs.* controls.)

When the data for T9$^+$ cells were examined, significantly increased numbers were detected using the small gates (controls' mean: 1.82%, median: 0; patients' mean: 10.2%, median: 6.5%, $p = 0.0017$). Using the wide gate setting the maximum number detected in the controls was 11%, and this was exceeded on five occasions in the patients—a significant difference using chi squared analysis ($\chi^2 = 4.91$, $p < 0.05$ for 1 df). The increase in the median from 3.5% to 6.0% for the group, however, failed to reach significance ($p = 0.2$).

Although on five occasions the patients had over 25% circulating T10 positive cells measured using small gates, the group had a slightly lower median value than the controls. Using the wide gate setting a population of T10 positive cells was also detected on a few occasions, but no significant difference between the controls and the trauma patients could be established.

There were insufficient data on trauma patients to permit a study over time following the injury, and in general this rather heterogenous group of patients were in hospital for less time than the burn patients. No clear picture of changes following injury emerged for T6$^+$ and T10$^+$ cells, although like the burn patients the increase in small T9$^+$ cells was probably present throughout the study period.

Discussion

The data presented here demonstrate that following injury the cellular composition of the PBMC population changes markedly with an increase in cells bearing T cell markers not normally found in peripheral blood. Examination of the morphology of the cells obtained after Ficoll/Hypaque separation revealed increased numbers of granulocytes, monocytes, LGL, and fewer mature lymphocytes. Immature lymphoid and myeloid cells were present in significant numbers as well as nucleated red cells and occasional mitotic figures. This has been described in burn patients by Volenec and colleagues[16] and a detailed study of this phenomenon in a larger group of patients has been submitted for publication.[17] The finding of similar changes after nonthermal injury suggests that this is part of the response to all types of injury. The presence of these cells suggested that cells of immature phenotype may also be present and prompted this investigation. Populations of cells positive for T6 (CD1), T9, T10, and Ia1 were identified frequently in burn patients, and nonthermal injury patients had significantly increased numbers of T6 and T9 positive cells.

The techniques of McA labeling and measurement of positively stained cells described here are based on those recommended by the relevant manufacturers and used standard reagents and equipment used widely elsewhere. However, certain departures from recommended and established protocols, and possible limitations of our techniques need to be discussed. As stated, our data (see Methods) showed that background staining using anti Ig-FITC alone or an irrelevant mouse McA and anti-Ig FITC gave similar results, so we adopted the former technique. However, where it appears that abnormal cell populations are present, some of which may contain a large number of Fc receptors,[16] the two methods could yield slightly different results, and this may account for a small part of the differences observed between controls and patients. It seems highly unlikely, however, that this explains the existence of large populations of cells quite separate from the background area, which we have frequently seen, that are described here. Although there are advantages to using flow cytometry to measure positively stained cells, such as heterogeneous cell population makes it impossible often to define the T cell constituent when using foward light scatter.

In normal PBMC suspensions it is possible to distinguish fluorescence due to the erythrocytes and due to PMNs and other larger cells, and a well defined T3$^+$ population often exists in between these. Because this was not the case when we began to study trauma and burn patients, it was recommended by Dr. Kenneth Ault, of the Brigham & Women's Hospital Analytical Cytology Laboratory, that we use a control T3 stained specimen to define the T cell population by size and to use this setting of the gates (called small gates to determine changes in the T cell subsets in patients. The wide gates setting (which included all the larger cells) was also used to provide, by comparison, information about the phenotypes of the larger cells within the PBMC population. It is important to state that the numbers obtained and reported here represent the percentage of cells passing through the gate that stain positively with the McA used, and cannot be extrapolated back to the peripheral blood to give absolute numbers of each circulating cell type for each patient. It has been suggested that this technique gives more consistent results from day to day[18] and indeed our range for the commonly used T3, T4, and T8 markers are very similar to those described by others.

With these reservations, we feel that these data show clearly that after thermal injury T6$^+$, T9$^+$, and T10$^+$ cells can be found in the peripheral blood, and T6$^+$ and T9$^+$ cells after nonthermal injury. What are these cells? When Wright-Giemsa stained smears of PBMC were examined, we found increased numbers of immature lymphoid cells, and also identified in both patient groups frequent increases in the contribution of LGL, granulocytes, and monocytes to the PBMC pool. Ortaldo et al.,[19] having obtained purified suspensions of these cell types by a variety of techniques, examined the percentage of cells that would bind a number of T cell McA. Less than 1% of PMN were T6$^+$, T10$^+$, or Ia$^+$, and only 1% of LGL, T6 positive. On average 35% of LGL were Ia$^+$ and 62% T10$^+$, leading to the suggestion that OKT10 was a useful marker for LGL. Monocytes showed widespread nonspecific low affinity binding, but specific binding only for OKM1 and Ia. This suggests that the T6 cells we identified are unlikely to be PMN, LGL, or monocytes. However, it is quite possible that the T10$^+$ cells occasionally seen are LGL.

A more likely explanation is that these McAs identify immature T cells, and that extrathymic maturation of T cells occurs in burn and trauma patients. This is supported by the morphological appearance of the PBMC where immature forms were frequently seen, and by the fact that the T6, T9, and T10 antigens are associated with various stages of intrathymic maturation. In addition, cord blood from normal full-term infants has been shown to contain on average 24% T6 positive cells and 58% T10 positive.[20] It is now realized however that these markers are not specific for thymocytes. Bone marrow cells have been examined for T cell markers and about a third of all cells were found to be T10 positive.[21] Immature B cells were very frequently OKT10$^+$, whereas mature B cells and erythroid precursors were T10 negative. No T6$^+$ cells were identified in bone marrow, but T6$^+$ cells have been identified in the tonsil and in lymph nodes.[22] Of particular importance is that the T6 McA will identify the Langerhans cell of the epidermis.[23] These cells are the principal antigen presenting cells in the skin and, as much, initiate the response to foreign antigen.[24] Although originally thought to be fixed, it is now clear that the Langerhans cells or their precursors circulate between the skin and local lymph nodes and, if depleted, are repopulated from the bone marrow.[25] A full-thickness burn will by definition destroy these cells and the larger T6$^+$ cells identified in the PBMC population may be circulating Langerhans cells or precursors engaged in repopulation of the regenerating or grafted skin.

Several studies have shown that activation of T cells produces changes in the surface antigens with the appearance of markers normally associated with immaturity. Hercend et al.[26] showed that activation of T cells by PHA, soluble antigen, or in mixed lymphocyte culture produced, as proliferation occurred, cells that were T9$^+$, T10$^+$, and IaI$^+$. This was confirmed by Burns et al.,[27] who also showed that T cells increase in size on activation but do not become T6 positive. It is now known that OKT9 recognizes the transferrin receptor present on dividing cells, including myelocytes and nucleated erythroid precursors from bone marrow, and immature thymocytes.[10,11] Aside from the increase in immature cell types found in turn and trauma patients, including nuleated red cells, evidence suggests that their PBMC population contains activated cells. Sakai, Daniels, and colleagues found that unstimulated PBMC showed considerable spontaneous activity in tissue culture as assessed by the incorporation of radiolabelled nucleic acid precursors,[28] and we have confirmed these findings in our laboratory. The consistent increase in small T9$^+$ cells seen here probably represents activated T cells. Circulating T10$^+$ cells were seen more frequently in burn than in trauma patients, but we are unable to explain this difference.

What are the implications of these findings? They suggest that following injury, just as immature PMN are released into the circulation, so is a population of immature T cells presumably destined to replace those that may be lost through hemorrhage or destruction at the injury site. That extrathymic development of T cells occurs is demonstrated by studies on athymic mice and man. Athymic mice still develop T cells and interestingly T6$^+$, T9$^+$, and T10$^+$ PBMCs were found in studies of patients with the DiGeorge Syndrome, a condition of congenital thymic aplasia.[29] Other than this rare condition, significant numbers of T6$^+$ and T9$^+$ cells are only detected in various types of T cell neoplasias and in cord blood.[20] This immaturity of the T cell population probably contributes to the decreased T cell response observed in these patients by many investigators.

These findings have important implications for work in this field. First, it is clear that the cells recovered after Ficoll-Hypaque separation of peripheral blood contain not only a considerable number of cells not of the lymphocyte series, but those T lymphocytes present frequently display markers of immaturity. If this "contamination" by PMNs and blasts is not accounted for in the dilutions necessary to prepare the final PBMC suspension, then spuriously low results from *in vitro* assays of lymphocyte function may be obtained. In addition, these data raise the question as to whether the principal immunological abnormality in burn and trauma patients is merely the functional immaturity of the circulating lymphocyte pool. Certainly Volenec and colleagues[16] found that burn patients with persistent immature cells within the PBMC had a worse prognosis than those with only transient abnormalities. However, it would be difficult to explain the presence of serum suppressive of lymphocyte function[2] and suppressor cells on this basis. Immature lymphocytes within the PBMC population may contribute to the abnormalities of lymphocyte function observed and are a potential target for immunomodulation.

In conclusion, following injury large populations of T6, T9, and T10 positive cells appear in the circulation. These cells can be identified within the PBMCs after Ficoll/Hypaque separation. Morphologic examination of these cells shows the presence of immature lymphoid and myeloid forms and suggests that this unusual T cell profile represents the appearance of immature T cells in the peripheral blood.

Acknowledgments

The authors gratefully acknowledge the technical assistance of Phil D'Eon and Kathy Collins and the expert advice of Dr. Kenneth Ault of Brigham & Women's Hospital regarding flow cytometry. We also thank Dr. Cox Terhorst, Dana Farber Cancer Institute, Boston, Massachusetts for providing the monoclonal antibody to T6 and for his many helpful discussions throughout the study. In addition, Ann Braswell provided invaluable editorial assistance.

Carcinoma of the Ampulla of Vater

DANIEL H. HAYES, M.D.,* JOHN S. BOLTON, M.D.,* GLADDEN W. WILLIS, M.D.,† and JOHN C. BOWEN, M.D.*

From the Departments of Surgery and Pathology,† Ochsner Clinic and Alton Ochsner Medical Foundation, New Orleans, Louisiana*

Thirty-five consecutive cases of adenocarcinoma of the ampulla of Vater seen over the past 36 years were reviewed The introduction of new diagnostic techniques over the course of this study improved the accuracy of preoperative diagnosis but did not lead to earlier diagnosis. The surgical resectability rate was 88%, and 53% of postoperative survivors were free of disease at 5 years. Of the 14 patients with metastases to regional lymph nodes, 27% survived disease-free for 5 years. Surgical mortality was 25% for the entire series but has been reduced to 6.6% over the past decade. Surgical mortality was primarily due to leakage of the pancreaticojejunostomy; the risk of pancreaticojejunostomy leak correlated inversely with the degree of chronic pancreatitis in the pancreatic remnant. In 35% of resected cases, a benign adenomatous component was contained within the cancer of the ampulla of Vater. Cure rates are good for this lesion. The most important factor in maximizing cure rate is careful attention to the technical details of pancreaticojejunostomy in order to minimize surgical mortality. Benign adenomas appear to be a frequent precursor of carcinoma of the ampulla of Vater.

THE PERIAMPULLARY AREA is anatomically complex and adenocarcinoma may arise from one of four types of epithelium: the mucosa of the ampulla of Vater, the pancreatic duct, the distal common bile duct, or the periampullary duodenum. Carcinomas from each of these four sites of origin may exhibit different growth patterns and different natural histories. In the clinical situation, the site of origin cannot always be distinguished, and surgical treatment for all resectable carcinomas in the periampullary area is essentially the same. However, when reviewing the natural history, cure rates, and nuances of diagnosis and surgical care, it is advantageous to separate these four lesions as clearly as possible.

Carcinoma of the ampulla of Vater is considered together with other periampullary cancers in most reports.$^{1-4}$ Furthermore, the criteria by which a cancer is judged to be ampullary in origin has not always been clear in previous reports.$^{2-6}$ In our experience, histology is not always helpful in distinguishing among the various sites of origin; this distinction is best made on the basis of gross surgical anatomy. The natural history may be obscured by inclusion of large tumors that encompass the distal bile duct and ampulla and invade the periampullary pancreas and duodenal wall such that an ampullary origin cannot be assigned with confidence. Conversely, overly rigid criteria may cause all but the smallest and most favorable lesions to be excluded.

To clarify the presentation, natural history, surgical resectability, cure rate, and distinctive features of diagnostic work-up and surgical technique, we revived our experience with carcinoma of the ampulla of Vater.

Materials and Methods

Hospital files and pathology records were systematically searched and records were identified and reviewed of all patients classified as having neoplasms of the periampullary region, head of the pancreas, ampulla of Vater, distal bile duct, or duodenum. From this group, patients with neoplasms of the ampulla of Vater were selected, using the preoperative diagnostic evaluation, surgeon's note, gross pathologic description, histology, and often specimen photographs (Figs. 1 and 2). In most cases, the gross surgical pathology and specimen photographs were most helpful. Cases in which the mucosa of the ampulla of Vater could be clearly identified as the site of origin of the tumor (*i.e.*, tumor confined to the ampulla of Vater or clearly infiltrating out from it into

the periampullary tissues) were included. Doubtful cases, where the site of origin could not be clearly assigned, were uncommon but were excluded from this series.

The cases were then submitted to intensive clinical and histopathologic review analyzing features of presentation, demographics, details of preoperative work-up, surgical treatment, postoperative follow-up, and histopathologic features. Survival rates were calculated by the product limit method of Kaplan and Meier.[7] Statistical comparisons were made using χ^2 analysis.

Results

Of 37 cases identified as neoplasms of the ampulla of Vater during the period of study (1949–1985), two were benign villous adenomas. The age of the 35 patients with malignant lesions ranged from 41 to 83 years with a median age of 62 years. Twenty-six patients were men and 11 women. The most common presenting signs are summarized in Table 1. The classic triad of fluctuating painless jaundice, palpable gallbladder, and anemia was present in only two patients. In nine patients, cholecystectomy had been performed within 10 months of diagnosis of carcinoma of the ampulla of Vater in the erroneous belief that the patients had only biliary stone disease.

Preoperative evaluation became much more accurate over the course of this study, largely due to the introduction of fiberoptic upper GI endoscopy and endoscopic retrograde cholangiopancreatography. An accurate preoperative diagnosis of carcinoma of the ampulla of Vater was established in 27% of patients prior to 1969, whereas after 1969 the preoperative diagnosis was correctly established in 73% of patients. However, the introduction of better diagnostic techniques did not improve the stage at diagnosis as judged by the status of the regional lymph nodes in resected specimens. Six of 17 patients prior to 1969 had positive nodes in their resected specimens, while eight of 14 patients after 1969 had positive nodes.

In 31 of 35 patients (88%) with malignant lesions, radical resections could be carried out (30 Whipple resections, 1 total pancreatectomy). In the remaining four patients, metastatic disease at presentation precluded radical resection and bypass alone was performed. One of two patients with benign villous adenomas underwent Whipple resection and the other underwent local resection. Of the 32 patients undergoing radical resection (31 for carcinoma, 1 for villous adenoma), there were eight postoperative deaths (25%). Postoperative mortality declined steadily throughout the period of study (Table 2) and over the past decade has been 6.6 ($p < 0.05$, comparing the last 10 years of study with the previous years of study). The causes of the surgical mortality are listed in Table 3. By far the most common cause of perioperative mortality was intra-abdominal sepsis due to leakage of the pancreaticojejunostomy. Of nine confirmed pancreaticojejunostomy leaks, six proved fatal.

Decade	Cases	Deaths	Mortality Rate (%)
1949–1955	1	0	0
1956–1965	5	1	20
1966–1975	11	6	54
1976–1985	15	1	6.6
Total	32	8	25

To further investigate the perioperative mortality, all factors that might influence leakage of the pancreaticojejunostomy were examined in detail. We studied leak rates by surgeon, configuration of reconstruction, anastomotic technique, quality of the pancreatic remnant, and use of ductal stents or surgical drains. Pancreaticojejunostomy leakage strongly correlated with the quality of the pancreatic remnant. In 10 patients with evidence of obstructive pancreatitis (dilated pancreatic duct, fibrosis of the pancreas as noted by the surgeon or pathologist, and/or preoperative increased serum amylase) there were no pancreaticojejunostomy leaks, while in the remaining 21 patients with a soft, normal pancreas undergoing Whipple resection (1 patient having a total pancreatectomy is excluded) the leak rate was 43%. This difference was statistically significant ($\chi^2 = 4.3$, $p < 0.05$). No other factor correlated statistically with the development of pancreaticojejunostomy breakdown. Over the past decade, only one of 15 patients developed a pancreaticojejunostomy leak, and this patient survived.

Excluding postoperative deaths, the five-year disease-free survival rate was 53% and the 10-year survival rate was 42% (Fig. 3). Median follow-up of patients who remain under active follow-up is 58 months. Fourteen patients (45%) had metastatic carcinoma involving lymph nodes in the resected specimen. These patients had a 5-year disease-free survival rate of 27% and a median survival of 37 months.

Only 12% of patients undergoing radical resection had a vagotomy added to the procedure. In almost all cases, a conservative gastrectomy (consisting only of the antrum of the stomach) was performed, such that 78% of the patients undergoing radical resection had neither a vagotomy nor an extensive (greater than 50%) gastrectomy. Although two patients developed stress upper GI hemorrhage associated with pancreaticojejunostomy leak and intra-abdominal sepsis, no patient developed symptomatic ulcers beyond the immediate postoperative period.

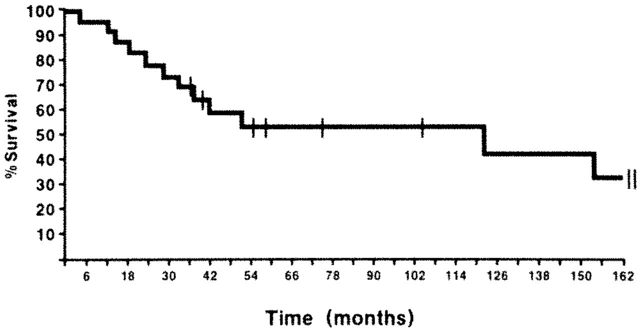

FIG. 3. Disease-free survival, patients with carcinoma of the ampulla of Vater surviving radical resection for cure. Tic marks signify the length of follow-up of patients who remain under active follow-up.

Histologically, carcinomas were classified as primarily infiltrating in 27 patients (84%) and as papillary in five patients (16%). In 11 of 31 specimens (35%) in which adequate tissue was available for detailed analysis, a benign adenomatous component was associated with the invasive carcinoma (Fig. 4A). These adenomatous components consisted of well-defined benign tubular or villous epithelial components in a broad vascularized stroma. Features of pseudostratification, increased nuclear/cytoplasmic ratio, loss of basal orientation, intraglandular budding and bridging, and increased mitoses were present in all cases to a variable degree (Fig. 4B). The presence of a benign adenomatous component correlated with size of the malignant portion of the tumor, being present in 48% (11 of 23) of patients with carcinomas less than 3 cm in size and 12% (1 of 8) in those greater than 3 cm in size.

Discussion

Diagnostic accuracy improved significantly over the course of the study with the introduction of fiberoptic upper GI endoscopy, ultrasonography, endoscopic retrograde pancreatography, and percutaneous transhepatic cholangiography. In our experience, ultrasonography has been the most helpful initial screening examination for the patient who presents with obstructive jaundice. The finding of stones within the gallbladder or common bile duct indicates the likelihood of primary biliary stone disease and suggests the need for cholecys-

tectomy and common bile duct exploration without further evaluation. Stones and carcinoma of the ampulla may coexist, however, (they coincide in 12 of 37 patients in this series) underlining the importance of careful evaluation of the ampulla at the time of common duct exploration for presumed stone disease. Helpful intraoper-

ative maneuvers include the Kocher maneuver with palpation of the ampulla, choledochoscopy, and on occasion, duodenotomy for direct visualization and biopsy of the ampulla. In addition, the preoperative finding of anemia or occult blood in the stool in a patient with biliary stone disease requires further work-up of the GI tract, including fiberoptic upper GI endoscopy with visualization of the ampulla.

Fiberoptic upper GI endoscopy has been the most accurate diagnostic test since it provides direct visualization of the ampulla of Vater and provides access for biopsy of any abnormality of the ampulla. In our experience, endoscopic retrograde cholangiopancreatography has been more productive than percutaneous transhepatic cholangiography for patients with distal common bile duct obstruction as defined by ultrasound, since it provides a direct look at the ampulla, and also provides a pancreatogram in addition to visualization of the common bile duct. This may be helpful in excluding carcinoma of the head of the pancreas by virtue of the absence of pancreatic ductal stricture.

In view of the long delay in nine patients in our series who had cholecystectomy prior to discovery of the carcinoma of the ampulla of Vater, we had hoped that the introduction of the newer diagnostic modalities would lead to a demonstrably earlier diagnosis as reflected in a more favorable stage of tumors in the latter part of our series. This however was not the case. Accurate preoperative diagnosis is still desirable, however, because it helps the surgeon to plan the operative procedure.

The 25% postoperative mortality is cause for concern. Fortunately, this mortality has been steadily declining and over the past decade has been 6.6%. Our experience of a declining mortality for pancreaticoduodenectomy parallels that of other institutions where a relatively large experience with lesions in the periampullary area can be accumulated by a relatively small number of surgeons. Better anesthesia, antibiotics, intensive care, and perioperative nutritional care have all played a role in this declining mortality, but improvement in surgical technique has been the most important factor (as evidenced by a sharp decline in pancreaticojejunostomy leaks over the past decade). The majority of these patients do not have obstruction of the duct of Wirsung with secondary changes of pancreatic ductal obstruction, pancreatitis, and pancreatic fibrosis.[8] In these cases, anastomosis of the soft pancreas, the capsule of which does not hold sutures well, is less secure. To our knowledge, this is the first report to show in a statistically significant way that the status of the pancreatic remnant strongly influences the fate of the pancreaticojejunostomy. Our efforts to provide a more secure pancreaticojejunostomy have centered around good mobilization of the transected end of the pancreatic remnant, invagination of the cut end of the pancreas into jejunum in preference to a duct to mucosa anastomosis, and use of horizontal mattress nonabsorbable sutures to lessen the chance of suture tearing through the soft pancreas resulting in dehiscence of the anastomosis.

The lack of marginal ulcer complications in this report is in conflict with the findings of Grant and Van-Heerden[9] and Scott et al.[10] In those reports a 6–36% incidence of marginal ulcer complications followed Whipple resections performed without an accompanying truncal vagotomy; furthermore, the marginal ulcers were virulent in their course and were responsible for significant morbidity and mortality. We have not experienced this complication and continue to employ conservative gastric resections without vagotomy in the majority of cases.

The 5-year disease-free survival rate is gratifying. Carcinoma of the ampulla of Vater is the most curable of all carcinomas of the upper gastrointestinal tract. Others have noted similar survival rates when reviewing carcinoma of the ampulla of Vater separate from other periampullary lesions (Table 4). In view of this relatively high surgical cure rate and the lack of effective adjuvant treatment, surgeons must be careful to maximize the cure rate by minimizing the perioperative mortality. Even in the presence of metastatic involvement of regional lymph nodes, surgical resection can be curative. Therefore, limited involvement of adjacent nodes should not preclude attempts at resection. We have not yet employed pylorus preservation in patients with carcinoma of the ampulla of Vater undergoing pancreaticoduodenectomy, out of concern that preservation of the pylorus might compromise the resection of regional nodes. However, we are following with interest recent reports suggesting that cure rates for carcinoma of the ampulla of Vater are not lessened by preserving the pylorus.[16]

The association of benign adenomas with invasive carcinoma of the ampulla has been noted by Baczako et al.[17] and Kozuka et al.[18] The known association of periampullary adenoma and carcinoma with familial polyposis syndromes and the finding in this and the previously mentioned series of a frequent association of adenoma and carcinoma of the ampulla of Vater in patients without familial polyposis suggests that an adenoma-to-carcinoma sequence may also play a role in the development of the more common nonfamilial form of carcinoma of the ampulla of Vater. Ryan et al.,[19] in a recent review, found that most duodenal villous lesions occurred at or near the ampulla of Vater. They speculated that carcinogens in the bile or pancreatic secretions might explain the finding of such a large portion of villous lesions of the ampulla in comparison to other areas of the duodenum and proximal small bowel.

Furthermore, the finding in this series that large cancers of the ampulla do not as frequently have an associated adenomatous component raises the possibility that an advancing invasive carcinoma might overgrow a precursor benign adenoma in some instances. If this assumption is correct, our finding of a benign adenoma in conjunction with invasive carcinoma in 35% of the cases would be a minimum estimate of this association. The low incidence of carcinoma of the ampulla of Vater does not make screening feasible, but the frequent association of adenoma and carcinoma in our series leads us to view with concern the occasional finding of a benign villous adenoma in the ampullary area. Because a negative endoscopic biopsy does not exclude the possibility of carcinoma within the adenoma, we believe that these should be excised in every instance. In some cases, this can be accomplished with a local resection, but Whipple resection should be carried out if the adenoma is not amenable to local resection and the patient is a good operative risk.

Impaired Nonspecific Cellular Immunity in Experimental Cholestasis

PATRICK T. ROUGHNEEN, M.B., CH.B., DAVID B. DRATH, PH.D., ANIL D. KULKARNI, M.S., and BRIAN J. ROWLANDS, M.D.

From the Department of Surgery, University of Texas Medical School, Houston, Texas

The abilities of polymorphonuclear leukocytes (PMN) and pulmonary alveolar macrophages (PAM), to demonstrate chemotaxis, phagocytosis, and superoxide release after bile duct ligation in the rat were investigated to determine the effect of cholestasis on nonspecific cellular immune mechanisms. Chemotactic response to C_{5a} and FMLP, phagocytosis of ^{14}C labeled *Staphylococcus aureus*, and zymosan-induced superoxide release were evaluated 21 days after bile duct ligation (BDL), sham operation, or in normal controls. Serum total bilirubin level was elevated after BDL ($p < 0.01$). Chemotactic ability was similar to each group. PMN phagocytic uptake of ^{14}C labeled *Staphylococcus aureus* was depressed in BDL ($p < 0.05$). BDL rats exhibited impaired PAM phagocytic indices and improved PMN superoxide release ($p < 0.03$). PAM superoxide release was similar in each study group. Alterations in phagocytic function with cholestasis are important deficits in nonspecific cellular immunity that may contribute to the high incidence of infective complications associated with obstructive jaundice.

SEVERAL CLINICAL STUDIES have reported a high incidence of infective complications in patients with obstructive jaundice.[1-7] The majority of such infective sequelae are due to enteric bacteria or their liberated toxins that result in the development of ascending cholangitis, septicemia, endotoxemia, and intra-abdominal sepsis in the cholestatic host.[7] The basis for this predisposition to infective complications is not understood, but may be due to alterations in nonspecific host defense mechanisms. Previous studies have demonstrated impaired reticuloendothelial function in patients and animals with obstructive jaundice.[8-10] However, little is known of the effect of cholestasis on extrahepatic, nonspecific cellular immune function. In this study, we investigated the ability of polymorphonuclear leukocytes (PMN) and pulmonary alveolar macrophages (PAM) isolated from cholestatic rats to demonstrate directed migration, phagocytosis, and superoxide release, critical in the elimination of invading bacterial pathogens.

Materials and Methods

Animals

Female Sprague-Dawley (SD) rats weighing 200–250 g (Timco Laboratories, Houston, TX) were housed in cages of five and subjected to a 12-hour alternate light-dark cycle. Throughout the study rats were fed standard rat chow (Purina Formulab 5008) and allowed water *ad libitum.* Animals were assigned to one of three groups: bile duct ligation (BDL), sham operation (Sham), and normal control (NC). Twenty-one days after operation the animals were killed and PMN and PAM populations obtained as described below.

Bile Duct Ligation

This was performed under ether anesthesia on the first day of the study: a central upper abdominal incision was made, the common bile duct identified, doubly ligated with two 3-0 silk ligatures, and divided.[11] High bile duct ligation was performed in the same position in all animals. In those animals undergoing sham operation, the common bile duct was identified and freed from the surrounding tissue only.

Serum Biochemistry and Histology

Serum total bilirubin determinations were performed in BDL, Sham, and NC groups at days 0 and 21 by the

Walters and Gerarde method.[12] Liver histology (H and E stain) was performed on livers excised from study animals at the time of sacrifice (Department of Pathology, University of Texas Medical School, Houston, Texas).

Cell Isolation

Polymorphonuclear leukocytes were obtained by giving rats an IP injection of 15 ml of 12% sodium caseinate 16 hours prior to sacrifice. The following day PMN were harvested from the peritoneal cavity by saline lavage. They were washed, pooled, and handled in a manner similar to that described below for PAM. Pulmonary macrophages were harvested from BDL, Sham, and NC rats by bronchopulmonary lavage on the day of sacrifice. Briefly, after rats were anesthetized with sodium pentobarbital (30 mg/rat), the abdominal aorta was severed and the trachea cannulated. Sodium chloride solution (7 mL of 0.9% solution) was instilled and removed seven times. The cells obtained following centrifugation and washing were greater than 95% PAM or PMN and all groups were 95% viable. Cells were then used either as suspensions (chemotaxis) or as monolayers (superoxide release and phagocytosis) prepared as described by Mitchell and coworkers.[13]

Chemotaxis

The chemoattractants included the synthetic tripeptide FMLP (Sigma Biochemicals, St. Louis, MO) at final concentration of 10^{-8} M and 10% C_{5a} activated serum, prepared by incubating homologous rat serum with zymosan particles at 37 C for 15–60 min. The attractant was added to the lower half of modified Boyden chambers containing M199 and 0.1% albumin. The upper half of the chamber contained 1.5×10^6 PMN or PAM harvested from BDL, Sham, or NC rats and suspended in medium (M) 199 containing 0.1% albumin. Control chambers contained only M199 and albumin in the lower half to assess random migration. The upper and lower halves of the chambers were separated by either an 8-μm (PAM) or 5-μm (PMN) pore, gelatin-coated polycarbonate filter (Nucleopore Corp., Pleasanton, CA). After the chambers were incubated for 2 hours at 37 C in 95% air and 5% CO_2, the filters were removed, fixed, stained, mounted on glass slides, and allowed to dry overnight before placing coverslips.[14] Migration was assessed by enumerating the PAM or PMN that had moved through the filter in 15 randomly selected oil power fields (×1000).

Phagocytosis of Labeled Bacteria

The live bacterial particle was used at levels consistent with biological reality (10 bacteria/macrophage). Monolayers consisting of 3×10^6 cells (when added) were formed on plastic surfaces at 37 C as previously described.[13] After 1 hour, the approximate 35% of cells that were nonadherent were washed off. Fresh Hank's balanced salt solution containing glucose (1 mg/mL) was added to the monolayers followed by the ^{14}C-labeled *Staphylococcus aureus* (strain 209P) at a multiplicity of 10 bacteria/phagocyte. At the indicated time, the particles were removed; the monolayers were vigorously washed in saline and dried in preparation for counting. Zero time counts were subtracted from subsequent measurements to account for bacterial adherence.[15] Protein determinations were performed on the monolayers as well as on the bacteria to express final results as micrograms of *S. aureus* ingested per milligram of monolayer protein.

Superoxide Release

Superoxide release was measured on monolayers consisting of 3.0×10^6 PAM as previously described.[16] Superoxide-dependent cytochrome C reduction was determined spectrophotometrically at 550 nm in the presence or absence of superoxide dismutase (Sigma Chemicals, St. Louis, MO). Measurements were performed both on cells at rest and following phagocytosis of opsonized zymosan. Zymosan particles were opsonized by initially suspending them in 0.9% saline, washing them and then incubating them with rat serum for 30 minutes. Following opsonization, it was stored, refrigerated, and used as a suspension when needed.

Bacterial Cultures

Samples of blood and bile were taken asceptically from BDL, Sham, and NC animals at the time of sacrifice and innoculated into 3.5 mL of Schaedler's broth (BBL, Cockeyville, MD, USA). Samples of broth were incubated aerobically at 37 C. Culture media was then checked for bacterial growth at 24 hours, 48 hours, and 5 days following incubation.

Statistical Analysis

All results were expressed as mean ± SD and Student's unpaired t-test was used for statistical analysis. A p value <0.05 was considered to be statistically significant.

Results

Serum Biochemistry and Histology

Initial serum total bilirubin levels in BDL, Sham, and NC groups were 0.2 ± 0.1, 0.2 ± 0, and 0.2 ± 0.1 mg/dL, respectively. Twenty-one days following operation, hyperbilirubinemia was evident in BDL animals compared to Sham and NC groups 6.3 ± 2.9 *versus* 0.03 ± 0.1 and 0.1 ± 0 mg/dL ($p < 0.01$).

TABLE 1. *Chemotactic Response to C_{5a} and FMLP in BDL, Sham, and Normal Control Groups**

	Polymorphonuclear Leukocyte			Pulmonary Macrophage		
Treatment	M199	FMLP	C_{5a}	M199	FMLP	C_{5a}
BDL	16.8 ± 5.3	43.5 ± 14.1	43.5 ± 19.8	12.3 ± 3.2	31.0 ± 4.2	34.5 ± 9.2
Sham	20.5 ± 2.8	39.8 ± 11.7	43.5 ± 14.5	10.5 ± 0.7	29.5 ± 2.8	27.0 ± 4.2
Normal control	16.5 ± 2.1	33.0 ± 1.4	33.0 ± 1.4	10.3 ± 2.5	28.3 ± 8.1	28.0 ± 8.5

* Chemotaxis on pooled samples (N = 10) was measured in modified Boyden chambers with either 10^{-8} M FMLP or 10% C_{5a} activated serum as the chemoattractants. PMNs or pulmonary macrophages were placed in the upper compartments of the chamber in M199 with 0.1% albumin. Either M199 (random migration) or attractant (chemotaxis) was added to the lower compartment. Results expressed as the mean number of migratory cells per 15 oil power fields ± SD. Differences between BDL, Sham, and Normal Control groups are not statistically significant.

Liver histology revealed bile duct proliferation and portal venule distension in BDL animals at the time of sacrifice. Minimal changes of peripheral fibrosis and hepatocyte swelling were also apparent in BDL animals.

Bacteriologic Changes

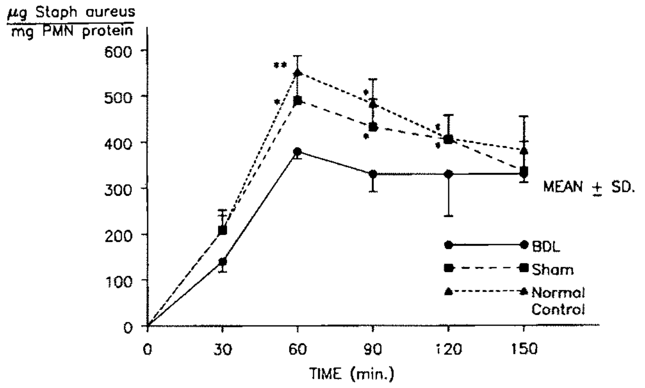
Aerobic and anaerobic cultures of blood and bile derived from experimental animals were sterile 1, 2, and 5 days following sample incubation.

Chemotactic Response to C_{a5} Activated Serum and FMLP

Random migration of PMNs showed no difference between BDL, Sham, and NC rats (Table 1). A satisfactory chemotactic response to C_{5a} activated serum and FMLP was seen in BDL rats, compared to Sham and NC animals in duplicate experiments. Similarly, experiments of PAM chemotactic response demonstrated effective migratory capacity in the BDL group compared to control animals (Table 1).

Phagocytosis of ^{14}C Labeled Bacteria

Polymorphonuclear leukocytes isolated from BDL animals demonstrated a diminished phagocytic ability to ingest ^{14}C labelled *S. aureus* at 30, 60, 90, 120, and 150 minutes compared to PMNs isolated from Sham and NC animals (Fig. 1). This effect was routinely demonstable in consecutive experiments. Similarly, kinetic studies of PAM phagocytic activity demonstrated reduced ingestive capacity in cells isolated from cholestatic animals compared to those obtained from control rats. Although serial studies consistently demonstrated deterioration of PAM phagocytic capacity in cholestatic animals, interassay variation of phagocytic indices was such that results are expressed as individual experiments rather than composite data.



*p<0.04 **p<0.001 compared to BDL.

FIG. 1. Polymorphonuclear leukocyte uptake of ^{14}C labeled *Staphylococcus aureus* at selected time intervals. Results represent two separate experiments performed on pooled samples (N = 5) from each group. Each determination was performed in duplicate and results expressed as mean ± SD.

There was uniform diminution of PAM phagocytic indices in each of three individual experiments (Fig. 2). In view of the small number of animals (N = 3) and the interassay variability of the phagocytic indices between these studies, we were unable to demonstrate statistically significant differences between study groups using both parametric and nonparametric statistical analysis. Each experiment demonstrated that PAM phagocytic indices varied from 50–80% of control values and were consistently suboptimal in comparison with normal control and sham groups. These observations suggest impairment of PAM phagocytic mechanisms in addition to those of the neutrophil.

Superoxide Release in Response to Zymosan Stimulation

Polymorphonuclear leukocytes isolated from cholestatic animals demonstrated increased superoxide release compared to those harvested from Sham and NC groups (Table 2). Duplicate experiments also revealed a tendency for Sham PMNs to release more superoxide than those obtained from NC animals, although the differences were not statistically significant ($p < 0.06$). This may be attributable to the effect of operative stress on PMN metabolism. Triplicate experiments on PAM superoxide metabolism suggested enhanced radical release in the Sham group, compared to BDL and NC animals, although the differences observed were not statistically significant (Table 3).

Discussion

Infective complications are commonly seen in patients with extrahepatic cholestasis;[1-7] however, little is known of the effect of cholestasis on host immune status. Previous work from our group using this BDL rat model has shown depressed responsiveness to phytohemagglutinin (PHA) mitogen and allogeneic F_{344} antigen *in vivo* and *in vitro* 21 days after the onset of obstructive jaundice, suggesting that specific cell mediated immunity is impaired.[17] Integrity of systemic and local nonspecific cellular immune mechanisms are essential in the host's defense against invading bacterial pathogens. Impairment of this component of host defense may therefore account for the high incidence of bacterial infections reported in these patients. Studies have demonstrated a diminished survival rate in BDL rats compared to Sham operated animals following experimental peritonitis.[18] This suggests an impaired effector response to bacterial infection *in vivo* in cholestatic animals.

Additional studies have demonstrated impaired Kupffer cell function in the bile duct obstructed host.[8-11] Little is known, however, of the integrity of extrahepatic, nonspecific cellular immune mechanisms in the cholestatic host, critical in the control and elimination of bacterial pathogens. In order for a phagocyte to be effectively involved in host defense it must be able to (1) localize microorganisms through its ability to demonstrate directed migration or chemotaxis; (2) engulf or phagocytose the microorganism; and (3) alter its own cellular metabolism to produce reactive oxygen metabolites with microbicidal properties. Our study attempts to assess each of these critical steps by evaluating PMN and PAM function during experimental biliary obstruction in the rat.

The ability of phagocytes to demonstrate directed migration *in vitro* to FMLP and C_{5a} was unaffected in this experimental model, suggesting integrity of this critical mechanism in the cholestatic host. The most dramatic effect of cholestasis was to inhibit the normal phagocytic uptake of ^{14}C labeled *S. aureus* by isolated PMN and PAMs. This inhibitory effect was consistently seen throughout the entire 150-minute incubation period in serial experiments. This suppression of phagocytic ability suggests a critical impairment of systemic and local nonspecific cellular immune mechanisms in the cholestatic host. Such alterations in phagocytic capacity may exist in cholestatic animals *in vivo* and would explain the high mortality noted in cholestatic animals following severe infective stress.[18] The basis for impaired phagocytosis in cholestatic animals remains unknown. Serum inhibitory factors may be present in cholestatic sera that block normal phagocytic mechanisms either directly or through action on the complement system or serum opsonins. Increased concentrations of serum bilirubin and bile salts may be important in this respect and further consideration of their role in suppressing normal PMN and PAM phagocytic activity warrants investigation.[19-21] Further studies also are required to examine phagocytic function *in vivo* in cholestatic animals.

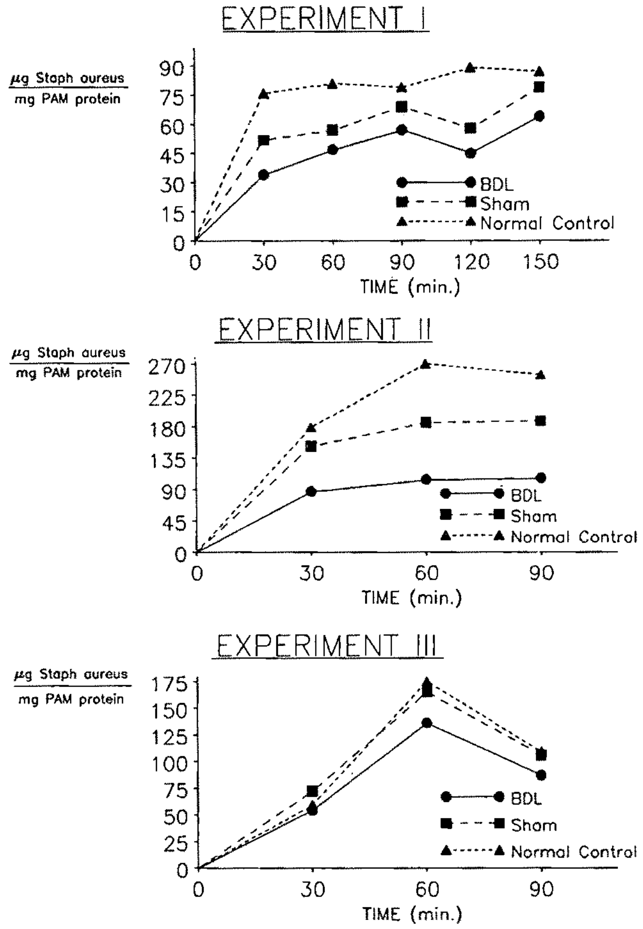


FIG. 2. Pulmonary macrophage uptake of ^{14}C labeled *Staphyloccus aureus* at selected time intervals in three separate experiments. Each experiment was performed on pooled samples (N = 8) from each group and each determination performed in duplicate to obtain mean values.

Studies invesigating superoxide metabolism consistently demonstrated enhanced PMN superoxide release in cholestatic animals compared to control groups. Furthermore, PMNs isolated from Sham rats released more superoxide than NC animals, suggesting that operative intervention alone augments PMN superoxide release.

TABLE 2. *Polymorphonuclear Leukocyte Superoxide Release in BDL, Sham, and Normal Control Groups**

Group	Superoxide Release
BDL	21.9 ± 2.2
Sham	10.7 ± 2.3†
Normal	4.0 ± 0.1‡

* Results are expressed as nanomoles of zymosan-stimulated superoxide release per milligram of cell protein in 30 minutes. The values represent the mean ± SD of two separate experiments on pooled samples (N = 5), each determination performed in duplicate.

† $p < 0.005$.

‡ $p < 0.003$ compared with BDL.

TABLE 3. *Pulmonary Macrophage Superoxide Release in BDL, Sham, and Normal Control Groups**

	Group	Superoxide Release
Experiment I	BDL	6.3 ± 2.3
	Sham	14.8 ± 2.8
	Normal Control	7.7 ± 1.8
Experiment II	BDL	8.9 ± 1.1
	Sham	11.1 ± 0.9
	Normal Control	12.2 ± 2.2
Experiment III	BDL	23.4 ± 3.0
	Sham	45.3 ± 5.2
	Normal Control	15.9 ± 1.3
Combined results of experiments I, II, and III	BDL	12.9 ± 9.2
	Sham	23.7 ± 18.7
	Normal Control	11.9 ± 4.1

* Results are expressed as nanomoles of zymosan-stimulated superoxide released per milligram of cell protein in 30 minutes. The values represent the mean ± SD of pooled samples from each experimental group (N = 6), each determination performed in duplicate.

Pulmonary macrophage superoxide release did not appear to be affected by coexisting cholestatis, although PAMs isolated from Sham animals again demonstrated increased superoxide release compared to BDL and NC groups. The basis of the differential effect of cholestatis on PMN and PAM superoxide release remains unknown, but may reflect inherent metabolic differences between the two cell populations. For example, it is well known that PAMs rely more on oxidative sources and mitochondrial respiration than PMNs, where functional processes are almost completely dependent on glycolysis.[22]

Alterations in PMN and PAM phagocytic ability and superoxide release associated with liver dysfunction may represent a critical degradation of nonspecific immune mechanisms in the cholestatic host. Improvement of liver function by therapeutic decompressive biliary drainage may have a therapeutic role in improving such impairments in PAM and tissue macrophage phagocytic capacity. Subsequent improvements of host defense may accordingly diminish the susceptibility of the cholestatic host to infective complications. It is of interest that Vane et al. demonstrated that prolonged periods of internal biliary drainage were required to reverse impaired Kupffer cell phagocytic function associated with biliary obstruction, despite the prompt improvement in liver function with drainage.[23] Further studies investigating the relative efficacy of internal and external biliary drainage in restoring host immune status are also required to determine the respective benefits of such procedures in lessening infective morbidity associated with obstructive jaundice.

Acknowledgment

The authors thank Saroj Kumar and Lan Le for their technical assistance, and Colleen Chudej and Susan Young-Sullivan for their help in preparing the manuscript.

Manufactured for Glaxo Inc.,
Research Triangle Park, NC 27709
by Abbott Laboratories, North Chicago, IL

Convenient
- ☐ *Ready to use–no mixing needed*
- ☐ *Premixed 100-ml bag, containing 50 mg ranitidine (as the hydrochloride)*
- ☐ *No need to refrigerate*
- ☐ *Stores for up to 18 months*

Cost effective
- ☐ *Saves pharmacy and nursing time*

Raises gastric pH in critical care patients for up to 8 hours*

No significant drug interactions with the hepatic P-450 enzyme system at recommended doses
- ☐ *No clinically significant drug interactions between ranitidine and theophylline, phenytoin, or warfarin*

Zantac® Injection
Premixed
ranitidine HCl/Glaxo

New premixed 100-ml bag containing 50 mg ranitidine HCl

*Some patients may require q6h dosing.

ZANTAC® Injection
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Pregnancy: *Teratogenic Effects: Pregnancy Category B:* Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC® Headache, sometimes severe, seems to be related to ZANTAC administration. Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain have been reported. There have been rare reports of malaise, dizziness, somnolence, insomnia, vertigo, tachycardia, bradycardia, premature ventricular beats, and arthralgias. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.

Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.

Although controlled studies have shown no antiandrogenic activity, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Incidents of rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia, have been reported, as well as rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
(NDC 0173-0362-38) 2-ml single-dose vials (Tray of 10)
(NDC 0173-0363-39) 10-ml multidose vials (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

Compazine®

brand of **prochlorperazine** Injection 5 mg./ml.

Available in 25 mg. suppositories, too.

Do not use 'Compazine' in pediatric surgery.

©SmithKline Beckman Corporation, 1985

See brief summary of prescribing information on adjacent page.

The antiemetic physicians prescribe most*

COMPAZINE®
brand of
prochlorperazine

See complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: For control of severe nausea and vomiting

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; pediatric surgery; use in children under 2 years of age or under 20 lbs.; use in children for conditions for which dosage has not been established

Warnings: The extrapyramidal symptoms which can occur secondary to 'Compazine' may be confused with the central nervous system signs of an undiagnosed primary disease responsible for the vomiting, e.g., Reye's syndrome or other encephalopathy. The use of 'Compazine' and other potential hepatotoxins should be avoided in children and adolescents whose signs and symptoms suggest Reye's syndrome.

May cause tardive dyskinesia in some patients on neuroleptic (antipsychotic) therapy, usually long-term. This syndrome consists of potentially irreversible, involuntary dyskinetic movements. The risk of tardive dyskinesia and likelihood of irreversibility are thought related to duration of treatment and total cumulative dose of neuroleptic drugs.

Use in patients with bone marrow depression only when potential benefits outweigh risks. Patients who develop a hypersensitivity reaction (e.g., blood dyscrasias or jaundice) to a phenothiazine generally should not be reexposed to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Prochlorperazine may intensify or prolong the action of other C.N.S. depressants.

Use in pregnancy is not recommended except in cases so serious and intractable that, in the physician's judgment, drug intervention is required and potential benefits outweigh possible hazards. There have been instances of prolonged jaundice, extrapyramidal signs, hyperreflexia or hyporeflexia in newborn infants whose mothers received phenothiazines. There is evidence that phenothiazines are excreted in the breast milk of nursing mothers.

Precautions: The antiemetic action of 'Compazine' may mask the signs and symptoms of overdosage of other drugs and may obscure the diagnosis and treatment of other conditions such as intestinal obstruction, brain tumor and Reye's syndrome (See Warnings). Postoperative aspiration of vomitus has occurred in a few surgical patients who received prochlorperazine as an antiemetic. When used concomitantly with cancer chemotherapeutic drugs, may obscure vomiting as a sign of these agents' toxicity. Deep sleep and coma have been reported with prochlorperazine, usually with overdosage.

Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent *in vitro*, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis

Permanently stop neuroleptic therapy if neuromuscular reactions occur in pregnant women or in children.

In children with acute illnesses or dehydration, use only under close supervision. Avoid high doses and parenteral administration when cardiovascular system is impaired since hypotension has occurred. Use cautiously in patients with glaucoma. Use with caution in persons who will be exposed to extreme heat since phenothiazines may interfere with thermoregulatory mechanisms. Phenothiazines can diminish the effect of oral anticoagulants. Phenothiazines can produce alpha-adrenergic blockade. Thiazide diuretics may accentuate orthostatic hypotension that may occur with phenothiazines. Antihypertensive effects of guanethidine and related compounds may be counteracted when phenothiazines are used concomitantly. Concomitant administration of phenothiazines with propranolol results in increased plasma levels of both drugs and may also precipitate phenytoin toxicity. Phenothiazines may lower the convulsive threshold; dosage adjustments of anticonvulsants may be necessary. Presence of phenothiazines may produce false positive phenylketonuria (PKU) test results. Patients should not receive 'Compazine' 48 hours before or 24 hours after myelography with the contrast medium metrizamide.

Adverse Reactions: Drowsiness, dizziness, amenorrhea, blurred vision, skin reactions. Hypotension. Cholestatic jaundice, leukopenia, agranulocytosis. Fatty changes in the liver have been observed in a few patients who died while receiving the drug (no causal relationship has been established). Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, tardive dyskinesia, and a variant, tardive dystonia. Contact dermatitis is a possibility if 'Compazine' Injection (solution) inadvertently gets on hands or clothing.

Other adverse reactions reported with 'Compazine' or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., severe hypotension in mitral insufficiency or pheochromocytoma). Grand mal and petit mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat and organophosphorus insecticides; dryness of mouth, nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, ejaculatory disorders/impotence, priapism, atonic colon, urinary retention, miosis and mydriasis; reactivation of psychotic processes, catatonic-like states, hypotension (sometimes fatal); cardiac arrest; pancytopenia, thrombocytopenic purpura, eosinophilia, hemolytic anemia, aplastic anemia; biliary stasis; hyperglycemia, hypoglycemia, glycosuria, lactation, galactorrhea, gynecomastia, menstrual irregularities, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis, asthma, laryngeal edema; angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia, mild fever after large I.M. doses; increased appetite; increased weight; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; neuroleptic malignant syndrome, which may be fatal; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits.

EKG changes have been reported. Discontinue long-term, high-dose therapy gradually.

Note: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported.

Supplied: Tablets—5, 10 and 25 mg., in bottles of 100; Spansule® capsules—10, 15 and 30 mg., in bottles of 50; Injection—5 mg./ml. in 2 ml. ampuls, 10 ml. vials and 2 ml. disposable syringes; Suppositories—2½, 5 and 25 mg.; Syrup—5 mg./5 ml.; Single Unit Packages of 100 (intended for institutional use only)—5 and 10 mg. tablets; 10, 15 and 30 mg. 'Spansule' capsules.

Parietal Cell Vagotomy as an Emergency Procedure for Bleeding Peptic Ulcer

JACK HOFFMANN, M.B., F.C.S.(S.A.), F.R.C.S.(ED), AGNETE DEVANTIER, M.D., TINA KOELLE, M.D., and HANS-ERIC JENSEN, M.D., PH.D.

From the Department of Surgery, Kommunehospitalet, Copenhagen, Denmark

Twenty-three selected patients presenting with massive bleeding from peptic ulcers underwent emergency parietal cell vagotomy (PCV). Ninteen patients had a duodenal ulcer, two a prepyloric ulcer, and one a gastric ulcer. The patients were studied retrospectively with regard to postoperative mortality and morbidity, early rebleeding, and recurrent ulceration. Two patients (9%) died after operation, one of rebleeding. No others suffered rebleeding. One further patient had major respiratory complications and 14 others developed minor complications. The remaining 21 patients were followed for between 2 and 72 months. Two patients (10%) developed recurrent ulcers. The authors conclude that parietal cell vagotomy may be used as an emergency operation for bleeding peptic ulcer in selected cases with an acceptably low mortality, rebleeding rate, and incidence of recurrent ulceration.

ALTHOUGH EMERGENCY PARIETAL cell vagotomy (PCV) for bleeding peptic ulcer was introduced by Professor David Johnston in 1973,[1,2] there have been only sporadic reports of its use for this indication from other surgeons in the intervening 14 years.[3-7] Of these, only two papers describe more than a few cases.[3,5] We have therefore undertaken a retrospective study of 23 patients who have undergone emergency PVC for massive bleeding from a peptic ulcer.

Patients and Methods

In a 6-year period from 1980 to 1986, 50 patients were operated on for massive bleeding from a peptic ulcer. Of these, 23 underwent PCV as an emergency procedure. The remainder had some other operation because their general condition indicated a more rapid procedure than PCV, because local conditions rendered PCV inexpedient, or because the surgeon considered a gastrectomy more appropriate. These 27 patients are not considered further.

Of the 23 patients undergoing PCV, 21 were men and two were women. Their ages ranged from 38–88 years with a mean of 62 years. Seven patients were aged 70 years and older. Twelve patients showed signs of shock or impending shock. Their preoperative and operative blood transfusion requirement ranged from 1 to 9 L (mean 6 L). Eleven had moderate chronic cardiopulmonary disease while the others were considered to be in good general condition.

Twenty patients had duodenal ulcers and two prepyloric ulcers. In one patient who had multiple gastric ulcers plus a duodenal ulcer, the bleeding source was one of the gastric ulcers.

The ulcers were approached in the following way in order to accomplish transfixion of the bleeding source: Nineteen had a longitudinal duodenotomy only. In 10 this was closed longitudinally and in nine, transversely. Two patients had gastrotomies only. One patient had a pyloroduodenotomy that was closed longitudinally without performing a pyloroplasty. In one patient the access is not described. All patients then underwent a PCV without a drainage procedure.

The patients were studied retrospectively with regard to operative mortality and morbidity, early rebleeding, and ulcer recurrence.

Results

One patient died after surgery from rebleeding after refusing reoperation. No other patient rebled. A second patient died from cardiac complications. One further patient had major respiratory complications but sur-

vived. Fourteen other patients had minor cardiac or respiratory complications, wound infection, urinary infection, or bacteremia from intravenous catheters.

The surviving 21 patients were followed for between 2 and 72 months (mean: 24 months) by personal interview, telephone, or by written questionnaire. One patient died 3 months after surgery of unrelated causes without evidence of rebleeding or recurrent ulceration. A second patient developed a gastroscopically proven recurrent ulcer with gastric retention and was reoperated 2 months after the original operation. The gastric retention was not due to the patient's duodenotomy. A third patient developed signs of gastric retention, refused any further investigation or surgery, and is being treated on long-term cimetidine and metacloplamide. His duodenotomy had been closed transversely. This patient has been regarded as having a recurrent ulcer but this has never been proved. A denervated pylorus may be the explanation for his symptoms. The 19 remaining patients have no symptomatic evidence of recurrent ulceration. The ulcer recurrence rate was thus two of 21 patients (10%). Both recurrences were among the patients with duodenal ulcers.

The single patient who had undergone a pyloric transection did not develop gastric retention.

Discussion

Although endoscopic methods of hemostasis are now being evaluated,[8,9] in most centers massive or recurrent bleeding from a duodenal ulcer demands surgical treatment. The choice then lies between vagotomy and antrectomy, and vagotomy alone. When considering which of the alternatives to choose, one must consider mortality and morbidity, incidence of early rebleeding, recurrent ulceration, and long-term postgastrectomy or postvagotomy side effects. Vagotomy and antrectomy has the advantage of having a lower recurrence rate than vagotomy alone, but this is outweighed by the higher mortality, morbidity, and incidence of long-term side effects following a procedure involving gastrectomy.[10] There is some evidence that the early rebleeding rate is lower after vagotomy and antrectomy than after vagotomy alone,[11,12] but acceptably low secondary hemorrhage rates are also reported following the latter procedure.[1-3]

If one, for the above reasons, chooses to do a vagotomy alone rather than a vagotomy plus antrectomy for the emergency treatment of bleeding duodenal ulcer, should this be a truncal vagotomy (TV) or a PCV? The main disadvantage of PCV in the acute situation is that it takes 30 minutes longer to perform than a TV,[1,2] which may be a drawback in these patietns who are often elderly, shocked, and suffering from concomitant diseases. A further detrimental aspect is that PCV will be followed by a higher incidence of recurrent ulceration than TV.[13] On the other side of the coin, PCV has a lower morbidity, mortality, and incidence of postvagotomy complications than TV at least in the elective situation.[13] A comparison of these complications in the emergency situation has not been published. If one considers that it is easier to treat a recurrent ulcer than severe postvagotomy symptoms, one might be tempted to opt for PCV rather than TV. Selective gastric vagotomy and drainage may be done for bleeding ulcers with a low mortality but with a relatively high rebleeding rate of 13.5%.[12]

Although Johnston originally reported 10 consecutive and therefore presumably unselected cases of PCV used for acute bleeding,[1] he subsequently states that one should not hesitate to do a TV in poor risk patients.[2] In the light of this selection, 65% of Johnston's patients underwent PCV and the rest TV. In our series half the patients had PCV. This attitude of selection of patients is echoed by others who advocate PCV in the patient with acute bleeding.[4,5,7] Relative contraindications to PCV when the more rapid TV should be chosen are old, frail patients, patients in shock, those with diseases in other organ systems, obesity, and other local factors such as adhesions that hinder the expeditious completion of PCV.

Having elected to do a PCV, how may the duodenum be approached in order to carry out transfixion of the bleeding ulcer? In most cases a duodenotomy, sparing the pyloric ring, grants adequate exposure. However, if exposure is poor, the pylorus can be transected longitudinally and reconstructed in the line of the incision.[2] It is not necessary to resuture the incision as a pyloroplasty. This can be done with impunity since no gastric outlet obstruction ensues as shown by five of Johnston's cases[2] and one of ours. It is stressed, however, that duodenotomy alone supplies sufficient exposure in the vast majority of cases. How should the duodenotomy be closed? In many of our cases we closed the defect transversely, but this seems unnecessary as those we closed longitudinally suffered no ill effects. This is shown in other reports as well.[1,3]

With regard to bleeding gastric ulcer, most surgeons, for fear of leaving behind a gastric cancer, would opt for a gastric resection, without vagotomy, in which the ulcer is included in the specimen. However, most of the arguments stated above concerning patients with bleeding duodenal ulcer apply as well to gastric ulcer, especially that gastric resection has a lower recurrent ulcer rate but at the expense of a higher operative mortality.[14] Some surgeons would prefer the greater immediate safety of a vagotomy provided adequate pre- or intraoperative biopsies have excluded malignancy. As far as choosing PCV over TV, the rationale is similar to that governing duodenal ulcer. The ulcer is approached *via* a gastrotomy, biopsied and transfixed, or preferably excised totally. If a PCV is to be performed, Johnston[2] warns that the gastrotomy should be made close to the greater curvature of the stomach in order to avoid damage to the vagal nerve fibers entering across the lesser curvature, and to obviate leaving an ischemic strip of gastric wall adjacent to the lesser curvature after the PCV has necessitated ligation of vessels supplying the right side of the stomach.

We have found reports of 80 patients in the literature treated for bleeding peptic ulcer by emergency PCV.[1–7] The vast majority of these are duodenal ulcers, but eight cases of gastric ulcer[1–3] and a single prepyloric ulcer[7] are also reported. There is not a single case of postoperative mortality or early rebleeding. Postoperative morbidity is low. Six papers encompassing 66 patients[1–5,7] report recurrent ulceration in six cases (9%) in a follow-up ranging from 1 month to 10 years.

If we pool our patients with those in the literature, out of 103 cases two died and one suffered postoperative rebleeding. This may be compared with a mortality of 20–30% for emergency gastrectomy in unselected cases.[11,12,15] Among the 89 patients in whom statistics of recurrent ulceration are given, the incidence was 9%. These very impressive results must be tempered by two facts: the patients treated in this paper and in most others in the literatuare were highly selected. Those having disadvantageous local or general conditions underwent some other operation. Secondly, the incidence of recurrent ulcer after PCV increases with time[13] so that the papers with short follow-up duration such as ours and others bias the data toward an apparently low recurrence rate. The extremely low incidence of early rebleeding is noteworthy and contrasts starkly with previous reports[11] of a 20% rehemorrhage rate after vagotomy.

From this study and from those previously published, it seems that PCV may be used as an emergency operation for bleeding peptic ulcer in selected cases with a low mortality, rebleeding rate, and incidence of recurrent ulceration.

Physiologic Assessment of the Four Commonly Performed Endorectal Pullthroughs

DIANE K. STOLLER, M.D.,* ARNOLD G. CORAN, M.D.,† ROBERT A. DRONGOWSKI, M.A.,‡ ESTELLE R. BANK, M.D.,§
and GERALD D. ABRAMS, M.D.‖

From the Section of Pediatric Surgery, C. S. Mott Children's Hospital and University of Michigan Medical School, Ann Arbor, Michigan

The popularity of the endorectal pullthrough for the treatment of benign mucosal diseases of the rectum has created a controversy regarding the need for a reservoir. The four currently advocated procedures, the straight endorectal anastomosis, the J pouch, the S pouch, and the lateral isoperistaltic ileal reservoir were evaluated in a puppy model with four animals in each experimental group. Measurement of rectal capacitance showed that all groups achieved 80–85% of control values at 6 months after surgery. Intestinal transit time decreased by one-half in all groups. Stool consistency, stool culture, water, and electrolyte absorption did not show any statistical superiority of one group over another. Stool frequency varied widely at 6 months; 10 stools per 8-hour period were counted in the lateral reservoir group *versus* 25 with the J pouches, and 16 with the straight and S groups. Stool frequency did not correlate with transit time, stool consistency, or rectal capacitance. Barium enemas showed that straight pullthroughs more closely resembled the measurements of the normal animal's endorectal canal. Based on these studies, there appears to be no advantage to adding a reservoir to the endorectal pullthrough.

MUCOSAL AND OTHER benign diseases of the colon and rectum, when requiring surgical intervention, were treated previously by complete protocolectomy with permanent ileostomy.[1,2] This procedure, which removes all the diseased tissue in the rectum, has become the standard surgical approach for both benign and malignant diseases of the rectum. The preservation of the normal pathway for defecation and the absence of an abdominal stoma have remained important to patients and surgeons and, thus, the operations designed to preserve the rectal sphincters, while simultaneously removing all existing and potential disease of the mucosa, have emerged.[3-7] The procedure consists of a standard abdominal colectomy, mucosal protectomy, and an endorectal ileoanal anastomosis. This removes all the rectal disease, preserves innervation to the rectum, bladder, and genitalia, and thus retains the usual pathway for defecation. This procedure, referred to as the endorectal pullthrough, has become the treatment of choice for ulcerative colitis, the potentially malignant disease, familial polyposis, and in some centers, for total colonic Hirschprung's disease.[8-14]

Variations of the endorectal pullthrough have emerged. The procedure, as originally described, involves a straight ileoanal anastomosis. Modifications have involved the creation of a pouch from terminal ileum in order to increase reservoir capacity and, thereby, decrease stool frequency. Initially, the Parks' S-shaped reservoir was introduced.[15] After reports of patients requiring intubation of their pouch for adequate evacuation, other procedures were introduced. Utsunomiya and colleagues described the J-shaped ileal reservoir with good results.[16] Finally, Fonkalsrud has described the lateral isoperistaltic pouch, created in two stages.[17] Proponents of the "reservoir"procedures claim that creation of these pouches improves stool frequency and continence, whereas proponents of the straight

pullthrough feel that the pulled-through ileum will dilate to the appropriate-sized reservoir over time.[18]

Although several large series of patients who have undergone the various endorectal pullthroughs have been reported, no controlled studies have been carried out, making physiological and clinical comparison of these four procedures difficult.[19–21] For this reason, the following controlled animal experiment was performed.

Materials and Methods

Sixteen 4-month-old, conditioned Beagle puppies were used; four animals were randomly assigned to each of the four experimental groups (straight endorectal pullthrough, J pouch, S pouch, and lateral isoperistaltic ileal reservoir). Beagle puppies have been used previously as an animal model for this type of experiment and were used here to facilitate comparison of this work with other studies.[22–26]

Before surgery, the following parameters were assessed in each animal: general health, stool consistency, perineal irritation, soiling, body temperature, hydration status, and body weight (Table 1). In addition, the following studies and analyses were performed: stool frequency, intestinal transit time, stool cultures, platelet count, hemoglobin concentration, hematocrit, white and red blood cell counts, water absorption using deuterium oxide, and electrolyte absorption using sodium bromide. Rectal manometrics and barium enemas were performed on all animals.

Water Absorption Studies

Deuterium oxide has been used previously to assess water absorption from the bowel in mammals.[27,28] A 2.5-mL/kg dose of deuterium oxide was given to each dog *via* an orogastric tube placed into the animal's stomach. Blood samples were drawn for deuterium oxide analysis prior to administration of the deuterium oxide at ½, 1, 2, and 3 hours after deuterium administration.

Following double-vacuum, freeze distillation of the serum to remove solutes and impurities, the serum distillates were analyzed for deuterium oxide concentration by the falling-drop method.[29]

Electrolyte Absorption Studies

Previous investigators have shown that sodium bromide absorption directly parallels the absorption of sodium chloride.[30–33] Sodium bromide concentration was used as a marker of sodium chloride absorption according to the formula described by Wolf and Eadie.[34]

A 4.0-mL/kg dose of 5% sodium bromide was administered *via* an orogastric tube and blood samples were obtained in the same manner as described under the water absorption studies. Serum bromide was analyzed by a spectrophotometric technique modified and refined in our laboratory for the accurate determination of serum bromide levels.[35]

TABLE 1. *Test/Parameter and Frequency Protocol*

Test/Parameter	Frequency
General health	Daily
Stool consistency	Daily
Perianal irritation	Daily
Soiling	Daily
Body temperature	Daily ×1 week, weekly thereafter
Hydration status	Daily
Body weight	Daily
Serum chemistries (bun, albumin, sodium, potassium, chloride, bicarbonate)	Preop, 1 and 2 weeks, 1, 3, and 6 months
Fecal fat analysis	Preop and monthly
Stool cultures	Preop and monthly
Hematology data (platelet count, hemoglobin, hematocrit, white blood cell count, red blood cell count)	Preop, 2 weeks, 1, 3, and 6 months
Water absorption (deuterium oxide)	Preop, 2 weeks, 1, 3, and 6 months
Electrolyte absortion (sodium bromide)	Preop, 2 weeks, 1, 3, and 6 months
Endoscopy of rectum	2 weeks, 1, 3, and 6 months
Biopsy of ileal mucosa	Preop and 6 months
Rectal manometrics (resting sphincter length, rectal capacity at various distances from anus)	Preop, 1, 3, and 6 months
Stool frequency	Preop and monthly
Transit time	Preop and monthly

Intestinal transit time with charcoal, stool frequency per 8 hours, evaluation of stool consistency, quantitative stool cultures, and sigmoidoscopy were carried out before and after surgery.

Manometric Studies

Manometric studies were used to evaluate postoperative continence. Continence, as defined by Gaston, consists of sphincter continence with its neurologic components and reservoir continence.[36] Normal sphincter continence should be present in all of the animals since rectal musculature preservation was achieved in all four endorectal pullthroughs. Reservoir continence is the variable factor and depends on the type of procedure and length of time since surgery.

The animals were given light general anesthesia (rompun and pentobarbitol) and the distal bowel was cleaned using a tap water enema. Studies have shown that anesthesia has no effect on rectal manometric pressure recordings.[28]

Small amounts of lubricant were applied to an Arndorfer rectal manometry probe (Arndorfer Medical Specialties, Inc., Greendale, Wisconsin), which was inserted through the anus and advanced 10 cm into the distal bowel. The probe is a continuous perfusion type with distal side ports and a balloon at the tip with a separate inflation port. The probe is attached to a pump for continuous, consistent perfusion of water and is then attached to a transducer and chart recorder. The studies performed were:

1. *Resting length of the anal sphincter.* The resting length of the anal sphincter was measured by steady withdrawal of the rectal probe using a pump at a continuous speed. Preoperative control values were obtained in each animal and postoperative changes were observed.

2. *Sphincter response to distension of the bowel.* A transient decrease of intraluminal pressure at the level of the proximal part of the anal sphincter should be observed following distension of the rectal wall. This normal rectoinhibitory reflex was observed before surgery and was reassessed after the pullthrough procedure. The probe was inserted into the rectum with the balloon at the distal tip. Increments of air were instilled into the balloon until responses were obtained at distances of 1–10 cm from the anus.

3. *Capacity of distal bowel.* The rectal probe and balloon were inserted in the same manner as previously described. Air was instilled into the ballon until a deflection was observed on the chart recorder. This was estimated to be the minimal tolerable capacity of the rectum, since this same deflection is observed in humans when they communicate an initial sensation of fullness in the rectum. Air was further instilled into the balloon until a second deflection was noted. This correlates with the maximum tolerable volume. These measurements were repeated at 1-cm intervals up to 10 cm from the anal verge. Changes in rectal capacitance after surgery are an important parameter to assess because stool frequency is directly related to rectal capacitance.

Operative Technique

Following the preoperative tests and assessments, each dog was prepared 24 hours prior to surgery with 250 mg of ampicillin and 10 mg of kanamycin, by mouth, four times. On the day of surgery, the animals received a mechanical bowel preparation consisting of a soap water enema followed by a flushing of the rectum with sterile saline until the returns were clear. The animals were then sedated with a subcutaneous injection of 2.5 mg/kg of xylazine, followed by general anesthesia *via* the intravenous administration of 20 mg/kg of sodium pentobarbitol. Immediately before surgery, 10 mg of chloramphenicol was given subcutaneously followed by irrigation of the rectum with a betadine solution. Sterile technique was observed throughout the operative procedure.

A total colectomy was then carried out to the level of the peritoneal reflection of the rectum. The submucosal stripping was then begun at the level of the peritoneal reflection and continued all the way down to the anus from the abdominal approach. Once the dissection was carried down to the anus, the top of the mucosal tube was grasped with a long clamp and everted outside the anal opening. At this point, attention was redirected to the terminal ileum depending on the type of procedure to be carried out. The following types of pullthroughs were performed:

1. *Straight endorectal pullthrough.* The straight endorectal pullthrough[18] was created as described by Coran. The distal ileum was anatomosed directly to the anus. The anastomosis between anorectal mucosa and the full thickness of ileum was with interrupted sutures of 4-0 Vicryl.

2. *J pouch.* The J pouch[16] was created from the terminal ileum and placed in the rectal muscular cuff. A long side-to-side anastomosis was performed using 4-0 silk interrupted sutures. The length of the pouch from anus to the most proximal portion was 5–7 cm, which is consistent with the size of the animal. The top of the rectal cuff was attached loosely to the pouch.

3. *S pouch.* The S or "Parks" pouch[15] was also created from the terminal ileum and then placed inside the rectal muscular cuff in a similar manner to that described for the J pouch. The terminal 20 cm of ileum was folded twice to give three segments of bowel, the proximal two of which were 5–7 cm long with the distal segment 7–9 cm long. The additional length of the terminal portion allowed for a 2-cm segment of ileum to project beyond the pouch for anastomosis. The ileum was opened on its antimesenteric border and the edges were then folded together to complete the pouch. The distal portion was pulled through and anastomosed in a manner identical to that described for the straight endorectal pullthrough. The top of the rectal cuff was attached loosely to the pouch.

4. *Lateral isoperistaltic ileal reservoir.* The lateral side-to-side ileal reservoir[17] is created in a two-stage procedure in the human. A one-stage procedure was used in this experiment with careful adherence to the dimensions and techniques as described by Fonkalsrud.[37] The proximal end of the distal ileum was oversewn with a purse-string suture and the distal end was anastomosed to the free edge of the anal mucosa. The second step of the procedure involved the construction of a side-to-side reservoir, which was performed at the same operation.

No temporary ileostomy was created in any of the animals.

Postoperative Evaluation

The following postoperative protocol was used. The animals were administered subcutaneous injections of 10 mg of chloramphenicol twice daily for 7 days. In addition, they received a subcutaneous administration of 10 mL/kg/24 hours of sterile normal saline for 7 days after surgery to help prevent dehydration in the immediate postoperative period. Dogs were allowed standard puppy chow and water *ad libitum* throughout the 6-month postoperative period. No special dietary supplements were added and no medication (*e.g.*, Metamucil®, Lomotil®, or immodium) was administered to reduce stool frequency.

The previously described tests and analyses were assessed in each of the experimental animals according to the frequency listed in Table 1. General health, stool consistency, degree of perineal irritation, presence of soiling, hydration status, and body weight were assessed on a daily basis. Body temperature was obtained daily for 1 week after surgery, and weekly thereafter. If fever occurred, appropriate evaluation was carried out and close monitoring was resumed until a normal temperature was reached. Blood chemistries and hematologic analyses were obtained during the postoperative course as clinically indicated. Fecal fat analyses, stool cultures, stool frequency, and intestinal transit time were obtained on a monthly basis. Rectal manometrics were performed at 1, 3, and 6 months after surgery. Water and electrolyte absorption studies were carried out during the second week after surgery, and at 1, 3, and 6 months. Rectal endoscopy was performed at 2 weeks, 1, 3, and 6 months after surgery. The rectal pouch was dissected intact at autopsy for histologic analysis as previously described.

Barium Enema

Barium enemas were performed under fluoroscopic control by a radiologist (E.R.B.). Several nonoperated animals were studied and used as controls. Measurements were taken to assess the following: (1) small bowel diameter at 5 cm above the rectal pouch, (2) anteroposterior diameter of the pouch, (3) measurement of the endorectum caudal to the pouch, and (4) length of the pouch.

Results

Hematocrit, mean corpuscular red cell volume, and platelet count showed no differences between groups. All animals showed an initial but unsustained drop in hematocrit in the early postoperative period, as would be expected since these major operations were undertaken without blood transfusions. All groups developed a leukocytosis (as high as 20,000), which was most marked during the first postoperative week.

Parameters such as weight, appearance, behavior, and posture assumed for defecation were all monitored by observation at frequent intervals. The animals' activity returned to the preoperative level by 1 month after surgery in all groups. The dogs were uniformly mildly dehydrated for approximately 2 months after surgery. Perineal irritation was found in over 50% of animals, even at autopsy. Fifty per cent of S pouches, 75% of J pouches, and 100% of the lateral and straight groups

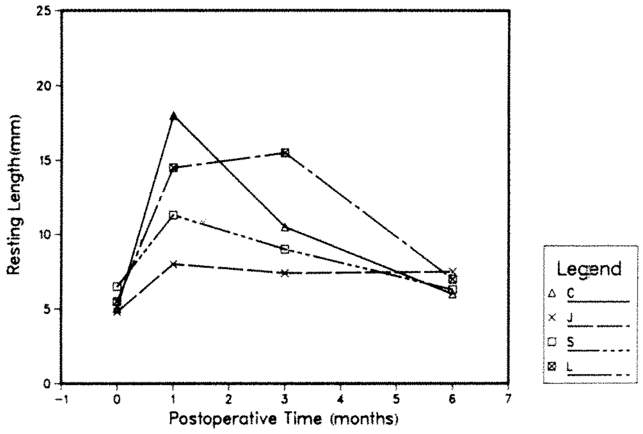

FIG. 1. Changes in mean resting sphincter length over 6-month period.

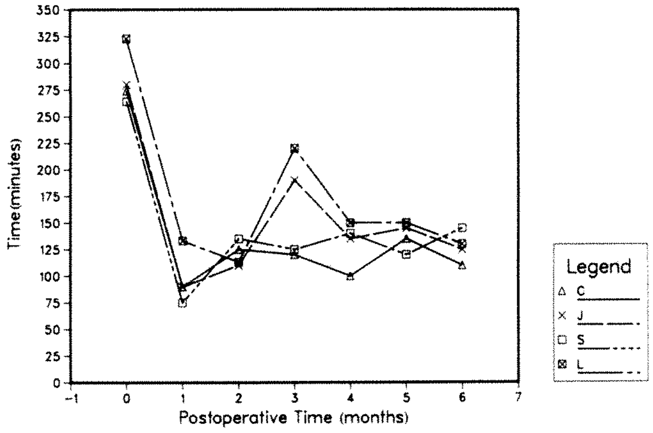

FIG. 3. Changes in mean intestinal transit time over 6-month period.

demonstrated the presence of perineal irritation (Table 2). The straight, S, and lateral reservoir groups were observed to have normal squatting posture while defecating. No animal with a J pouch was observed to have normal posture while defecating; straightening of the body while standing against a wall or lying prone was frequently observed at defecation in these animals. Body weight increased from 2 to 3 kg over the 6-month period in all groups. All animals weighed 6–7 kg at the onset of the experiment and 7 to 9 kg at the 6-month period.

Manometric data are shown in Figures 1 and 2. The resting sphincter length was found to be 5–6 cm in all groups both before and 6 months after surgery. There was a transient increase of two to three times the original length at 5 weeks after surgery, which gradually returned to normal by 6 months in all groups except the J pouches, in whom no significant postoperative changes occurred. Maximum volume or rectal capacitance is expressed as a percentage of control value. The four groups uniformly achieved 80–85% of control at 6 months. The lateral and S pouches decreased to their lowest maximum volume of 50 and 47%, respectively, at 1 month, whereas the lowest maximum volume for the straight group was 75%. The J pouches continued to decrease in volume until 3 months after surgery, when they reached their lowest volume of 50%. The difference between the straight pullthrough dogs and the lateral pouch dogs was statistically significant ($p < 0.05$).

Intestinal transit time in all dogs before surgery was 275–325 minutes (Fig. 3). All groups demonstrated similar patterns of maximum decrease to nearly 75 minutes at 1 month after surgery and a gradual rise to 125–150 minutes at 6 months; this was approximately one-half of the preoperative value. Stool frequency showed greater variation between groups and did not correlate with transit time (Fig. 4). The J pouch dogs experienced 25 stools per 8-hour waking period, the straight and S pouches had 16 stools, and the lateral reservoir animals had 10 stools at the end of the study period. Consistency of stools (Table 2) did not appear to correlate with either frequency or transit time. Only 25% of the J, straight, and lateral pouch dogs achieved a formed stool at the

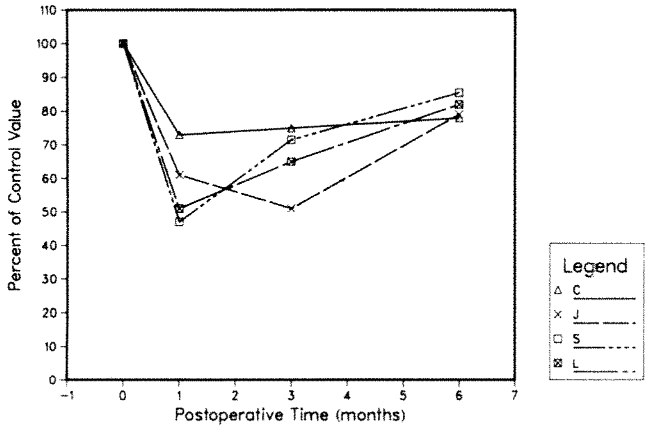

FIG. 2. Changes in mean rectal capacitance over 6-month period.

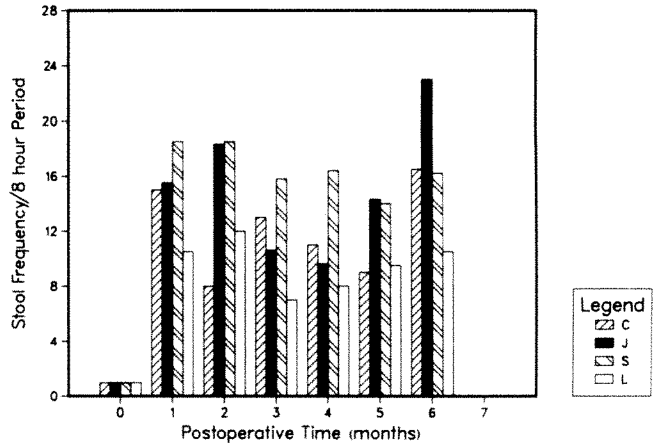

FIG. 4. Changes in mean stool frequency over 6-month period.

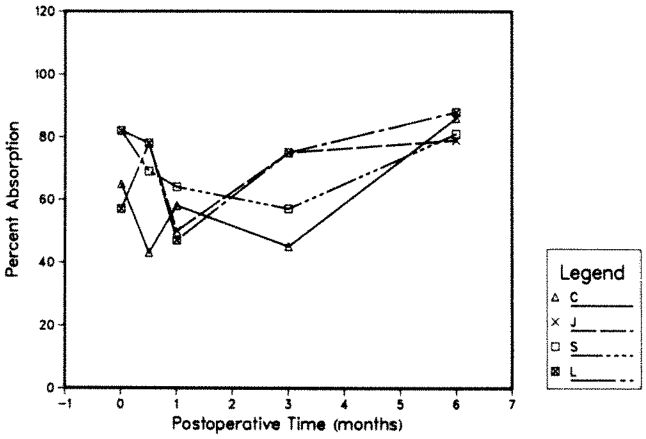

FIG. 5. Changes in mean deuterium oxide (water) absorption over 6-month period.

six-month period, while none of the S pouch dogs produced a formed stool.

Postoperative stool cultures in all groups showed normal canine intestinal flora. Overgrowth of particular organisms or appearance of organisms not usually found in Beagle feces did not occur.

Mean water absorption is depicted in Figure 5. The dogs showed a general decrease in absorption at the 2-week and 1-month time periods, followed by an increase in absorption to preoperative values at the 6-month time period. The final mean water absorption percentages in all the animal groups were 84%, which is the same as the preoperative values. Electrolyte absorption remained unchanged in the straight and S groups. In the J group there was a transient increase at 1 month, followed by a decrease at 3 and 6 months. In the lateral reservoir group there was an increase at the 2-week period that decreased at 1 month, then reversed and continued to increase until the end of the study period (Fig. 6). The final electrolyte absorption percentages at the 6-month period were statistically the same as the preoperative values in all groups, even the lateral reservoir animals.

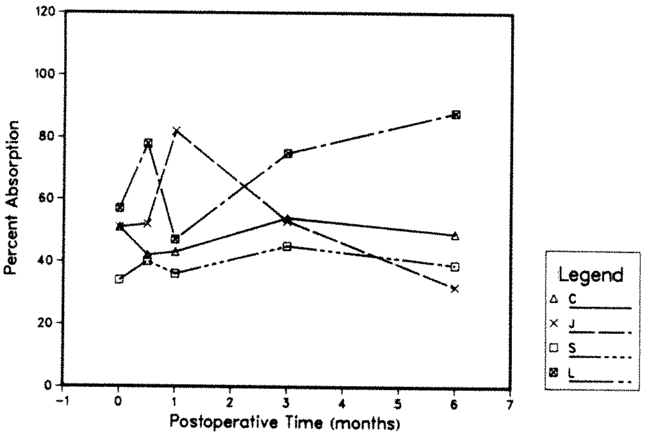

FIG. 6. Changes in mean bromide (electrolyte) absorption over 6-month period.

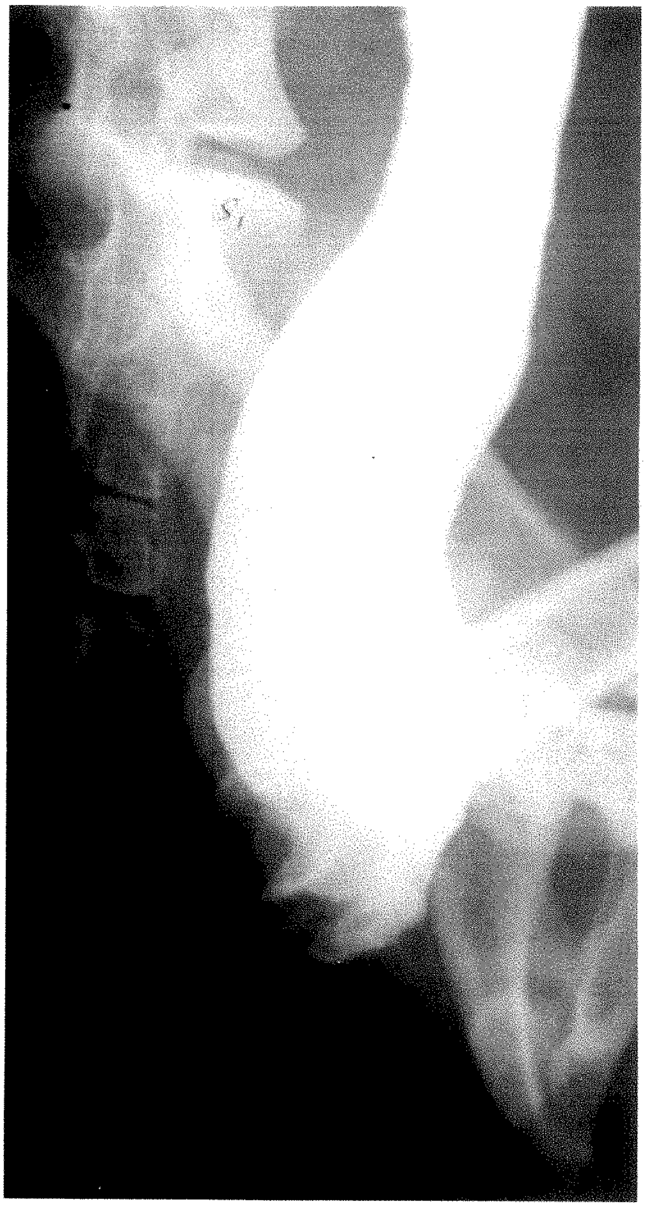

FIG. 7. Barium enema in normal dog.

Barium enemas were obtained 6 months after surgery. The configuration of the straight pullthroughs most closely approximated that of the normal animal's endorectal canal; however, the volume of the straight pullthrough was generally smaller than seen in the other groups (Figs. 7 and 8). One dog with a straight pullthrough developed moderate dilatation of the ileum within the endorectal canal and tapering caudally at the anal canal. The remaining three dogs with a straight pullthrough had only mild dilatation of the neorectum that was comparable to the ileum proximal to the rectal

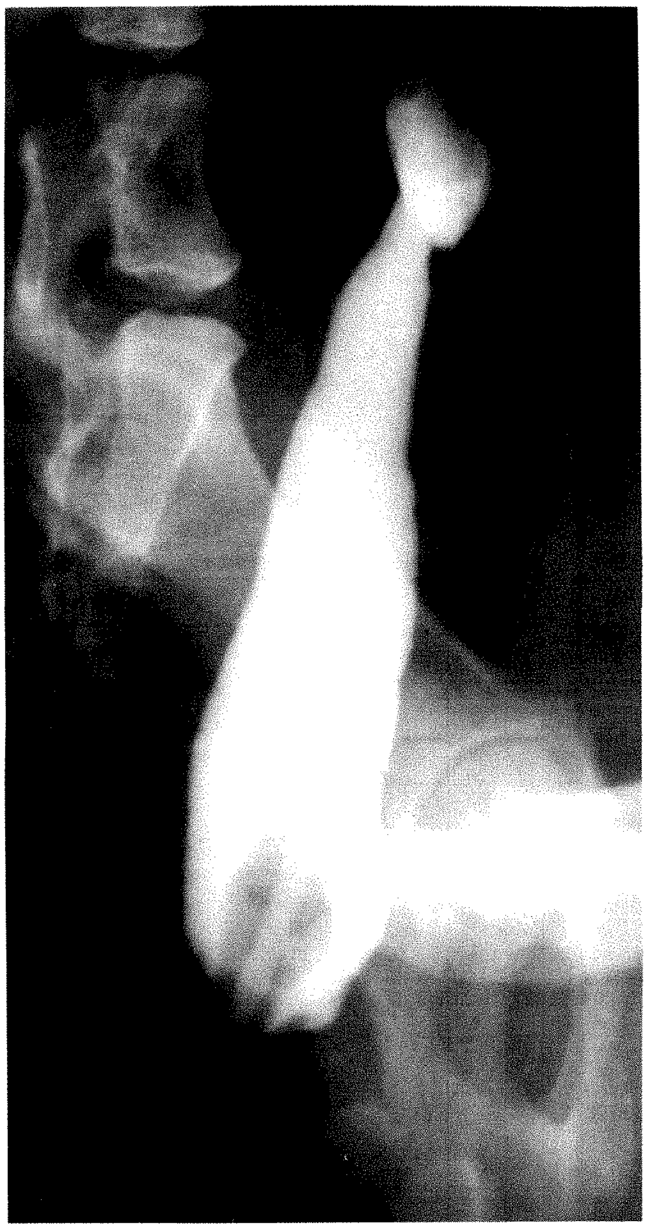

FIG. 8. Barium enema 6 months following endorectal pullthrough with straight ileoanal anastomosis.

cuff. In both the S group (Fig. 9) and the lateral group (Fig. 10), a discrete reservoir was present; however, there was an abrupt transition between the small bowel proximal to the cuff and the small bowel within it. All dogs in the J group (Fig. 11) had an abrupt change in caliber between the small bowel proximal to the cuff and the neorectum; there was a discrete outpouching at the top of the cuff in all of these dogs. The diameter of the small bowel approximately 5 cm above the top of the rectal cuff was greatest in the straight group, suggesting a larger reservoir proximal to the cuff in this group.

Histopathologic evaluation was done for all animals when killed 6 months after pullthrough, except for one in the S pouch and one in the lateral reservoir groups. In each group, the muscularis of the pulled-through segment of ileum was generally bound to the rectal muscular cuff by a thin layer of young scar tissue. Mucosae appeared intact in the region of ileoanorectal anastomosis. The appearance of the terminal ileal (neorectal) mucosa at autopsy was generally not significantly different from that of the ileal sample taken at the time of operation. Minimal mucosal distortion was occasionally evident in the anastomotic region. Microscopic nests of trapped columnar epithelium among the fused muscle layers were evident in only two animals, one in the S pouch group and one in the lateral reservoir group. In the former animal, these nests were situated in an apparent sinus tract, presumably communicating with the bowel lumen in the anastomotic region.

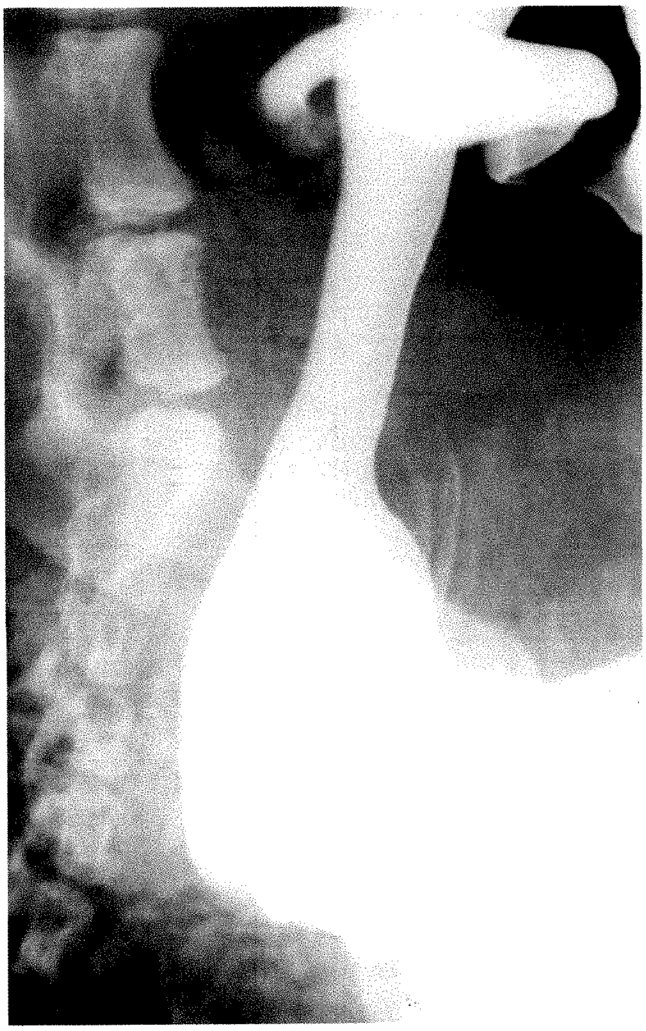

FIG. 9. Barium enema 6 months following endorectal pullthrough with S pouch.

Discussion

The endorectal pullthrough procedures most commonly used in the clinical setting and the procedures evaluated in this investigation are the S pouch, the J pouch, the lateral isoperistaltic ileal reservoir, and the straight pullthrough. The S or Parks' pouch, which was the first reservoir described, is created from three loops of bowel and is placed in the rectal cuff, allowing influence over it by the rectal sphincters, which theoretically facilitate emptying. The disadvantage of the S pouch is the dilatation of the reservoir with subsequent stasis and the related serious problem of pouch inflammation (pouchitis). The theoretical advantage of the lateral ileal reservoir pouch is normal evacuation because both loops are isoperistaltic. However, a portion of the lateral reservoir lies above the rectal cuff; thus, emptying is not totally influenced directly by the rectal sphincters. The J pouch is similar but somewhat smaller than the S pouch and does not dilate as much; however, although reservoir capacity is less, it increases gradually over time. The straight pullthrough has the advantage of greater technical ease of performance than with the reservoir techniques but has the disadvantage of a smaller rectal capacity initially. This rectal capacity increases over time. In this study, the time required to achieve adequate reservoir capacity in the straight pullthrough was longer than in the surgically created pouches. In addition, stasis does not occur in the straight neorectum, so pouch inflammation is not a problem.

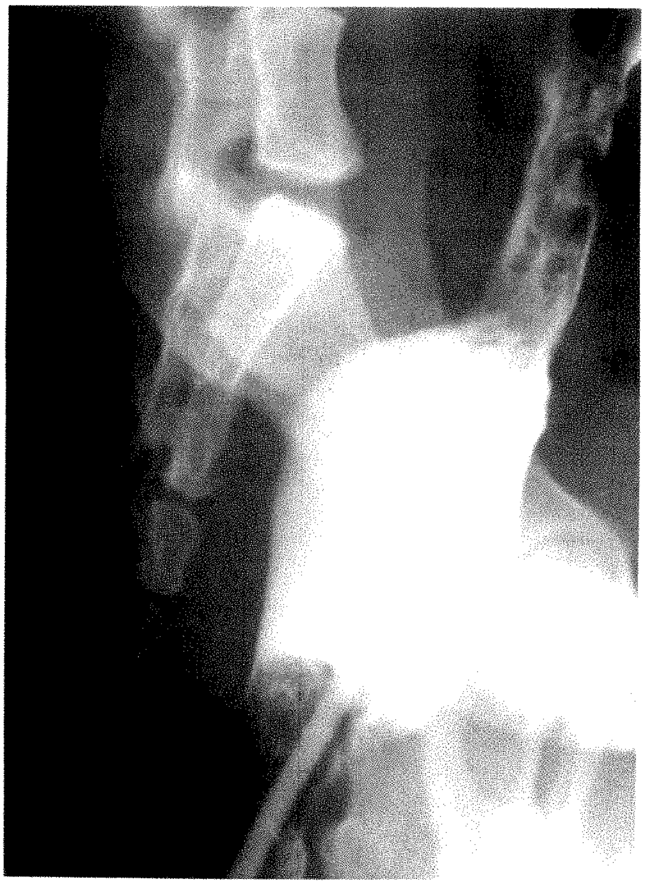

FIG. 10. Barium enema 6 months following endorectal pullthrough with lateral ileal reservoir.

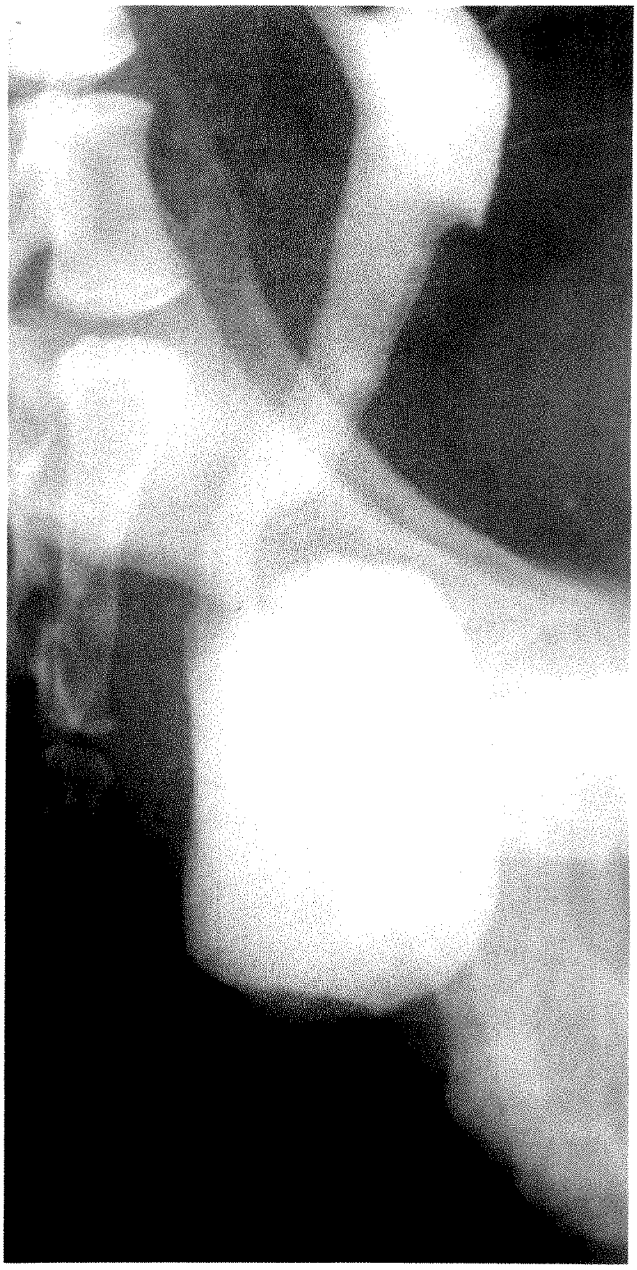

FIG. 11. Barium enema 6 months following endorectal pullthrough with J pouch.

Proponents of the reservoir procedure feel that this approach more closely mimics the normal situation.[15-17] The reservoir function of the rectum is one of the important factors responsible for normal continence. The accumulation of feces in the pouch before expulsion allows for better water absorption, which results in a more formed stool and, thereby, in a decrease in stool frequency. The decreased loss of water and electrolytes in the feces also obviously reduces the risk of dehydration. However, the water and electrolyte absorption data in this study showed no differences between any of the groups and a return to preoperative levels at 6 months. In addition, none of the clinical parameters such as stool consistency or stool frequency were improved by the creation of a reservoir; nor did physiologic parameters such as reservoir capacity improve by the presence of a pouch. In fact, reservoir capacity was greatest in the straight group. Therefore, there appears to be no clinical or physiologic advantage to adding a reservoir to the endorectal pullthrough.

Experience with the Straight Endorectal Pullthrough for the Management of Ulcerative Colitis and Familial Polyposis in Children and Adults

ROSS A. MORGAN, M.D.,* PETER B. MANNING, M.D.,* and ARNOLD G. CORAN, M.D.†

From the Section of Pediatric Surgery, Mott Children's Hospital, The University of Michigan Medical School, Ann Arbor, Michigan

The first significant experience with the straight endorectal pullthrough for the management of ulcerative colitis was presented before the American Surgical Association in 1977 by Lester Martin. Since then the operation with or without modification has been used extensively. High stool frequencies in some series led to disenchantment with the straight anastomosis and to the development of various reservoir procedures to increase rectal capacity and thereby reduce frequency. As a result, no large series of straight pullthroughs is available for comparison with the reservoir modifications. Between September 1977 and September 1986, 72 children and adults, 61 with ulcerative colitis and 11 with familial polyposis, underwent endorectal pullthrough (ERPT) and straight ileoanal anastomosis under the overall direction of a single surgeon (AGC). Sixty patients have undergone ileostomy closure and form the basis of this study. Mean age at operation was 22.7 years (range 4–48 yr), and duration of active disease averaged 6 years. One-half of the patients underwent total abdominal colectomy with ERPT as a primary procedure. There were 11 cases of adhesive bowel obstruction following ERPT, and in six patients in the series permanent revision to a Brooke ileostomy was required. One patient died of hepatic failure in the late postoperative period. Follow-up has ranged from 3 months to 9 years. Mean stool frequency for the group as a whole at 3, 6, 12, 24, and 36 months was 11.8, 11.2, 9.6, 9.0, and 8.3 per 24 hours, respectively. Daytime continence was achieved in all patients. Occasional nocturnal soiling occurred in 11.1% of patients at 1 year. Stool frquency and continence were also analyzed by age group above and below 18 years and above and below 30 years. There were no statistically significant differences between these groups. The authors conclude from this study that ERPT with straight ileoanal anastomosis remains an appropriate alternative for children and adults with ulcerative colitis or familial polyposis and compares favorably with the more complicated ERPT involving a reservoir.

NEARLY A DECADE has passed since Lester Martin presented the first large series of endorectal pullthroughs (ERPT) with straight ileoanal anastomosis (IAA) for benign disease of the colorectum before the American Surgical Association in 1977.[1] High stool frequencies prompted researchers into the reservoir capacity and peristaltic abnormalities of the neorectum and led surgeons to develop a variety of reservoir "pouches" to increased rectal volume and thereby decrease frequency.[2-10] The impetus for this approach stemmed from Kock's attempts to create a continent ileostomy.[11] The physiology and relative merits of the various pouch configurations have been extensively reviewed.[12]

Initially conceived by Ravitch and Sabiston,[13] it has now been well established that ERPT with some form of ileoanal or ileopouch-anal anastomosis is the preferred alternative to standard Brooke ileostomy for patients requiring total colectomy for ulcerative colitis and familial polyposis. Most large series report a high degree of patient satisfaction regardless of the type of ERPT.

Promising early experience with ERPT and straight ileoanal anastomosis at the University of Michigan Medical Center[14-19] led us to pursue this approach as the primary alternative to abdominal wall ileostomy in patients requiring total colectomy for ulcerative colitis and familial polyposis. This report reviews our experience with this procedure in chidlren and adults over the past 9 years.

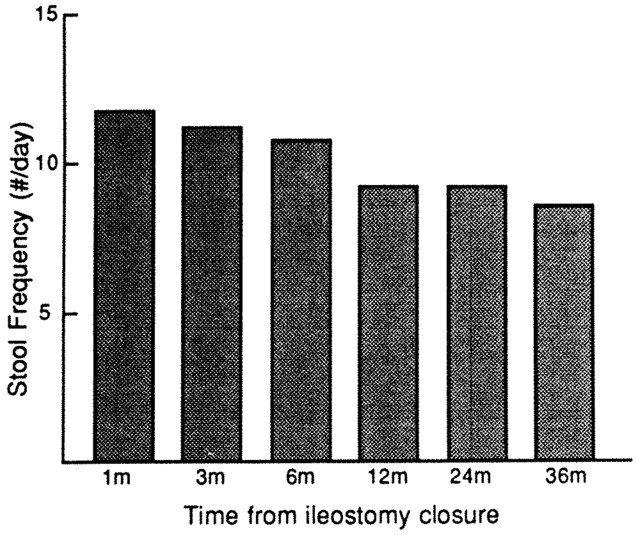

FIG. 1. There is a steady decline in stool frequency following ileostomy closure.

Materials and Methods

Between September 1977 and September 1986, 72 children and adults (61 with ulcerative colitis and 11 with familial polyposis) underwent endorectal pullthrough (ERPT) with straight ileoanal anastomosis under the overall direction of one surgeon (AGC). Sixty patients have undergone ileostomy closure and form the basis of this study. Mean age at operation was 22.7 years (range 4–48 yrs), and duration of active disease averaged 6 years. One-half of the patients underwent total abdominal colectomy and ERPT with temporary diverting loop ileostomy as a primary procedure.

All patients underwent preoperative contrast radiologic studies and sigmoidoscopic or colonoscopic examination with histologic confirmation of the diagnosis.

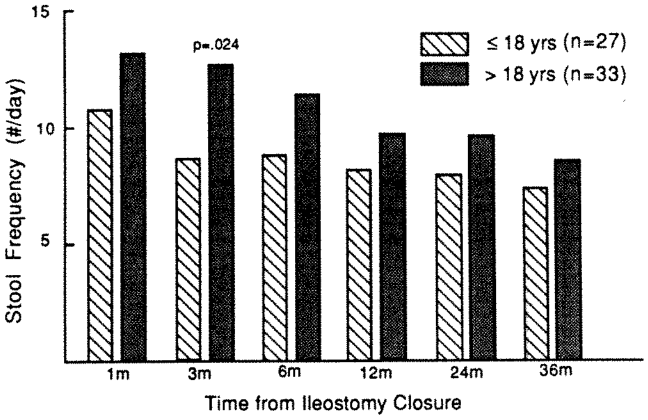

FIG. 2. No significant difference in stool frequency existed between those patients older than and younger than 18 years of age, except at the 3-month follow-up interval.

Standard bowel preparation prior to surgery included a clear liquid diet for 48 hours, oral erythromycin and neomycin the day before surgery, and intravenous ampicillin and gentamicin at midnight and on call to the operating room. Parenteral antibiotics were continued until the fifth postoperative day.

The technique of operation has been described in detail in previous reports.[15,16] To summarize, mucosal proctectomy is begun just below the peritoneal reflection of the rectum. A 4–5 cm muscular rectal cuff is developed. Ileoanal anastomosis is performed using absorbable polyglycolic acid sutures. A closed system drainage catheter is left posteriorly between the muscular cuff and the distal ileum for 24–48 hours. All but six patients underwent a diverting loop ileostomy. Ileostomy closure was performed at an interval of 3–6 months following ERPT.

Follow-up was complete in all patients and involved monthly visits until 6 months after ileostomy closure. The patients were seen every 3 months for 1 year and then yearly. Sigmoidoscopy with or without biopsy of the anastomosis was carried out at each yearly visit to detect any dysplastic changes in the cases of ulcerative colitis and any evidence of new polyp formation or malignant degeneration in the cases of familial polyposis.

The charts of all patients were reviewed for operative details, complications, and postoperative functional results. Patients who had not been seen for 1 year were sent a detailed questionnaire. Stool frequencies were compared at intervals and between age groups using the paired Student's t-test.

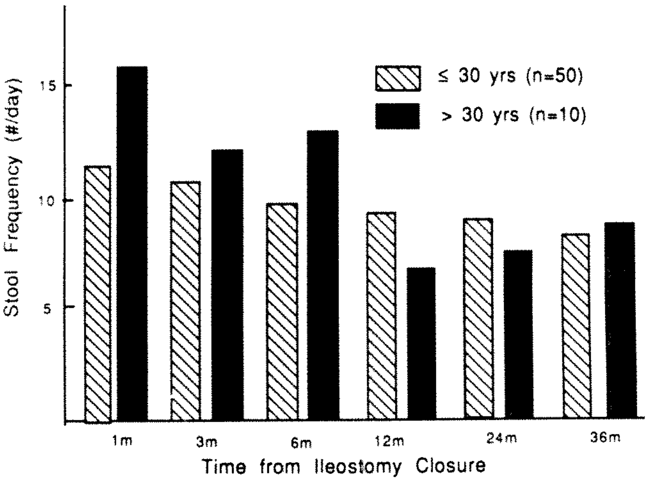

FIG. 3. No significant differences existed in stool frequency between those patients older than or younger than 30 years of age.

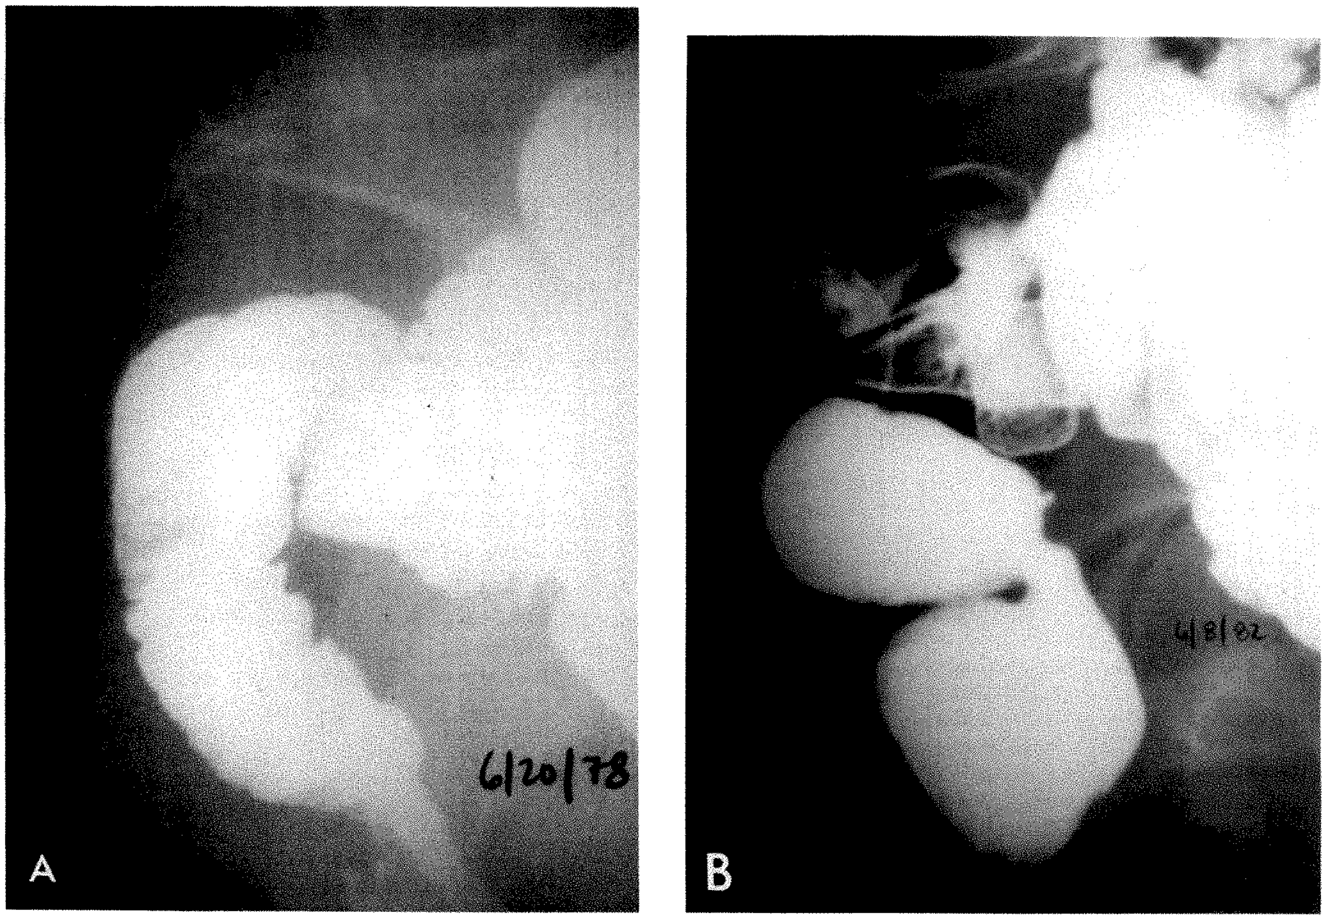

FIG. 4A and B. *A*. Radiographic appearance of the neorectum 2 months following ERPT and straight IAA, just before ileostomy closure. The endorectal canal appears normal but slightly decreased in size. *B*. Appearance of the neorectum 4 years later. The endorectal canal has dilated significantly and appears normal.

Results

Follow-up has ranged from 3 months to 9 years, with an average of 12 months. Overall operative mortality was 1.5% representing a single death that occurred in a steroid-dependent patient who developed small bowel obstruction, sepsis, and ultimately fulminant hepatic failure 8 months after surgery. There were 11 cases of adhesive bowel obstruction following ERPT, six of which required an enterolysis. Pelvic abscess occurred in two patients (3.3%) and required operative drainage. A third patient with a pelvic phlegmon was treated conservatively, with resolution of the infectious process on intravenous antibiotics. Two women developed rectovaginal fistulas, which healed with temporary diversion. Minor wound infections occurred in two patients.

There were no anastomotic leaks. In five patients the ileoanal anastomosis was felt to be narrowed on early digital rectal examination. None of these patients were symptomatic and on later follow-up the anastomoses were felt to be normal.

Six patients (10%) were revised to a standard Brooke ileostomy. One additional patient with familial polyposis was found to have anaplastic carcinoma at the anal margin on histologic examination of the mucosal proctectomy specimen and required abdominal perineal resection. One of the six patients, a 10-year-old girl, who developed recurrent inflammatory bowel symptoms was subsequently found to have Crohn's disease in spite of the fact that a second review of her colon pathology after her ERPT again suggested the diagnosis of ulcerative colitis. Small bowel biopsy many months after ERPT was typical of Crohn's disease even though histologic evaluation of the terminal ileum at the time of ERPT was normal. Two other patients were diverted as treatment for rectovaginal fistula. Only three patients (5%) were reviewed because of dissatisfaction with stool frequency.

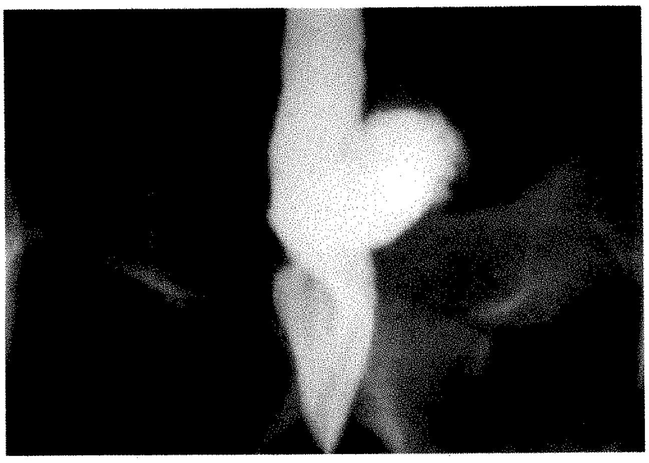

FIG. 5. The endorectal canal appears normal 2 years following ERPT and straight IAA.

Daytime continence was achieved in all but two patients at 3 months, and this reached 100% at 1 year. No patient has had major soiling difficulties. Occasional nocturnal leakage was reported in 11.1% of patients at 1 year.

Mean stool frequency for the group as a whole declined progressively over time to approximately 8 semiformed stools per 24-hour period at 3 years (Fig. 1). All patients were able to evacuate spontaneously.

Stool frequency was also analyzed by age groups above and below 18 and above and below 30 years. There were no statistically significant differences between these groups (Figs. 2 and 3).

Discussion

A recent review of the literature on the endorectal pullthrough suggests that while the addition of a reservoir has led to decreased frequency of bowel movements, it has also created some new problems.[12] These vary from a slightly higher incidence of pelvic abscess to stasis, pouchitis, and inability to evacuate the pouch spontaneously.

Rates of pelvic sepsis in the range of 20% are routinely reported in patients undergoing J or S reservoir procedures.[8,9,20] This is likely due to local disruptions of long suture lines. Even with abscess drainage, pelvic inflammation and scarring has led to anastomotic strictures and the need for revision in some patients.[12] In the current series, pelvic abscess occurred in only two patients (3.3%).

With the development of larger capacity reservoirs, stasis and pouchitis have become an increasing problem. Many series report a 25% incidence of clinically significant pouchitis, often requiring suppressive antibiotic therapy. Of perhaps more concern is the 64% incidence of chronic microscopic inflammation reported by Nicholls in the recent update of the St. Mark's experience with the S reservoir.[20] This is in contrast to our series, in which routine biopsies of the ileum at the ileoanal anastomosis, which are done on a yearly basis routinely, have shown no significant inflammation. Careful follow-up of these patients seems warranted to rule out late development of dysplastic changes, as anectodal cases of carcinoma in the neorectum have been reported.[21]

Finally, spontaneous evacuation has become a problem in at least one large series of S reservoirs.[20] In that report, 53% of the patients were unable to spontaneously evacuate the reservoir and required catheterization for drainage.

Adhesive small bowel obstruction has continued to be a significant source of postoperative morbidity. In the current series, 11 of 72 patients (15.3%) developed bowel obstruction requiring enterolysis after ERPT. This is comparable to the frequency in other reports.[8,9,12]

The variety of ERPT procedures currently in vogue is evidence of the absence of an ideal operation. As discussed, the trend toward highly continent reservoirs is not without problems. Although stool frequencies on the average are somewhat higher with the straight ERPT than with the reservoir modifications, these differences tend to disappear 1–2 years after the procedure. This is further substantiated by our observation that the neorectum created by the straight IAA progressively dilates during the 1- to 2-year period following ERPT and finally attains a normal appearance on barium enema (Figs. 4 and 5).[22] Our current experience suggests that ERPT with straight anastomosis offers the advantages of a shorter operation, complete spontaneous evacuation, absence of pouchitis, and a lower incidence of pelvic sepsis.

We conclude from this study that ERPT with straight ileoanal anastomosis remains an appropriate alternative for children and adults with ulcerative colitis or familial polyposis and compares favorably with the more complicated ERPT incorporating a reservoir.

Coloanal Anastomosis in the Management of Benign and Malignant Rectal Disease

DAVID B. DRAKE, M.D., JOHN H. PEMBERTON, M.D., ROBERT W. BEART, JR., M.D.,
ROGER R. DOZOIS, M.D., and BRUCE G. WOLFF, M.D.

The aim was to determine the efficacy, safety, and long-term clinical and functional results of coloanal anastomosis in patients with complicated benign and malignant rectal disease. Twenty-nine patients underwent coloanal or colopouch-anal anastomosis for either carcinoma of the rectum not technically amenable to conventional low anterior resection, severe radiation injury, large benign lower third tumors, or complications of previous operations. The mean age of the patients was 61 years and 82% were men. A diverting colostomy was constructed in 55% of the patients. The mean (±SEM) length of follow-up was 20 ± 3 months. There was no operative mortality. Transient urinary retention, however, occurred in 40%, anastomotic stricture in 28%, and anastomotic leakage in 3.4%. Four patients (14%) could not have intestinal continuity restored and therefore were considered failures. The stool frequency for all remaining patients (N = 25) was 3 ± 1 per day (mean ± SEM) and did not vary with age, sex, or indication for operation. Complete continence was achieved by 84% of patients, but no patient was incapacitated by poor bowel function. In patients in whom a conventional colorectostomy is impractical or unwise, coloanal anastomosis is a safe and efficacious alternative operation that preserves anal continence.

OPERATIONS DESIGNED to preserve the anal sphincter have evolved slowly since Kraske described excision of the rectum and anastomosis of the sigmoid colon to the external sphincters and perianal skin in 1875.[1] In 1885, Kocher reported a transsacral approach that facilitated resection and primary anastomosis for neoplastic growths low in the rectum.[2] In the early 1900s, however, the excellent results obtained by Miles with combined abdominoperineal resection for rectal cancer dampened interest in operations that preserved the sphincters.[3]

From the Department of Surgery, Sections of Gastroenterologic and Colon and Rectal Surgery, Mayo Medical School, Mayo Clinic, and Mayo Foundation, Rochester, Minnesota

In subsequent decades, better understanding of the direction of lymphatic spread of rectal cancer[4] moderated the view of radical resection held by Miles, thereby renewing interest in sphincter preservation. Dixon advocated anterior resection in the 1940s,[5] but it was not until the reports of Mayo et al.[6] and Wilson and Beahrs[7] that the operation achieved widespread popularity. It is now widely accepted that anterior resection is the procedure of choice in the surgical management of cancers in the middle and upper thirds of the rectum.

For tumors not amenable to low anterior resection for technical reasons, abdominal transsacral resection, abdominal transsphincteric resection, and abdominal anal pullthrough operations have been proposed as alternatives to abdominoperineal resection.[3,8,9] These procedures, however, never became popular, principally because the operations were difficult to perform and complications difficult to manage (such as posterior fistulae). Moreover, predictable functional results were rarely achieved.[10,11] However, coloanal anastomosis (that is, abdominal resection, endorectal mucosal dissection, and direct anal anastomosis, as described by Parks[12]) holds promise; the technique is essentially Soave's.[13] Early reports of bowel function following surgery were good. Recently, this technique has been reported to be useful in patients with benign and malignant rectal tumors and in patients with radiation injury.[14-16] The aim of this study was to determine the safety, efficacy, and long-term clinical and functional results of coloanal anastomosis in the management of benign and malignant rectal disease.

Materials and Methods

From January 1979 to August 1986, the records of all patients undergoing coloanal anastomosis at the Mayo Clinic were reviewed. Age, sex, indication for operation, type of operation, length of hospital stay, and morbidity and mortality were recorded for each patient. Functional results (in terms of the number of stools per day), the presence of fecal incontinence, and the need for motility altering agents were likewise evaluated. Follow-up was conducted by telephone and/or questionnaire.

Surgical Technique

The rectum is mobilized to the coccyx posteriorly, to the levators laterally, and to the distal prostate or vagina anteriorly. If the operation is for cancer, the rectum is oversewn or stapled below the tumor. Endorectal mucosal resection is then performed *via* the *perineal* approach in a manner similar to that described for ileoanal anastomosis.[17] The specimen is removed. The end of the colon is then brought through the resulting muscular cuff of the rectum and anastomosed to the mid anal canal. Alternatively, a preanastomotic J-shaped colon reservoir can be constructed by hand or with the stapler, and the apex of the pouch anastomosed to the anal canal (Fig. 1). The left colon and splenic flexure should be mobilized in their entirety in order to ensure that the colon reaches the anus without tension. The pelvis is drained by two suction catheters placed behind the neorectum from above. A diverting loop ileostomy or colostomy should be constructed in most patients.

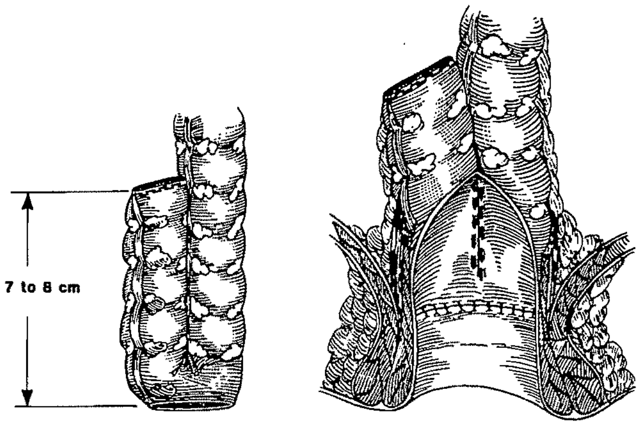

FIG. 1. Diagram of a colopouch-anal anastomosis. The pouch has been constructed with the stapler, incorporating 7–8 cm limbs. The anastomosis to the anal canal is hand sewn. The rectal muscle cuff is short (4 cm).

Results

Thirty-nine patients have undergone coloanal anastomosis and 29 have been followed for a minimum of 3 months, forming the basis for this report. There were 24 men (82%) and five women (17%). The mean age at the time of operation was 61 years (range: 45–75). Indications for operation included carcinoma of the rectum (19 patients), radiation injury (5 patients), villous adenoma (3 patients), and complications of prior surgical procedures (2 patients). Three patients had a *preanastomotic reservoir* constructed. All coloanal anastomoses were handsewn. Sixteen (55%) of the patients had a protective colostomy constructed that was closed a mean of 12 weeks after coloanal anastomosis. The mean (±SEM) length of hospitalization was 14 ± 1 days after the coloanal procedure and 9 ± 1 days after closure of the colostomy. Follow-up was complete in 28 of 29 patients; the mean (±SEM) length of follow-up was 20 ± 3 months (range: 3–54 months).

Mortality and Morbidity (Table 1)

There was no operative mortality. Transient urinary retention occurred in 10 patients (40%) and one patient has required continuous self-catheterization. Eight patients (28%) had an anastomotic stricture that required

† LAR = low anterior resection.

intermittent dilatation. One patient developed an anastomotic dehiscence for an overall leak rate of 3.4%.

Four patients (14%) underwent reoperation. One developed a mesenteric hematoma causing obstruction of the colon while another developed an anastomotic leak and required diversion. A third patient developed a severe stricture necessitating diversion and the last patient required re-exploration after anal dilatation performed elsewhere perforated the pulled-through colon segment.

Four of the 29 patients (14%) had complications that prohibited re-establishment of intestinal continuity and were considered failures. Postoperative radiation therapy caused a severe stricture in one patient that necessitated permanent diversion. One patient returned for colostomy closure but, because bilateral hepatic metastases were discovered, continuity was not restored. The third patient required a diverting colostomy for recurrent pelvic tumor and the last patient remained diverted because of a nonhealing anastomotic sinus.

Results in patients with rectal cancer. Eighteen patients underwent coloanal anastomosis for adenocarcinoma of the rectum and one for hemangiopericytoma. The distribution of the adenocarcinomas by Dukes classification (Asler-Coller modification) was: Dukes A, one patient (5%); Dukes B_1, four patients (22%); Dukes B_2, four patients (22%); Dukes C_1, one patient (3.4%); and Dukes C_2, eight patients (44%). The mean (±SEM) distance of the tumors *above the anal verge,* by proctoscopic examination, was 8 ± 1 cm. The mean distal clearance was 4 cm (range: 1.5–5 cm) (Table 2). Eight patients (44%) had postoperative radiation therapy.

TABLE 3. *Survival and Recurrence After Coloanal Anastomosis for Adenocarcinoma of the Rectum**

Dukes Stage (Astler-Coller)			Dead of Disease		Recurrence

Overall	18	(100)	2/18	11%	5/18	27%

* Follow-up, 20 ± 3 months (mean ± SEM).

Urinary retention occurred in 9/19 patients (47%) but has persisted in only one. Stricturing at the anastomosis was a recurring problem in 6 of 19 patients (31%), and one patient experienced an anastomotic leak. Four patients, as previously noted, were unable to undergo re-establishment of intestinal continuity. The mean length of follow-up of the patients with cancer was the same as for the entire study group. Five patients experienced recurrence of the tumor, four had distant recurrence only, and one had both local and distant disease (Table 3). Two patients with Dukes C lesions (11%) had died of metastatic liver disease at the time of follow-up.

Results in patients with radiation injury (Table 1). There were five patients in this group. Three patients had an anterior rectal ulcer and a concomitant rectal-urethral fistula, one a strictured rectal lumen, and one a transfusion-dependent proctitis. Urinary retention occurred in one patient (20%) and none experienced an anastomotic stricture or leak.

Results in patients with benign disease (Table 1). Three of the five patients in this group had large, nearly circumferential villous adenomas and two had complications of previous low anterior resection. Urinary retention did not occur, but two of five patients (40%) experienced anastomotic strictures.

Functional Results

The mean (±SEM) stool frequency for *all patients* was 3 ± 1/24 hours and did not vary with the indication for operation; the mean number of stools/24 hours was 2.6 in the cancer patients, 2.3 in the irradiated patients, and 3.5 in the patients operated on for benign disease (Table

4). Moreover, stool frequency was not influenced by the age or sex of the patients. Stool frequency decreased during the first postoperative year with most patients relying on stool bulking agents and antidiarrheal medications to maintain their stooling patterns. Of the patients with a functioning coloanal anastomosis (N = 25), fecal continence was achieved by 84% and 61% of patients had three stools or less per day. Three patients were intermittently incontinent and wore protective pads. Importantly, no patient was incapacitated by poor bowel function or required a permanent diverting colostomy for this reason.

Discussion

The proper role of coloanal anastomosis has not been defined. Experience with the procedure has been scant, principally because of the widespread use of circular staplers; at our institution, the coloanal procedure accounted for less than 2% of the sphincter-saving operations performed during the study period. We have documented, however, that coloanal anastomosis and, more recently, colopouch-anal anastomosis can be performed safely, is efficacious, and can restore enteric continence in selected patients with benign or malignant rectal disease.

The use of coloanal anastomosis has been reported previously in the management of complicated radiation injuries of the rectum and for large villous tumors.[14,15,18] We have also found the coloanal procedure helpful in the management of two patients who had complications from prior low anterior resection; its use in a patient with a severe anastomotic stricture and in a patient with an anastomotic leak requiring fecal diversion restored intestinal continuity successfully in otherwise difficult situations. In the management of adenocarcinoma, coloanal anastomosis has traditionally been restricted to those patients in whom it was technically difficult to safely perform an end-to-end anastomosis very low in the pelvis, but in whom acceptable margins of resection could be obtained by anterior mobilization.

Our experience supports the finding of others[14-16,19] that coloanal anastomosis can be performed safely. There were no operative deaths in this series. Morbidity related to pelvic sepsis and anastomotic breakdown, potentially the most serious complications, occurred in only one patient, but a protective colostomy had not been constructed. Only one-half of the patients in this series were diverted at the time of the original operation and, although not mandatory, temporary colostomy or ileostomy would seem prudent.

Problems with transient urinary retention in 34% of patients and anastomotic stricture in 27% were the most common major complications. Ninety per cent of the patients with urinary difficulties were in the group resected for cancer; the etiology of the urinary retention, therefore, was likely related more to the extent of the pelvic resection required in patients with such cancers of the rectum[20] than to the coloanal anastomosis procedure itself. All but one patient regained normal bladder function.

Anastomotic stricture, although easily managed by dilatation, was a distressing problem; its occurrence to some degree in nearly 30% of the patients was nearly twice that reported after ileal pouch-anal anastomosis.[12] This high rate of stricture may have been partially related to the pelvic radiation that 13 of the patients received.

Four patients who underwent coloanal anastomosis for rectal cancer failed; however, only one failure could be attributed to technical problems, the remainder being due to progression of disease.

Eighteen of the coloanal procedures were performed for adenocarcinoma of the rectum. The margins of resection were wide because the majority of the tumors were in the mid-rectum. Local control was, therefore, excellent; only one patient had a pelvic recurrence (5%). This incidence of local recurrence appears to be somewhat less than the 28% reported by Pilipsher et al.[22] after anterior resection, but the follow-up in our patients was shorter. Distant spread was identified during follow-up in five patients (27%); four of these had a Dukes C_2 lesion at the time of the procedure. The rate of distant recurrence after coloanal anastomosis is slightly higher than the 20% reported by Pilipsher et al.[22] for anterior resection and is likely more indicative of the stage of disease than failure of the operation. These data, therefore, would support the findings of others[16,19,23] that coloanal anastomosis appears to be justified in the management of mid-rectal cancers.

Overall, functional results were good in this group of patients whose mean age was 61 years. Enteric continence was achieved by 84% of the patients; this result compares favorably with those of others who report that more than 75% of patients achieved predictable control of bowel function after coloanal anastomosis.[16,23] Interestingly, these data also compare favorably with those reported after low anterior resection; Mayo and Cullen observed that about 82% of patients could expect a "good result" after anterior resection.[24] Importantly, we found no significant difference in daily stool frequency nor in the incidence of incontinence between the patients operated on for cancer, radiation injury, or benign disease. In the cancer patients, stool frequency and incontinence were not affected by adjuvant radiation therapy.

Urgency and frequency of defecation, however, continue to cause problems after coloanal anastomosis. Several authors have shown that decreased capacity and compliance of the pulled-through proximal colon correlates directly with increased stool frequency and decreased continence.[19,25,26] Keighley and Matheson demonstrated a marked reduction in the neorectal capacity of their coloanal patients compared to preoperative values (64 ± 31 mL *vs.* 268 ± 24 mL).[25] Two recent papers have reported the use of J-shaped preanastomotic colon pouches.[19,27] Not surprisingly, Lazorthes et al. found that capacity was greater when a reservoir was constructed than when the end of the colon was anastomosed directly to the sphincters.[19] They were also able to demonstrate a significant correlation between the maximal tolerable volume of the neorectum and stool frequency. Functional results in their series were good; 86% of the patients had less than three stools per day at the end of 1 year. Based on reports of dramatic improvement in functional results after adaptation of an *ileal* pouch in patients undergoing ileoanal anastomosis,[28] it seems reasonable to expect that the increased capacity and distensibility provided by a *colonic* pouch would similarly decrease urgency and stool frequency after coloanal anastomosis. Although our experience with a preanastomotic pouch was limited to three patients, predictable and reliable function was achieved in each.

Unlike an *ileal* pouch, the colon reservoir need not incorporate limbs longer than 7 or 8 cm. Endorectal mucosectomy may be performed in the standard manner,[17] except that 1–2 cm of rectal mucosa can be spared, *if desired,* in an attempt to improve sensation after surgery. Martin has advocated such an approach in ileoanal patients,[29,30] but we have not found it necessary to leave any rectal mucosa *in situ,* as more than 70% of our patients after ileal pouch-anal anastomosis can distinguish gas from stool after *total* rectal mucosal excision.[21] Finally, impeccable hemostasis, good perfusion of the pouch, a tension-free anastomosis, and adequate drainage will minimize stricture formation and the incidence of pelvic sepsis.

The indications for coloanal anastomosis are limited but are not infrequently encountered. They include severe radiation proctitis causing pain and/or bleeding, and radiation-induced ulcers with or without concomitant fistulae. Coloanal anastomosis is particularly attractive in such patients because 80–90% of the diseased rectum is removed, the most distal 4–5 cm of mucosa is excised, and healthy nonradiated proximal bowel is anastomosed directly to the anal sphincters. The anastomosis, therefore, does not depend on the possibly tenuous blood supply of the remaining radiated rectum for its security.

Another indication for coloanal anastomosis is in patients with large benign tumors, in the lower or middle third of the rectum, which are not amenable to transanal or parasacral resection. Coloanal anastomosis is also useful in patients with a compromised low anterior anastomosis. Finally, coloanal anastomosis is indicated in patients with malignant tumors in the middle third of the rectum in whom an end-to-end colorectostomy, stapled or not, may be fraught with difficulty or hazard due to technical factors. Coloanal anastomosis, however, should *not* be considered an alternative to abdominoperineal resection for cancers in the lower one-third of the rectum, but rather as an alternative to low anterior resection in patients with difficult *middle third* lesions.

In conclusion, coloanal anastomosis is safe, efficacious, and preserves anal continence in a variety of difficult situations in which it is impractical or unwise to attempt anastomosis of the colon directly to the full thickness of the rectum. Moreover, the functional results after coloanal anastomosis are good; the daily stool frequency and rate of continence achieved after coloanal anastomosis compare favorably with those reported after low anterior resection. Importantly, in the management of rectal cancer, local recurrence rates appear to be as low as those reported for anterior resection. These encouraging clinical and functional results of coloanal anastomosis should, therefore, prompt careful but wider application of the technique in selected patients with complicated benign and malignant rectal pathology.

The Impact of Colonoscopy on the Early Detection of Colonic Neoplasms in Patients with Rectal Bleeding

JOSE G. GUILLEM, M.D.,* KENNETH A. FORDE, M.D.,* MICHAEL R. TREAT, M.D.,* ALFRED I. NEUGUT, M.D., PH.D.,† and CAROL A. BODIAN, DR.P.H.‡

From the Departments of Surgery, Medicine,† Biostatistics,‡ and Comprehensive Cancer Center, Columbia-Presbyterian Medical Center, New York, New York*

A retrospective analysis was made of 372 consecutive patients who underwent colonoscopy because of rectal bleeding. The three distinct patterns of bleeding studied were chronic (224 cases), recent major (93 cases), and acute bleeders (55 cases). In 50% of the cases, colonoscopy detected a lesion other than diverticula. These lesions consisted of several forms of colitis, arteriovenous malformations (AVMs), ulcers, and most importantly, neoplasms in 34% of the cases. In 13% of the cases, an invasive neoplasm was detected and 76% of them were early stage (Dukes A or B). A third of the neoplasms were located proximal to the splenic flexure. Among patients with a negative barium enema, 35% had a neoplasm detected on colonoscopy. These findings were similar for the three distinct patterns of rectal bleeding studied. These data support the need for colonoscopy in all types of rectal bleeders, regardless of the results obtained by BE.

THE INCIDENCE OF colorectal cancer continues to rise and is responsible for more than 60,000 deaths per year in the United States.[1] Despite advances in the treatment of this disease, survival figures in the 1980s differ little from those of 30 years ago.[1,2] Since colon carcinogenesis proceeds slowly through the adenoma-carcinoma sequence,[3] with discernible preneoplastic stages, early detection and removal of precursor lesions is feasible and should reduce colon cancer mortality. Furthermore, since early stage cancers have a good prognosis,[4,5] the identification and resection of these nascent carcinomas should also improve mortality statistics. The need for improved screening of high-risk asymptomatic individuals, as well as the thorough evaluation of symptomatic patients, is therefore evident.

Rectal bleeding is a common symptom of colon polyps as well as colon cancers.[6] In fact, bleeding is thought to be a more frequent symptom of early than late colorectal cancer.[7] Traditionally, it has been taught that the rate and color of bleeding may suggest the site of the lesion (proximal *vs.* distal) or its cause (diverticular *vs.* cancer). Because of this, the need for a complete diagnostic evaluation, including colonoscopy, in different types of rectal bleeders (*i.e.*, acute *vs.* chronic), and the expected yield of adenomatous polyps and early stage cancers from such a thorough evaluation remain unclear.

The purpose of this study was to address these unresolved issues for three distinct patterns of rectal bleeding (chronic, recent major, and acute bleeders) by retrospective analysis of a large population of patients who were colonoscoped because of rectal bleeding.

Patients and Methods

Among patients with rectal bleeding, a consecutive series of 372 patients underwent colonoscopic evaluation at the Surgical Endoscopy Unit (SEU) of the Columbia-Presbyterian Medical Center between the years 1973 and 1986. The patients ranged in age from 3 to 94 years, with a mean of 63 years. Their records, including endoscopic, radiologic, and pathologic reports, were reviewed. According to a protocol implemented in 1973, all patients with rectal bleeding evaluated in the SEU were routinely classified according to their pattern of bleeding at the time of their evaluation as chronic bleeders, recent major bleeders, and acute bleeders.

Presented at the Annual Joint Meeting of the New York Surgical Society and Philadelphia Academy of Surgery, New York, NY, on March 11, 1987.

Submitted for publication: April 24, 1987.

The group of chronic bleeders (N = 224) were patients who were referred for colonoscopy because they had experienced multiple episodes of small amounts of bright or dark red blood per rectum (not requiring transfusion), or had been noted to be anemic on routine laboratory studies, which led to the detection of fecal occult blood. These patients underwent elective colonoscopy. Recent major bleeders (N = 93) were those patients who had an episode of significant rectal bleeding requiring emergency admission to the hospital and transfusion. They had spontaneous cessation of their bleeding and were then colonoscoped while still in the hospital, after receiving a standard bowel preparation. Acute bleeders (N = 55) were those patients who were being considered for emergency operation but for whom the usual studies, including angiography in some cases, had not provided a definitive diagnosis. These acute bleeders underwent emergency colonoscopy while actively bleeding, with simply a saline enema to clear the rectum but no formal bowel preparation.

Rigid proctoscopy and barium enema (BE) (postevacuation or double-contrast) were attempted on most of the patients. However, because of the personal preference of the referring physician or patient refusal, 30% of the cases underwent colonoscopy without a prior BE. All 372 patients were included in the study regardless of the results of their precolonoscopy studies. The BE findings were classified as "normal," "abnormal" (including masses, filling defects, strictures, diverticula, or possible lesion), or "not studied." BE results were taken from the official radiologic reports.

At the time of colonoscopy, an attempt was made to examine the cecum when clinically feasible. For elective colonoscopies, if the cecum was not visualized because of inadequate bowel preparation, a second colonoscopic examination was attempted and the findings of the more complete colonoscopy were used. Partial colonoscopies where no abnormalities were discovered were included in the "negative" group.

The diagnosis of carcinoma was proven by colonoscopic biopsy or polypectomy, and further information on their histologic grade was obtained from the surgically resected specimens. Carcinomas were classified into Dukes' original ABC categories.[8] Polyps containing intraepithelial or intramucosal carcinoma or severe dysplasia or atypia were classified as carcinoma *in situ* (CIS). Colonoscopies were done with a variety of colonoscopes manufactured by the Fujinon, Olympus, and Pentax companies.

Statistical comparisons were made by chi square tests of association and ridit analysis.[9] Ridit analysis applies to variables measured on an ordinal scale. It calls for identification of one group as a standard and relates the scale distribution of each study group to the scale distribution of the standard. Since colon neoplasms can be naturally scaled according to increasing order of severity, ridit analysis was used to determine the statistical significance of the observed differences in scale distribution of colonic neoplasms among the three groups of rectal bleeders. We chose the chronic rectal bleeding group as the standard (Tables 3 and 4).

Results

Three hundred and seventy-two patients were examined by colonoscopy. Of these, 106 had a precolonoscopy BE that was normal, 156 were abnormal, and 110 were not studied. The overall colonoscopy and BE results for the study sample are summarized in Table 1.

Overall, colonoscopy visualized a significant lesion in 51% of patients with rectal bleeding. One hundred and twenty eight (34%) of the lesions were neoplastic and of these 61 (48%) were malignant (CIS or invasive tumors).

In the group with a normal BE, 51 (48%) had a significant lesion detected on colonoscopy. The significant lesions consisted of colitis (ischemic, radiation, or inflammation) (7%), arteriovenous malformations (AVM) (5%), colonic ulcers (2%), and neoplastic lesions (35%). Of the neoplastic lesions, three were CIS and eight were invasive tumors. Therefore, in 10% of the patients with rectal bleeding and a normal BE, a malignant lesion was detected on colonoscopy.

In the group with an abnormal BE, consisting of 156 patients, (including diverticula, mass, filling defects, strictures, or those interpreted as "inconclusive" but suggestive of a lesion) 83 (53%) had a significant lesion detected on colonoscopy. Colonic neoplasms were found in 68 of the 156 patients (44%). Eight were CIS and 31 were invasive. Overall, 25% of the patients with rectal bleeding and a positive BE had a malignant lesion detected on colonoscopy.

In the group without a precolonoscopy BE, 56 of the 110 cases (51%) had a significant lesion detected on colonoscopy. In these cases, colonic neoplasms were found in 23 (21%) of the colonoscopies performed. Three were CIS and eight were invasive. Therefore, in 10% of patients with rectal bleeding and no precolonoscopy BE, a malignant lesion was detected on colonoscopy.

Among patients who had a BE performed, there was no statistically significant difference in the colonoscopic detection of neoplasms between patients with a normal BE (37/106) and those with an abnormal BE (68/156).

The neoplastic lesions were found in patients ranging in age from 32 to 87 years (Fig. 1). Most of the neoplastic lesions were found in patients greater than 40 years of age; in patients older than 60, 39% of the cases with rectal bleeding had a neoplasm. The largest percentage of adenomas (23%), CIS (6%), and invasive carcinomas (22%) detected per 10-year age group were in the 7th, 8th, and 9th decades, respectively. The apparent 5- to 10-year lag period between the diagnosis of adenoma-

* Colitis = due to inflammation, radiation, or ischemia, AVM = arteriovenous malformation; Adenoma = all listed are adenomatous polyps (6 hyperplastic polyps are not included); CIS = *in situ* carcinoma; NA = invasive carcinomas for which a resection was not performed and Dukes staging was therefore not possible; Negative = anal lesions such as hemorrhoids, fissures, warts, etc., or cases of partial colonoscopy (due to fixation, strictures, poor patient compliance, poor bowel prep, or spasm), and totally normal colonoscopies.

† Abnormal = diverticula, mass, filling defects, strictures, or "inconclusive."

tous polyps and carcinomas is consistent with the concept of the adenoma-carcinoma sequence.[3]

The colonoscopic findings as a function of type of rectal bleeding are shown in Table 2. Although the overall percentage of significant lesions detected was similar among the three types of rectal bleeding, there were several individual differences. The proportion of adenomatous polyps detected in the chronic rectal bleeding cases was twice as large as the comparable percentage among the recent major and acute rectal bleeding cases ($p < 0.005$). In contrast, AVMs and diverticula were more frequently detected in the acute and recent major bleeding cases, when compared with the chronic rectal bleeding cases ($p < 0.001$). The frequency of negative colonoscopies in chronic rectal bleeding cases was significantly greater than in the recent major and acute rectal bleeding cases ($p < 0.005$). Based on these analyses, it is unclear which pattern of bleeding signifies a worse prognosis in terms of colonoscopic findings.

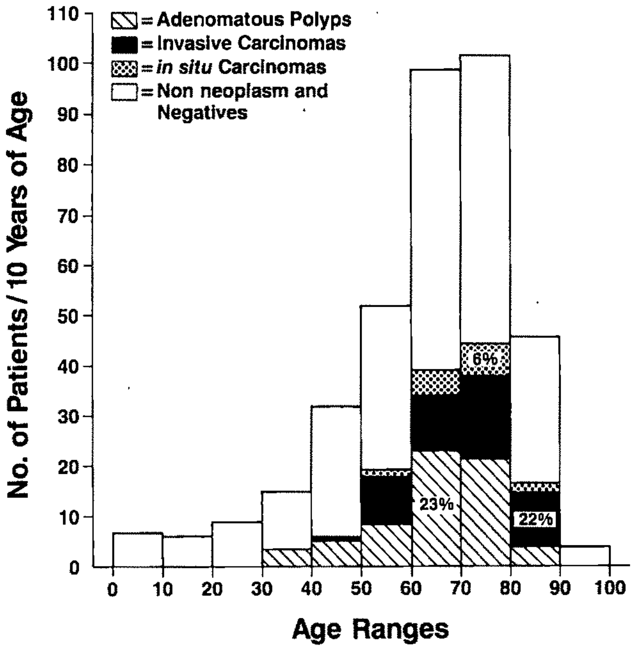

FIG. 1. The per cent distribution of diagnostic categories within each age group is represented by the designated patterns.

In order to better understand the differences in the colonoscopic findings among the three bleeding groups, the colonoscopic findings were grouped and ranked according to degree of severity (Table 3). Based on the assumption that the severity of colonoscopic findings increased in going from negative colonoscopies (least severe), through non-neoplastic findings, adenomatous polyps, *in situ* carcinomas to invasive carcinomas (most severe), ridit analysis did not detect any significant difference in the severity of colonoscopic findings among the three distinct patterns of rectal bleeding ($p > 0.45$). Therefore, although significant individual differences exist in the colonoscopic findings among the three distinct patterns of rectal bleeding, the overall degree of severity in the findings is the same for the three groups.

The percentage of neoplasms potentially amenable to definitive treatment by polypectomy (adenomatous polyps and *in situ* carcinomas) were 64, 68, and 53% for chronic, recent major, and acute bleeders, respectively. Therefore, whatever the pattern of bleeding, colonoscopy, on the average, detected a neoplasm in 34% of the cases of which 64% were potentially curable by polypectomy during their initial diagnostic colonoscopy.

Invasive carcinomas were found in 47 of the 372 patients studied (13%). In 41 of these patients, a surgical resection was performed and staging was therefore possible. The other six patients were too ill, refused to undergo an operation, or had a rectal cancer treated with repeated local fulgurations. Where staging was possible, it was found that 31 of the 41 colorectal cancers (76%)

* Colitis = due to inflammation, radiation, or ischemia, AVM = arteriovenous malformation; Adenoma = all listed are adenomatous polyps (6 hyperplastic polyps are not included); CIS = *in situ* carcinoma; NA = invasive carcinomas for which a resection was not performed and Dukes staging was therefore not possible; Negative = anal lesions such as hemorrhoids, fissures, warts, etc., or cases of partial colonoscopy (due to fixation, strictures, poor patient compliance, poor bowel prep, or spasm), and totally normal colonoscopies.

were localized to the bowel wall (Dukes A or B) (Table 4). This high percentage of early stage lesions was noted regardless of the pattern of bleeding. Ridit analysis revealed no significant difference in the severity of neoplastic lesions that were detected among the three types of bleeders.

The location of neoplasms is summarized in Table 5. Although neoplasms were found throughout the entire colon, about a third of both benign and malignant neoplasms were found proximal to the splenic flexure. Among the three patterns of bleeding, chronic bleeders had the lowest, and acute bleeders had the highest percentage of neoplasms located proximal to the splenic flexure. This twofold difference was statistically significant ($p < 0.05$).

Discussion

The exact role of colonoscopy in patients with rectal bleeding has not been fully defined. In people over 40 years of age, the long-term morbidity and mortality associated with rectal bleeding lies in its relationship to colon cancer.[10] Therefore, the evaluation of the role of colonoscopy in rectal bleeders should focus primarily on the impact it will have on the detection and removal of early colonic neoplasms.

Clinical studies[7,11] have shown that in 40–60% of patients harboring one or more colonic neoplasms, the predominant symptom is rectal bleeding. Since clinical[12] as well as pathologic studies[13] have demonstrated a lack of correlation between rectal bleeding and the histologic stage of a tumor, rectal bleeding does not necessarily indicate the presence of an advanced cancer. In fact, bleeding is thought to be a symptom of polyps[13] and early, rather than late, colorectal cancer.[7]

Because the majority of carcinomas, adenomatous polyps, and diverticula occur on the left side of the colon,[11] within reach of a 60-cm flexible sigmoidoscope, the traditional approach to rectal bleeders consists of flexible sigmoidoscopy and BE. This approach would be expected to detect most bleeding colorectal cancers, since most of the colon cancers presenting with a symptom of rectal bleeding are located in the rectosigmoid, as opposed to the right side of the colon.[6,7] Several studies have shown, however, that this approach may be inadequate since 41% and 33% of colonic neoplasms will be

TABLE 3. *Relation Between Bleeding Pattern and Increasing Severity of Colonoscopic Findings*

Chronic (N = 29)	9 (29)	12 (43)	8 (28)
Recent major (N = 5)	0 (0)	4 (80)	1 (20)
Acute (N = 7)	3 (43)	3 (43)	1 (14)
Total (N = 41)	12 (29)	19 (46)	10 (25)

* Dukes A = cancer invading into the submucosa and/or muscularis propia and limited to the bowel wall; Dukes B = cancer invading through the mulscularis propria into the fat or fibrous tissue; Dukes C = cancer metastatic to lymph nodes.

missed by routine and air-contrast BE, respectively.[14–16] Furthermore, 30 to 56% of neoplastic lesions have been found to be proximal to the splenic flexure[17,18] and, therefore, beyond the reach of a standard 60-cm flexible sigmoidoscope.

Previous studies indicate that the diagnostic yield of colonoscopy in detecting malignancy in patients with rectal bleeding ranges from 6.6 to 19%.[17,15] Whether such rates justify routine colonoscopy for all types of rectal bleeders cannot be determined from these studies since they dealt with small numbers of patients,[19] did not differentiate between acute and chronic bleeders,[15] or had conflicting results regarding the early detection of colonic cancers. Depending on the study,[18,20,21] colonoscopy for rectal bleeding detected different percentages (range: 52–78%) of carcinomas confined to the bowel wall.

This study demonstrates the efficacy of colonoscopy in the early detection of colon carcinomas in patients with three major types of rectal bleeding. Our colonoscopy yields of 34% neoplasms (benign plus malignant lesions) and 13% malignant neoplasms among rectal bleeders are consistent with published reports.[15,17] Likewise, the high percentage (>75%) of early stage lesions (limited to the bowel wall) detected by colonoscopy in rectal bleeders in this study has previously been documented,[21] although conflicting reports also exist.[18] To our knowledge, this is the first report to demonstrate the colonoscopic detection of a high percentage of early stage colorectal cancer lesions as a function of the type of rectal bleeding.

The routine use of colonoscopy in rectal bleeders has been questioned by proponents of the flexible sigmoidoscopy and BE combination. Our finding that colonoscopy revealed neoplastic lesions in 37% of patients with a negative BE, and that a substantial number (33%) of these lesions were located proximal to the splenic flexure, demonstrates the enhanced detection-rate that can be achieved with colonoscopy. Furthermore, since colonoscopy can serve as both a diagnostic as well as a therapeutic tool, pedunculated neoplastic polyps and noninvasive carcinomas are potentially curable during the initial diagnostic-therapeutic colonoscopy. In this series, 64% of the neoplasms detected by colonoscopy would have been amenable to this treatment.

Several studies have documented a recent change in the subsite distribution of colon cancer[22] and of benign adenomatous polyps[23] from distal to more proximal lesions. Because of these findings, the adage that 65% of colorectal cancer is within reach of the rigid proctoscope may no longer be tenable. Our results give further credence to this shift of lesions from distal to more proximal sites, and emphasize the increased need for a complete colonoscopic evaluation of rectal bleeders. Our results demonstrate that in rectal bleeders only 51% of the adenomatous polyps and 55% of the malignant neoplasms detected are located in the rectosigmoid region.

The findings of a substantial number of early stage neoplastic lesions located proximal to the splenic flexure in patients with an apparently negative BE were obtained regardless of the pattern of bleeding. These findings suggest that colonoscopy should be performed routinely in all types of rectal bleeders, including acute bleeders. Although some authors have questioned the efficacy of colonoscopy in acute rectal bleeders,[24] we have found it feasible.[25] The present data demonstrate that colonoscopy is not only feasible, but also very effective in detecting early stage colon cancers in acute rectal bleeders. In fact, the need for complete colonoscopic evaluation may be greater in acute bleeders than in chronic bleeders, as one would have expected. The percentage of neoplastic lesions located proximal to splenic flexure in acute bleeders was two times greater than in the chronic bleeders.

Our study population consists of patients with rectal bleeding who were referred for colonoscopy after an ini-

TABLE 5. *Relation Between Bleeding Pattern and Distribution of Neoplasms*

	Site of Neoplasm							
	Proximal				Distal			
Bleeding Pattern	Cecum	Ascending	Transverse	Total	Descending	Sigmoid	Rectum	Total
Chronic (N = 91)	12	3	8	23 (25%)	14	51	3	68 (75%)
Recent major (N = 22)	7	1	1	9 (41%)	4	8	1	13 (59%)
Acute (N = 15)	0	3	5	8 (53%)	3	4	0	7 (47%)
Total (N = 128)	19	7	14	40 (31%)	21	63	4	88 (69%)

tial screening by proctosigmoidoscopy. It is conceivable that a number of the patients who were chronic rectal bleeders never came to colonoscopy for a variety of reasons, including: (1) the screening physician did not feel it was indicated (i.e., pattern of bleeding, age of patient); (2) a cause for the bleeding was discovered on rigid or flexible sigmoidoscopy (hemorrhoids, fissures, warts, or diverticula) and the work-up terminated at that point; or (3) the patient was lost to follow-up after the initial screening. This would result in a selected population in which the detection of anal lesions would be low and colonic lesions, such as neoplasms, higher than in the nonselected population. The possibility of a selection process is not a concern with the cases classified as recent major and acute rectal bleeding, since all patients presenting with these patterns of bleeding underwent colonoscopy. This may explain the higher detection rate of neoplasms in the cases with chronic rectal bleeding when compared to the recent major and acute rectal bleeders.

In this analysis, the negative colonoscopy group includes cases in which the sole finding was an anal lesion such as hemorrhoids, fissures, warts, etc., cases with only a partial colonoscopy (due to external fixation, strictures, poor patient compliance, poor bowel prep, or spasm), and cases with totally normal colonoscopies. Despite this, the frequency of a totally negative colonoscopy (22%) in patients who did not have a precolonoscopy BE was about the same as the frequency of finding a colonic neoplasm. Therefore, if colonoscopy is used as the initial screening tool in rectal bleeders, our data predict that colonoscopy would find a benign or malignant neoplasm in about a third of these patients. This is exclusive of patients with chronic rectal bleeding in whom an etiology for the rectal bleeding was found by precolonoscopy studies, thereby obviating further work-up. A large proportion of these neoplasms (adenoma and CIS), so detected by colonoscopy, would be amenable to a concomitant therapeutic polypectomy.

In summary, this study demonstrates that in patients with rectal bleeding, colonoscopy will often: (1) detect neoplastic lesions not seen by BE (35%); (2) detect neoplastic lesions located proximal to the splenic flexure and threfore beyond the reach of a flexible sigmoidoscope (35%); and (3) detect early stage colon carcinomas (76% of cancers that were staged were Dukes A or B), and thus provide a probable improvement in prognosis. These findings were similar for the three distinct patterns of rectal bleeding studied. Our data, therefore, support the need for colonoscopy in all types of rectal bleeders, regardless of the results obtained by BE. Since a large percentage of the neoplasms (64%) detected during the initial colonoscopy were amenable to a concomitant polypectomy, colonoscopy may be the most prudent diagnostic tool in patients who present with rectal bleeding, especially those at highest risk for the development of colon neoplasms.

This study examines the influence of the properties of various vascular graft materials on the bacterial adherence process of two different strains of *Staphylococcus epidermidis* (mucous and normucous producing). Dacron® grafts (both knitted and woven), Teflon® grafts, and Dacron grafts coated with one and two layers of silicone were studied because these materials differ significantly in porosity, hydrophobicity, and surface charge (zeta potential). Graft segments were immersed in ^{3}H-labeled bacteria solution for periods ranging from 5 to 180 minutes and liquid scintillation techniques were used to quantify bacterial adherence. The porous knitted Dacron material had a significantly higher rate of bacterial adherence than either the woven Dacron or Teflon ($p < 0.05$). Silicone coating (either one or two layers) reduced adherence by a factor of four for the knitted Dacron ($p < 0.05$) and by a factor of two for woven Dacron ($p < 0.05$). The mucous producing strain of *S. epidermidis* displayed significantly better adherence to woven and knitted Dacron than the normucous producing strain, but only when 0.25% dextrose was added to the bacteria solution. These findings indicate that the highly porous knitted Dacron grafts have the highest propensity for bacterial adhesion. Graft materials with the most negative zeta potentials are more resistant to bacterial adherence. Silicone coating of Dacron material significantly changed adherence characteristics, suggesting that this may be a viable strategy for protecting implantable medical devices containing materials to which bacteria readily adhere.

INFECTION OF A PROSTHETIC device, especially a vascular graft, is catastrophic. Documented morbidity as high as 75% (for aortic implants) has been associated with graft infection, and limb amputation rates have been reported as high as 50%.[1] Bacteria can be introduced into the graft site at the time of implantation or *via* transient blood bacteremia.[1-3] Whatever the means, bacteria are frequently present in the circulation in sufficient quantities to cause graft infection. Current estimates are that between 1.5 and 7% of all implanted grafts ultimately become infected.[1-3]

When infection occurs, *Staphylococcus epidermidis* is the most prevalent pathogen cultured from implanted medical devices, especially vascular grafts.[3-6] Studies of pathogenic organisms causing infection in implanted medical devices have shown that *S. epidermidis* is the infecting organism in the following percentage of cases: vascular grafts, 60%[4]; hip joints, 50%[5]; and heart valves, 30%.[5] Frequently pathogenic *S. epidermidis* colonies produce a mucoid growth, also known as glycocalyx or slime film, which becomes adherent to the surface of the implanted device.[7] An example of this phenomenon is shown in Figure 1. The production of mucous is believed to facilitate bacterial adhesion and may represent a critical factor in the pathogenesis of medical device infections.[7,8]

A decisive step in the pathogenesis of graft infection is the irreversible attachment of bacteria to the graft surface which, for the purposes of this paper, will be considered adherence. Adherence is determined by complex physicochemical interactions between the graft and the bacteria. These interactions, in turn, are governed by the surface properties of the graft material and the infecting bacteria. Theoretically, the three properties of materials that should have the most influence on bacterial adherence are graft porosity, surface tension, and electronegativity.[9-11]

Graft porosity is often defined as the water permeability of the graft material (in units of mL H_2O/cm^2 surface area/min) at a transmural pressure gradient of 100 mmHg. In a more general sense, it is an indication of the spacing, or distance between adjacent fibers of the graft material (*i.e.*, the interstitial space). The amount of interstitial space within the graft material matrix will determine how readily blood will pass through the graft wall and how easily tissue surrounding the graft can penetrate the interstices of the material to incorporate it into the body's cellular matrix. The porosity of a synthetic graft is strongly determined by the manufacturing process used (*i.e.*, weaving, knitting, stretching, etc.) and is not necessarily an intrinsic property of the material itself.

The surface tension of a graft material determines how readily an interface can form between the surface of a graft material and another surface (solid or liquid). An interface, or contact, between two surfaces will only occur if it is energetically favorable. Thermodynamic analysis of particle adhesion to surfaces predicts that hydrophobic materials with a low surface tension will result in maximal bacterial adherence.[10]

Electrostatic interactions have been shown to influence the adhesion of bacteria to a substrate.[10,11] When the bacteria and a substrate have the same charge, bacteria will be repelled by an electrostatic force dependent on the electrical potential of each surface. This repulsion results in an energy barrier to adhesion. The electrical potentials of the bacteria and the graft material are due to the presence of charged chemical groups on each surface. For bacteria and synthetic graft material, these charged groups are typically negative and are formed by dissociated acid moieties such as COO^-.[12-14] The charged groups cause the formation of an electrical double layer adjacent to the surface. The electrical potential of the surface is approximated by the electrical potential across the double layer, which is defined as the zeta potential.[13,15]

This study had two primary objectives: to assess the influence of graft material properties on bacterial adherence (*S. epidermidis*) and to determine if this correlated with theoretical expectations. Dacron grafts, both knitted and woven, Teflon (polyetrafluoroethylene) grafts, and Dacron grafts coated with one and two layers of silicone were examined. The material properties of the three grafts and those coated with silicone are shown in Table 1. Previous studies have shown that these synthetic materials have statistically different amounts of bacterial adherence,[9,18-22] but *S. epidermidis* adherence has rarely been tested and the effect of silicone coating on bacterial adherence has not been examined. The second objective was to determine whether a mucous-producing strain of *S. epidermidis* will adhere to vascular grafts more readily than a normucous-producing strain. Adherence data were collected *in vitro*, suspending the bacteria and the grafts in phosphate buffered saline (PBS) to limit bacterial growth during the experiments. For some of the experiments, 0.25% dextrose was added to the PBS solutions because some authors have suggested that sugar molecules facilitate the development of the mucous layer.[12] This low concentration would not support rapid bacterial growth but would provide a substrate for mucous production. Adherences were examined quantitatively by using radiolabeled bacteria, and qualitatively by using scanning electron microscopy.

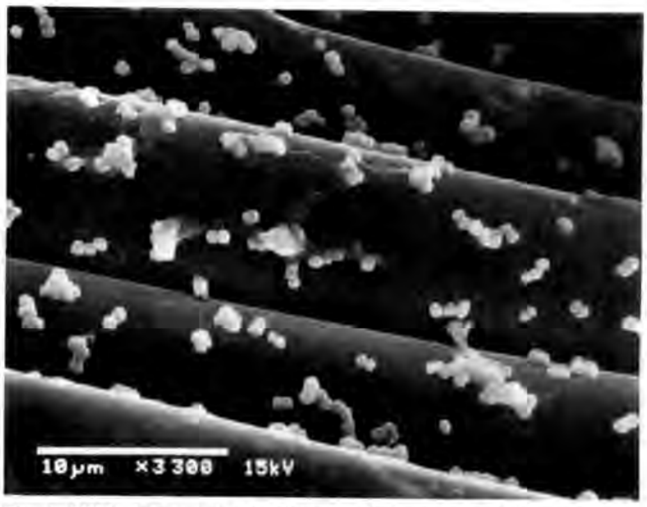

FIG. 1. SEM photograph of a slime-producing strain of *S. epidermidis* (ATCC 14990) attached to the fibers of a woven Dacron graft after 3 hours of immersion in a nutrient broth (0.25% dextrose w/v) solution of 10^8 CFU/mL.

Experimental Methods

Graft Materials

Three different commercially available vascular grafts were used in the experiments: Sauvage Bionit (Bard Biochemical), a knitted Dacron graft; Cooley Low Porosity (Meadox Medical), a woven Dacron graft; and Gortex

TABLE 1. *Graft Material Properties*

Material	Surface Tension[16] (dynes/cm)	Zeta Potential[17] (mv)	Porosity* (mL/min/cm²)
Dacron® (PET)†	43	−9	1500 (knitted) 50 (woven)
Teflon® (PTFE)	18.5	−17	1
Silicone	24	−15 to −21	—

* Porosities for the Dacron grafts were obtained from the respective manufacturers.

† Both Dacron and Teflon are registered trademarks of DuPont.

(W. R. Gore & Associates), a Teflon graft that has been stretched to produce a microporous structure consisting of nodes of polytetrafluoroethylene (PTFE) interconnected by thin fibrils. Additionally, woven and knitted Dacron grafts were dip coated with silicone (polydimethylsiloxane).

Graft Preparation

PTFE graft segments were cut to an approximate length of 2 cm. The crimped graft segments were cut to lengths that reflected a 2-cm length in their uncrimped or elongated state. The degree of crimping was determined by taking the weight ratio of crimped graft to uncrimped graft (obtained from the manufacturers). All grafts had inside diameters of 6 mm. The outside diameters were 7 mm, 6.5 mm, and 7.27 mm for the knitted Dacron, woven Dacron, and PTFE grafts, respectively.

Silicone Coating Procedure

The solution used to coat the Dacron grafts was prepared from Cardiomat 40, made by Kontron Cardiovascular. This is an ultrapure silica-free (or filler-free) solution of 50% (w/v) room temperature vulcanizing polydimethylsiloxane (PDMS) in 2/1 THF-dioxane. The solution was subsequently diluted further with THF-dioxane to approximately 27% PDMS. This dilution yielded the most uniform coat of silicone on both types of Dacron.

The graft segments were completely immersed for 5 minutes and then hung vertically to dry for 24 hours. If a graft was to receive a second coat, it was dried for only 30 minutes and then reimmersed. Porosities of the silicone-coated graft materials were measured at a transmural pressure gradient of 100 mmHg.

Bacteria

The bacteria used in the experiments were two different American Type Culture Collection (ATCC) strains of *S. epidermidis:* 14990 (a mucous-producing strain) and 12228 (a nonmucous-producing strain). Each strain was subcultured onto agar plates and stored at 4 C. This procedure was repeated several days before each experiment.

Preparation of ^{3}H-Labeled Bacteria Solution

Bacteria were transferred sterilly from an agar plate (containing cells that had been recultured the previous day) to Mueller-Hinton Broth (Difco Laboratories, Detroit, MI). ^{3}H-Thymidine (ICN Radiochemicals, Irvine, CA), having a total activity of 0.5 μCi, was then added to this solution. The solution was incubated overnight at 37 C, with the ^{3}H-Thymidine becoming incorporated into the bacterial DNA.

The next day, the bacteria were washed and resuspended in 0.1 N phosphatase buffered saline (PBS), pH 7.4, to produce a solution with an approximate concentration of $1–5 \times 10^8$ CFU/ml. Measurement of the final supernatant for radioactivity yielded values not statistically above background, indicating that ^{3}H-label had been well-incorporated into the bacteria.

The concentration of organisms in the bacteria-PBS solution was determined by measuring the turbidity of the solution at 440 μm using a Johnson Laboratories dual beam spectrophotometer. A standard curve of bacterial concentration *versus* optical density for the two strains was developed using a Coulter particle counter (Coulter Electronics model ZBI, with a 30μm aperture tube).

To determine the concentration of radioactivity (cpm/mL) in the solution, 5 1-mL samples of each bacterial solution were saved for liquid scintillation counting. By dividing the bacterial concentration by the radioactive concentration, the number of bacteria per radioactive count could then be determined.

In Vitro *Bacterial Adherence*

The bacterial solutions were kept at 37 C and mildly agitated. For the dextrose experiments, a concentration of 0.25% w/v dextrose was mixed into each solution immediately prior to graft immersion. Graft segments were completely immersed in a stable horizontal position.

Graft segments were removed from the bacterial solution after intervals of 5, 10, 20, 30, 40, 50, 60, 80, and 180 minutes and then washed in PBS to remove nonadherent bacteria. The specimens were transferred to scintillation vials containing 5 mL of 0.1 N NaOH and vortexed to remove and lyse adherent bacteria.[18] As a control mechanism, the background activity of the graft segments was determined by immersing uncontaminated segments under similar conditions. All the vials of NaOH solution were adjusted to a pH of 7 using dilute HCl.

Graft segments were then removed from the vials and 15 mL of water accepting xylene-based liquid scintillation cocktail (Aquasol, New England Nuclear) was added. The radioactivity of the bacteria in each vial was measured using a Hewlett-Packard Model 2405 Scintillation Counter. Counting time for all samples was 4 minutes. Counting efficiency was approximately 28%.

Calculation of Number of Adherent Bacteria

Absolute values for adherent bacteria were determined using the equation:

$$\text{\# of adherent bacteria} = \frac{\text{weight 2 cm graft segment} \times \text{count} - \begin{pmatrix}\text{background of}\\ \text{uncontaminated}\\ \text{graft segment}\end{pmatrix} \times (\text{\#bac/count})}{\text{weight sample graft}}$$

Adherence was expressed as bacteria per unit surface (cm^2) and bacteria per unit weight (gm) for 2 cm lengths.

Scanning Electron Microscopy

Graft segments were immersed in bacterial solutions (not containing the ^{3}H-thymidine label) using the procedure previously described. Upon removal from the bacterial solution, the graft segments were washed once in PBS and then fixed for 24 hours in a solution containing 2.5% glutaraldehyde and 0.1 N sodium cacodylate buffer. Samples were then postfixed by immersion in a 1% buffered osmium tetroxide solution for 3 hours. The graft segments were then washed with distilled water, immersed in 1% thiocarbohydride for 20 minutes, and then rewashed. The samples were dehydrated in graded solutions of ethanol and then critically point-dried in a Tousimis Model 780 dryer (Tousimis Research Corp., Rockville, MD). They were then mounted on metal stubs, sputter-coated with gold palladium, and examined on an Amray 1200B Scanning Electron Microscope (Amray, Inc., Bedford, MA).

Statistical Analysis

Data were compared for statistical significance with analysis of variance and the two-tailed Student's t-test. P values of <0.05 were considered significant.

Results

Adherence for the knitted Dacron was roughly four times that of either the PTFE or woven Dacron per surface area throughout the experiment (Fig. 2). This difference was statistically significant ($F = 3.24$, $p < 0.05$) for all time periods. While there was no significant difference between the PTFE and the woven Dacron, the PTFE tended to have a lower adherence for the first 30 minutes of contact with the bacterial solution.

When woven Dacron grafts were coated with a single layer of silicone, porosity was lowered by a factor of 6 ($p < 0.05$), whereas for the knitted Dacron, porosity was not significantly changed. The double silicone coating decreased the porosity of both types of Dacron grafts to values approaching zero. Silicone coating of knitted Dacron grafts lowered bacterial adherence by approximately a factor of four for all time periods (Fig. 3A), while adherence to the woven Dacron was lowered by a factor of two (Fig. 3B). These differences were statistically significant for both materials ($p < 0.05$); there were no statistically significant differences, however, in the

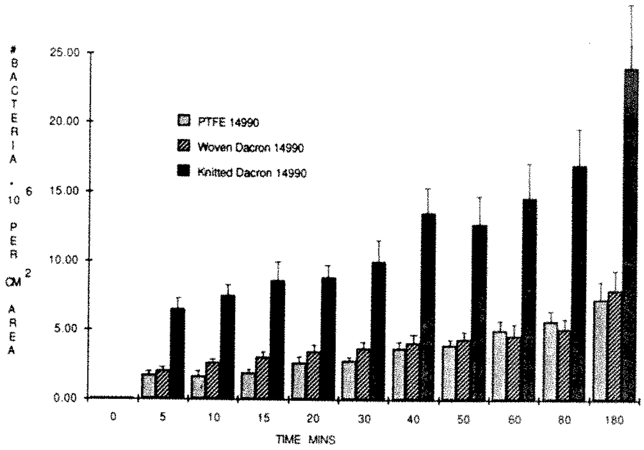

FIG. 2. Bacterial adherence per cm^2 surface area for PTFE, woven and knitted Dacron (N = 11).

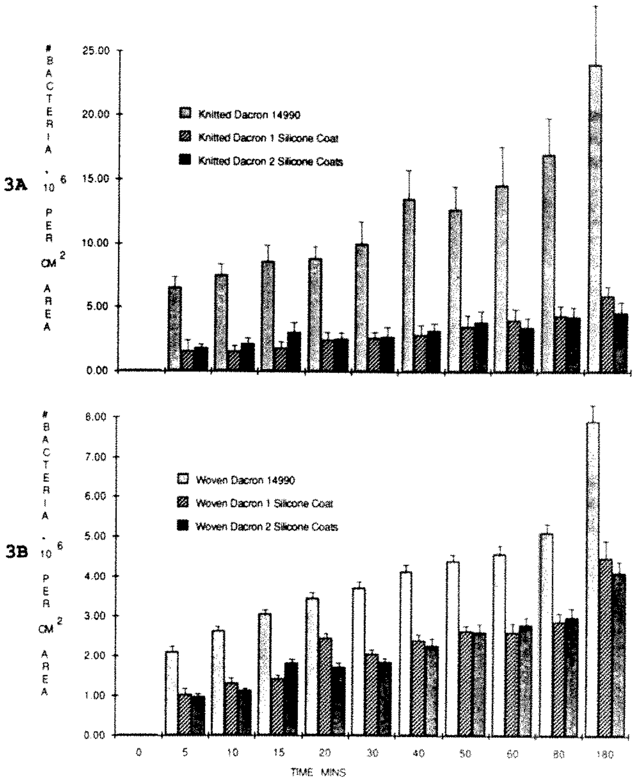

FIG. 3. Bacterial adherence (ATCC 14990) per cm^2 surface area for (*A*) knitted Dacron uncoated, and coated with one and two layers of silicone (N = 7) and (*B*) woven Dacron uncoated, and coated with one and two layers of silicone (N = 7).

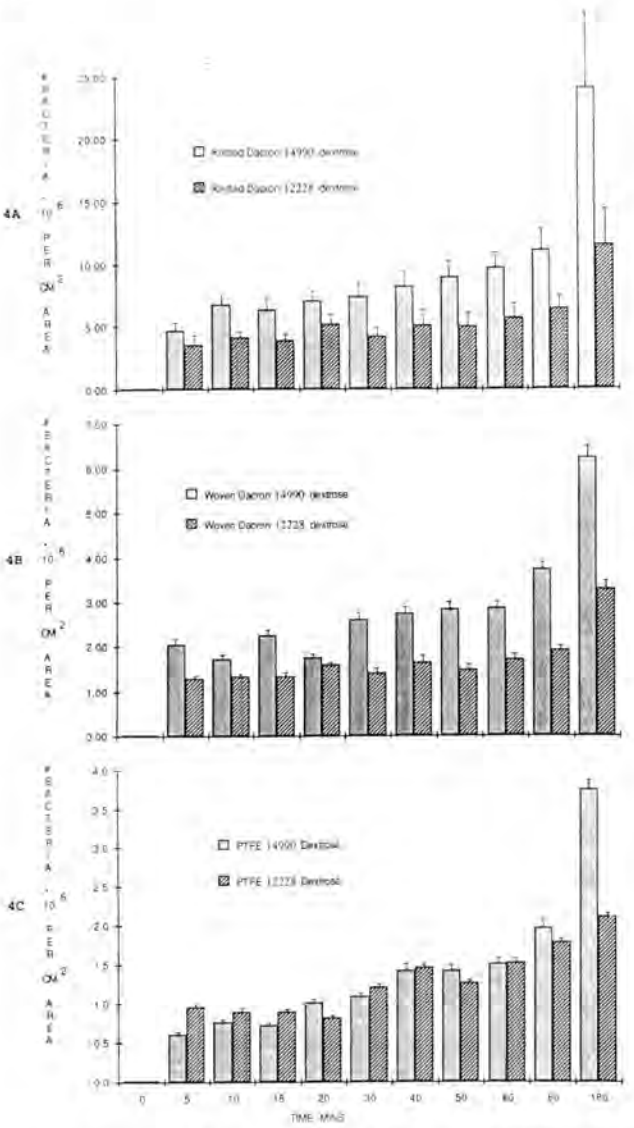

FIG. 4. Adherence of *S. epidermidis* strains 14990 and 12228 grown in PBS with 0.25% dextrose added to (*A*) knitted Dacron (N = 4), (*B*) woven Dacron (N = 4), and (*C*) PTFE (N = 4).

single *versus* double silicone-coated grafts in spite of the differences in porosity. When the adherence of single-coated knitted and woven Dacron grafts was compared to the adherence to PTFE, there were no statistically significant differences for any of the three materials at any of the time periods.

No significant difference in adherence existed between the two strains of *S. epidermidis* at any time for any of the three materials in PBS buffer. However, when 0.25% dextrose was added to the bacterial solutions, strain 14990 adhered to woven and knitted Dacron segments in significantly greater ($p < 0.05$) quantities (Figs. 4A and B). Data were inconclusive for the PTFE segments (Fig. 4C).

Adherence values for the graft materials appeared to increase in a nonlinear, almost exponential manner with time. To characterize the time course of bacterial adherence, experimental data were fit (using linear regression) to the first order kinetic equation:

$$A(t) = A_f(1 - e^{-kt})$$

where A(t) is the number of adherent bacteria as a function of time, k is the attachment rate constant, and A_f is the final number of adherent bacteria. Table 2 lists the rate constants and correlation coefficients for each combination of material and bacterial strain. There was good agreement between the experimental and calculated data for each material. The rate constants were highest for siliconized materials, because the silicone adherence curves had the lowest maximal value and the rate constant reflects how quickly the adherence curve for each material reaches its maximum value. There was no correlation between rate constants and bacterial strain.

Scanning Electron Microscope Observations

The qualitative observations from the scanning electron microscope (SEM) photographs agreed with the quantitative results. Figures 6A and B are SEM photographs of a sample of PTFE that had been immersed in a solution of *S. epidermidis* (14990, ~10^8 CFU/mL) for 10 and 30 minutes. In contrast, samples of knitted Dacron immersed for 10 and 30 minutes in the same solution (Fig. 5A and B) have larger numbers of adherent bacteria.

Although bacteria adhere in concentrated patches to both knitted and woven Dacron by 30 minutes, bacteria have attached individually with a discrete distance between cells even in these dense patches. For the knitted Dacron, many of the dense patches occur on recessed fibers, sheltered from the surface and any hydrodynamic shear forces. In contrast, the close packing of fibers in

TABLE 2. *Correlation Coefficients and Rate Constants from Kinetic Model*

Material	Bacterial Strain	Correlation Coefficient	k $(min)^{-1}$
PTFE	14990	−0.98	0.0175

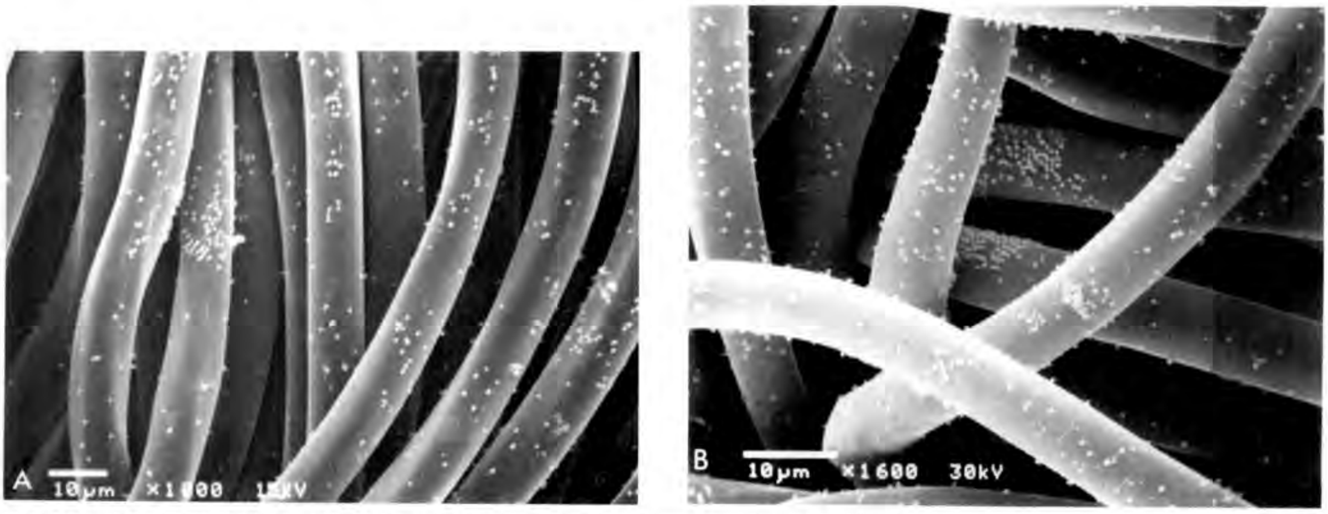

FIG. 5A and B. *A*. SEM photograph of a segment of knitted Dacron immersed for 10 minutes in a solution of *S. epidermidis* (14990, ~10^8 CFU/mL); *B*. SEM photograph of a segment of knitted Dacron immersed for 30 minutes in a solution of *S. epidermidis* (14990, ~10^8 CFU/mL).

the woven Dacron samples does not allow bacteria to pass as readily into the interstitial spaces.

When the grafts were immersed for 3 hours in a nutrient solution containing 10^8 CFU/mL of the mucous-producing strain (14990), bacteria on the grafts had a mucous film surrounding them and appeared to be in aggregated groups, connected to the surface *via* the mucous film (Fig. 1).

Discussion

Graft porosity is a major factor affecting bacterial adherence. The highly porous knitted Dacron graft material has the greatest propensity for bacterial adherence. Woven Dacron, which is much less porous, has significantly less bacterial adherence even though the other material properties are identical. Hydrophobic, electronegative materials, such as PTFE and silicone, have less bacterial adherence than Dacron, which has the highest surface tension and zeta potential. Silicone coating the woven and knitted Dacron grafts alters all three of the prementioned properties and significantly reduces bacterial adherence.

Graft materials that are porous provide bacteria with greater access to the interstices of the graft, effectively increasing the available surface area for adherence. We expected silicone coating to decrease the access to the interstitial spaces of knitted Dacron and woven Dacron grafts and subsequently demonstrated a significant reduction in bacterial adherence to both knitted and woven graft samples after such treatment. This reduction was significantly greater for the knitted Dacron, which could be expected to have the larger reduction in interstitial surface area from silicone coating. However,

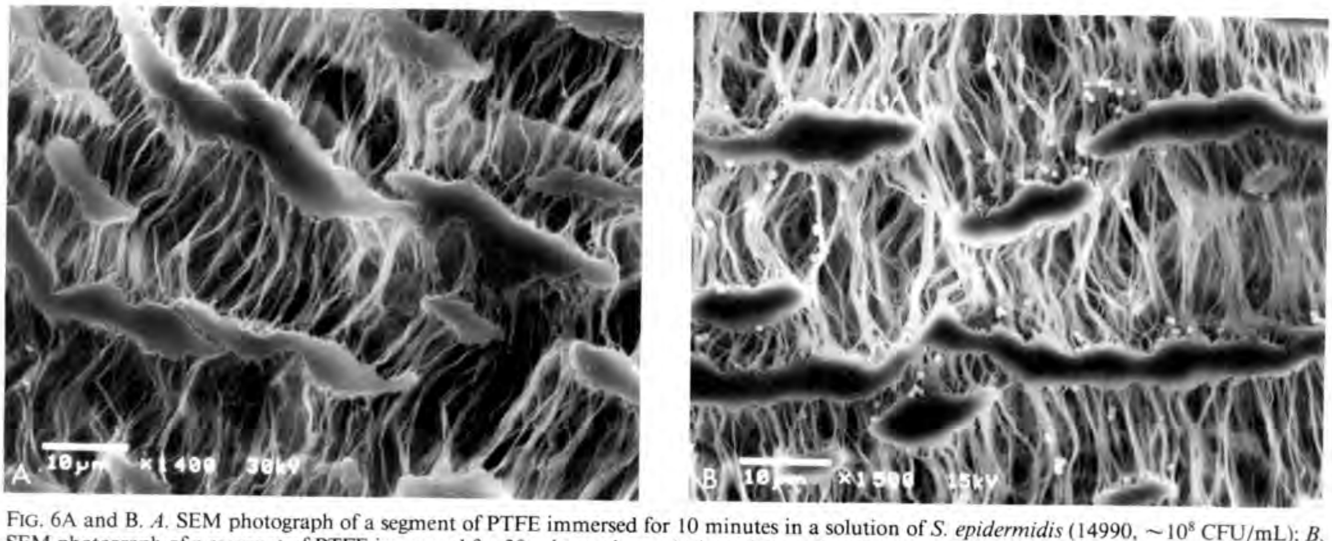

FIG. 6A and B. *A*. SEM photograph of a segment of PTFE immersed for 10 minutes in a solution of *S. epidermidis* (14990, ~10^8 CFU/mL); *B*. SEM photograph of a segment of PTFE immersed for 30 minutes in a solution of *S. epidermidis* (14990, ~10^8 CFU/mL).

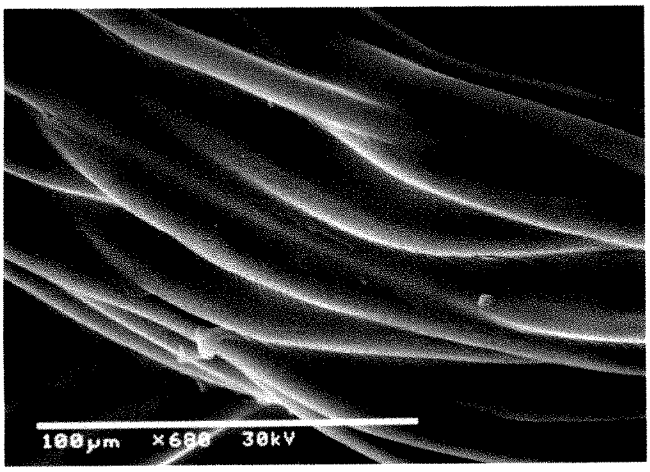

FIG. 7. SEM photograph of a segment of knitted Dacron graft coated with one layer of silicone.

there was no statistically significant difference in the measured porosities of the single silicone-coated knitted Dacron and the uncoated knitted Dacron graft segments, although there were significant differences in bacterial adherence. Additionally, while the porosity of the double silicone-coated knitted Dacron was reduced to almost zero, no significant difference existed in amounts of bacterial adherence between the single and double silicone-coated knitted Dacron graft segments. Unfortunately, porosity measurements, which use water, are probably not the most appropriate measure of the interstitial space between graft fibers, especially if one is interested in correlating bacterial adherence with surface area available for bacterial adherence. The SEM photographs show the silicone filling the interfibril spaces and suggest that surface area for bacterial adherence is decreased (Fig. 7).

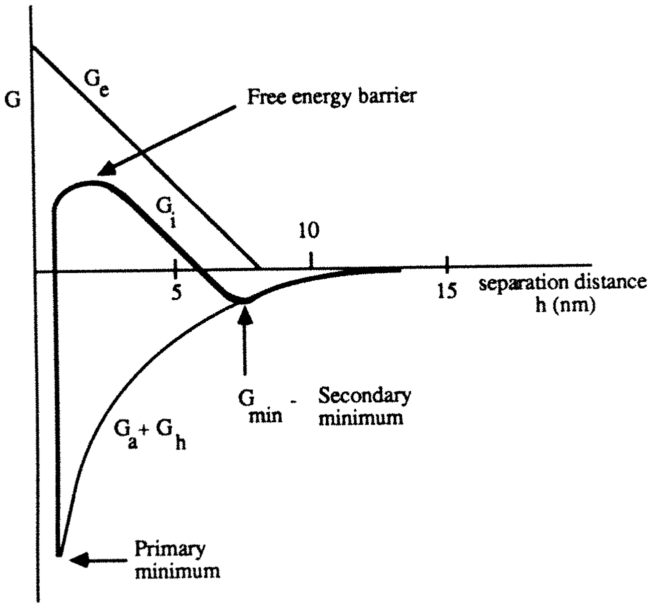

FIG. 8. Interactive free energy *versus* separation distance for a changed spherical colloidal particle approaching a like-charged planar surface.

Results from several other studies have shown that bacterial adherence rates for the highly porous knitted Dacron vascular grafts are significantly greater for a variety of bacteria than for the other lower porosity graft materials.[19-22] Also, porous materials were shown by Merrit et al.[23] to have significantly higher rates of infection than nonporous materials when implanted subcutaneously in mice that were challenged with *Staphylococcus aureus.*

Theoretically, bacterial adhesion to a surface depends on the electronegativity and hydrophobicity of the type of bacteria and on the surface characteristics of the material. These interactions can be analyzed using the three main forces responsible for surface-particle interactions in liquids.[15] The attractive forces are van der Waals (or London Dispersion forces) and hydrophobic interactive forces, which occur when both surfaces tend to repel water. Repulsion is caused by electrostatic forces occurring when the bacteria and surface have the same electrical charge. The summation of forces is defined as the interactive free energy, or G_i, which can be expressed as:

$$G_i = G_a + G_h + G_e$$ [15,24]

where G_a, G_h, and G_e are the van der Waals, hydrophobic, and electrostatic forces, respectively. A schematic representation of G_i is shown in Figure 8.

Adhesion occurs when the free energy of the system is minimized, which is when work must be done to separate an organism that has contacted a surface.[25] Theoretically, there are two discrete distances in which free energy is minimized.[26,27] As indicated in Figure 8, these distances are known as the primary and secondary minimums. At the primary minimum, the particle is sitting very close to the surface (<1 nm). Attachment at this point is irreversible (*i.e.*, adherence) because the particle is in a very deep energy trough. However, in order to be captured in a primary minimum, a particle striking the surface must have sufficient kinetic energy to overcome the free energy barrier resulting from electrostatic repulsive forces. At the secondary minimum, the particle is sitting in a minor energy trough (prior to the free energy barrier) and is only loosely attached to the surface. Because electrical repulsion forces decay more rapidly with distance than dispersion forces, bacteria are attracted to the surface until repulsive become significant.[11,15] An organism will stay at this point, in a metastable or reversible state of adsorption. The degree of reversibility depends on the depth of the energy trough. Detachment is caused by fluid shear forces in the microenvironment of the bacteria. If bacteria can remain in a secondary minimum long enough, they can produce mucous and use this network of polysaccharide fibrils to permanently anchor themselves to a surface.[12,15]

Of the manufactured grafts we examined, PTFE had the lowest degree of bacterial adherence. *S. epidermidis* is hydrophobic.[9] Also, bacteria that produce mucous have a negative surface charge.[11,12] On a theoretical basis, therefore, the *S. epidermidis* used in this study were expected to adhere in greater numbers to the more hydrophobic materials and in lesser amounts to the more electronegative materials.[10,11] PTFE, however, is both hydrophobic and electronegative. The electronegative repulsive force between the bacteria and the material surface clearly outweighed the attractive forces from the hydrophobic interactions between the organisms and the surface.

Other investigators have reported similar results. Abbott et al.[11] and Newmann et al.[10] have also shown that adhesion is inversely proportional to the negative electrical surface charge or zeta potential of bacteria, particularly in solutions with low electrolyte concentrations. Neither of these studies, however, examined *S. epidermidis* interaction with the plastics, Teflon or Dacron. Brown et al.[28] compared PTFE patches to polypropylene mesh patches in abdominal wall repairs complicated by intraoperative contamination with *S. aureus*. The PTFE patches had significantly fewer adherent organisms at removal. Sugarman[19] observed reduced microbial adherence to PTFE for a variety of bacteria with negatively charged surface groups and proposed that the electronegative nature of PTFE was a contributing factor. While Sugarman did not examine *S. epidermidis* adherence, Schmitt and co-workers[21,22] have also examined *S. epidermidis* using a 24-hour innoculation period and reported similar results; PTFE had the lowest number of adherent bacteria of the samples tested. They did not examine silicone-coated grafts.

Further evidence that electrostatic repulsion is important in decreasing bacterial adherence is provided by the results of our silicon coating experiments. When Dacron grafts were coated with silicone, increasing the hydrophobicity and electronegativity, bacterial adherence was significantly reduced. Implanted medical devices made of silicone have been in use since 1959.[29] Although the nonporous structure of silicone has been assumed to be resistant to bacterial adherence, this study is unique in that we were able to show that even porous devices with a silicone coating are relatively resistant to bacterial adherence.

This study also investigated whether bacterial production of a mucous biofilm contributes to the process of bacterial adherence to graft materials. SEM photographs demonstrated the facilitative role of the mucous in the attachment process. Organisms can initially become incorporated into the mucous layer that adherent bacteria produce even before they establish contact with the graft. This allows bacteria to accumulate in large aggregated groupings. Without the mucous film, bacteria only adhered to the surface on an individual basis with a discrete distance between cells. Negatively charged latex particles display similar behavior.[11] This type of discrete adherence is due to electrostatic lateral repulsive forces between particles, which the mucous film seems to be able to minimize. The statistical differences in adherence between the mucous-producing (14990) and non-mucous-producing (12228) strains of *S. epidermidis* also supported the concept of a facilitative role for the mucous film. However, this difference was only manifested when 0.25% (w/v) dextrose was added to the suspending PBS solution, suggesting that bacteria need a minimal concentration of substrate to produce the mucous. This has been previously confirmed and the formation of mucous is assumed to require energy and nutrients.[12,21,22]

The results from this study, as well as others, point to a general conclusion regarding bacterial adhesion to vascular grafts. Optimal resistance to bacterial adherence and infection can be expected from vascular prosthetics, which have properties most similar to those of the native artery or vein. Therefore, a prosthetic graft should have a smooth, relatively nonporous surface that is somewhat electronegative and a surface tension of approximately 25 dynes/cm.[10,30] Presently, the synthetic medical material most closely matching these criteria is silicone, followed by PTFE. Any process that can alter the physical and morphologic properties of a synthetic material to more closely resemble those of living tissue should improve the resistance of that material to infection. One such process, which has already shown potential for reducing graft infection, is the preseeding of the vascular graft with autologous endothelial cells.[31,32] Further studies using absorbable materials for arterial conduits may demonstrate a potential for decreasing the long-term risk of infection.[33]

Finally, as the number of patients who might benefit from the implantation of some form of medical device rises, further studies must be directed toward determining how host, bacteria, and foreign body interact *in vivo*. With this knowledge, it will be possible to devise strategies that will decrease the percentage of devices that must be removed because of chronic infection. Organisms such as *S. epidermidis*, once considered incapable of producing infection, can become pathogenic in individuals with prosthetic devices.[4–8] Additionally, evidence is accumulating that prosthetic devices alter the immune competency of a host.[34,35] Individuals with prosthetic devices probably need prophylactic antibiotic protection during certain events associated with significant bacteremia, but cannot be given continuous treatment without a corresponding increase in the evolution of antibiotic resistant strains of bacteria.[36] Attempts at bonding antibiotics to grafts have shown some promise, but effective drug levels are not maintained for longer than a period of weeks.[37] Over 20 years ago, Folkman and Long[38] demonstrated that drugs could be absorbed by silicone and released over periods of time ranging up to several months. If antibiotics can be absorbed by silicone, this may present another avenue where silicone-coated medical devices will help resist bacterial contamination. For the field of implanted medical devices to evolve to its full potential, more infection-resistant, biocompatible materials need to be developed.

Acknowledgments

The silicone coating procedure we used was developed by Mr. James H. Donachy and Dr. William S. Pierce of the Division of Artificial Organs, Department of Surgery, the Pennsylvania State University. Their assistance was greatly appreciated. This technique is similar to that described by Asher et al.[39] We also thank Drs. John A. Waldhausen and Brian L. Thiele, who reviewed the manuscript and provided guidance throughout these studies.

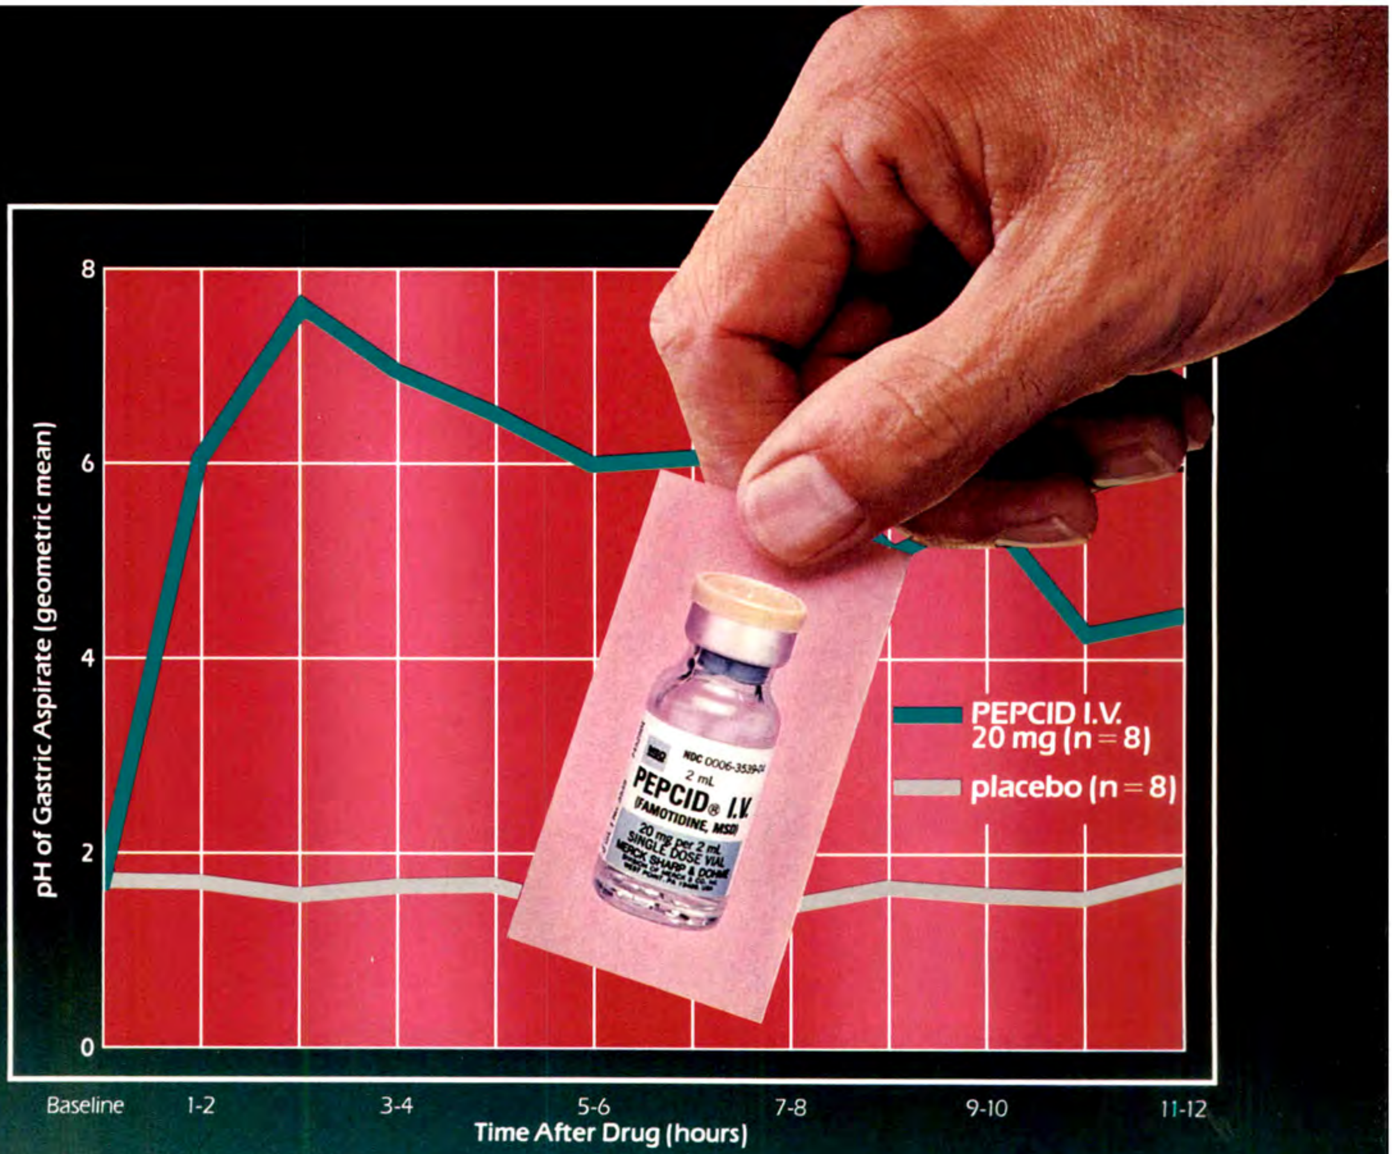
For a Brief Summary of Prescribing Information, please see last page of this advertisement.

Only one H_2 antagonist controls pH for up to 12 hours on a single dose

PEPCID® I.V. (Famotidine, MSD) is indicated in some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or as an alternative to the oral dosage forms for short-term use in patients who are unable to take oral medication.

The recommended dosage is 20 mg q12h. Dosing intervals may need to be prolonged or dosage reduced in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine. PEPCID I.V. is contraindicated in patients who are hypersensitive to any component of this medication. The adverse reactions reported for PEPCID Tablets may also occur with PEPCID I.V. In addition, transient irritation at the injection site has been observed with PEPCID I.V.

Copyright © 1987 by Merck & Co., Inc.



A double-blind, placebo-controlled study[1] involving eight volunteer hypersecretor subjects. The pH of gastric aspirates was measured hourly for 12 hours following single intravenous doses. PEPCID I.V. maintained the mean gastric pH above 4.0 at all time points throughout the 12-hour period with one 20-mg I.V. dose.

SHARP&
DOHME

TABLETS
Pepcid®
(Famotidine|MSD)
20 mg and 40 mg

ORAL SUSPENSION
Pepcid®
(Famotidine for
Oral Suspension|MSD)
40 mg per 5 mL

INJECTION
Pepcid® IV
(Famotidine|MSD)
20 mg per 2 mL

Contraindications: Hypersensitivity to any component.

Precautions: ***General:*** Symptomatic response to therapy does not preclude the presence of gastric malignancy.

Patients with Severe Renal Insufficiency: Longer intervals between doses or lower doses may be needed in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine (see Clinical Pharmacology and Dosage and Administration sections of Prescribing Information).

Information for Patients: The oral suspension should be shaken vigorously for 5-10 seconds prior to each use, and unused constituted oral suspension should be discarded after 30 days.

Drug Interactions: No drug interactions have been identified. Compounds tested in man include warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In rats and mice given oral doses up to approximately 2500 times the recommended human dose for active duodenal ulcer, there was no evidence of carcinogenic potential, no evidence of a mutagenic effect, and fertility and reproductive performance were not affected.

Pregnancy: *Pregnancy Category B*—There are no adequate or well-controlled studies in pregnant women. Use during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether famotidine is secreted into human milk; however, it is secreted into the milk of lactating rats. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: No dosage adjustment is required based on age but may be necessary in severe renal impairment (see Clinical Pharmacology section of Prescribing Information).

Adverse Reactions: The adverse reactions listed below have been reported during domestic and international clinical trials in approximately 2500 patients. In the placebo-controlled clinical trials, the incidence of adverse experiences with PEPCID Tablets, 40 mg at bedtime, was similar to that with placebo.

Incidence Greater than 1%: The following adverse reactions have been reported to occur in more than 1% of patients on therapy with PEPCID in controlled clinical trials and may be causally related to the drug: headache (4.7%), dizziness (1.3%), constipation (1.2%), and diarrhea (1.7%).

Causal Relationship Unknown: The following other adverse reactions have been reported in clinical trials. While a causal relationship could not be established for these infrequently reported events, causality cannot be excluded. *Body as a Whole*—Fever, asthenia, fatigue. *Cardiovascular*—Palpitations. *Gastrointestinal*—Nausea, vomiting, abdominal discomfort, anorexia, dry mouth, liver enzyme abnormalities. *Hematologic*—Thrombocytopenia. *Hypersensitivity*—Orbital edema, conjunctival injection. *Musculoskeletal*—Musculoskeletal pain, arthralgia. *Nervous System/Psychiatric*—Paresthesias; grand mal seizures (single report); psychic disturbances including depression, anxiety, decreased libido, hallucinations (single report); insomnia; somnolence. *Respiratory*—Bronchospasm. *Skin*—Alopecia, acne, pruritus, rash, dry skin, flushing. *Special Senses*—Tinnitus, taste disorder.

The adverse reactions reported for PEPCID Tablets may also occur with PEPCID Oral Suspension or PEPCID I.V.; in addition, transient irritation at the injection site has been observed with PEPCID I.V.

Management of Overdosage: There is no experience to date with deliberate overdosage. Up to 640 mg/day have been given to patients with pathological hypersecretory conditions with no serious adverse effects. In the event of overdosage, treatment should be symptomatic and supportive. Unabsorbed material should be removed from the gastrointestinal tract, the patient should be monitored, and supportive therapy should be employed.

Dosage and Administration: ***Duodenal Ulcer:*** The recommended adult oral dosage for active duodenal ulcer is 40 mg h.s.; most patients heal within 4 weeks, and it is rarely necessary to use the full dosage for longer than 6 to 8 weeks. A regimen of 20 mg b.i.d. is also effective. For maintenance therapy, the recommended oral dosage is 20 mg h.s.

Pathological Hypersecretory Conditions (e.g., Zollinger-Ellison Syndrome, Multiple Endocrine Adenomas): The dosage varies with the individual patient; the recommended adult oral starting dosage is 20 mg q6h, but some patients may require a higher starting dosage. Dosages should be adjusted to individual patient needs and continued as long as clinically indicated; up to 160 mg q6h have been administered to some patients with severe Zollinger-Ellison syndrome.

Oral Suspension: The Oral Suspension may be substituted for Tablets for those patients who cannot swallow tablets.

Directions for Preparing PEPCID Oral Suspension: Prepare suspension at time of dispensing. Slowly add 46 mL Purified Water. Shake vigorously for 5-10 seconds immediately after adding the water and immediately before use.

Stability of PEPCID Oral Suspension: Unused constituted oral suspension should be discarded after 30 days.

Intravenous Administration: In some hospitalized patients with pathological hypersecretory conditions or intractable ulcers, or in patients who are unable to take oral medication, the recommended intravenous dosage is 20 mg q12h. For preparation of solutions for injection or infusion and for compatible diluents, please see Prescribing Information. Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Concomitant Use of Antacids: Antacids may be given concomitantly if needed.

Dosage Adjustment for Patients with Severe Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance less than 10 mL/min), the elimination half-life of famotidine may exceed 20 hours, reaching approximately 24 hours in anuric patients. Although no relationship of adverse effects to high plasma levels has been established, to avoid excess accumulation of the drug, the dosage may be reduced to 20 mg h.s. or the dosing interval may be prolonged to 36 to 48 hours as indicated by the patient's clinical response.

How Supplied: Tablets, containing 20 mg or 40 mg famotidine, with hydroxypropyl cellulose, hydroxypropyl methylcellulose, iron oxides, magnesium stearate, microcrystalline cellulose, starch, talc, and titanium dioxide as inactive ingredients, in bottles of 30 and unit-dose packages of 100; Oral Suspension, containing per 5 mL after constitution with 46 mL Purified Water, 40 mg famotidine, with citric acid, flavors, microcrystalline cellulose and carboxymethylcellulose sodium, sucrose, and xanthan gum as inactive ingredients, and sodium benzoate 0.1%, sodium methylparaben 0.1%, and sodium propylparaben 0.02% added as preservatives, in bottles of 400 mg famotidine for constitution; Solution for intravenous injection, containing 10 mg famotidine per mL, with L-aspartic acid 4 mg, mannitol 20 mg, and water for injection q.s. 1 mL as inactive ingredients, and benzyl alcohol 0.9% added as preservative to the multidose vial, as 10x2-mL single-dose vials and as 4-mL vials.

Meet the Challenge With

PIPRACIL® IV/IM

Piperacillin Sodium/Lederle

First Line of Defense

Please see brief summary of prescribing information on next page.

PIPRACIL as Prophylaxis: Unexcelled by Mefoxin®* in Preventing Infection

95% Successful in a Multicenter Clinical Trial[1,a]

Unsurpassed by Mefoxin clinically

Satisfactory response rate[b]	
PIPRACIL	95%
Mefoxin	89%

Postoperative stay[c]	
PIPRACIL	11.0 ± 1.3 days
Mefoxin	11.9 ± 1.9 days

[a] Includes gastrointestinal, biliary tract, and other intra-abdominal surgery.
[b] Satisfactory response: no evidence of bacterial infection within 3 to 10 weeks after the last dose of antibiotic.
[c] Time from administration of the first dose of study medication to time of hospital discharge.

Highly Active Against Important Intra-abdominal Pathogens[2-4]

Percent of strains susceptible *in vitro*[a]			
	PIPRACIL	Mefoxin	Claforan®*
Enterococci[b]	91%	34%	28%
Bacteroides fragilis	92%	84%	58%
Escherichia coli[b]	86%	96%	99%
Pseudomonas aeruginosa[b]	90%	2%	32%

[a] Although a useful guide, *in vitro* activity does not necessarily correlate with clinical response.
[b] Isolated from surgical wounds.

Convenient Dosage Schedule

Intra-abdominal surgical prophylaxis, 2g/dose for four doses[a]

[a] Please see full prescribing information for complete dosage schedule.

Meet the Challenge With PIPRACIL® IV/IM Piperacillin Sodium/Lederle

First Line of Defense

LEDERLE LABORATORIES
A Division of American Cyanamid Company
Wayne, NJ 07470

PIPRACIL®
STERILE PIPERACILLIN SODIUM FOR INTRAVENOUS AND INTRAMUSCULAR USE

A Brief Summary
Consult package insert for full prescribing information.

INDICATIONS AND USAGE: Therapeutic. PIPRACIL is indicated for the treatment of the following serious infections caused by susceptible strains of the designated organisms: Intra-abdominal, urinary tract, gynecologic, lower respiratory tract, skin and skin structure, bone and joint, gonococcal infections, and septicemia.

Prophylaxis. PIPRACIL is also indicated for prophylactic use in surgery including intra-abdominal (gastrointestinal and biliary) procedures, vaginal hysterectomy, and cesarean section.

CONTRAINDICATIONS: A history of allergic reactions to any of the penicillins and/or cephalosporins.

WARNINGS: Serious and occasionally fatal hypersensitivity (anaphylactic) reactions have been reported in patients receiving therapy with penicillins. These reactions are more apt to occur in persons with a history of sensitivity to multiple allergens.

There have been reports of patients with a history of penicillin hypersensitivity who have experienced severe hypersensitivity reactions when treated with a cephalosporin. Before initiating therapy with PIPRACIL® sterile piperacillin sodium, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, and other allergens. If an allergic reaction occurs during therapy with PIPRACIL, the antibiotic should be discontinued. The usual agents (antihistamines, pressor amines, and corticosteroids) should be readily available. SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN AND INTRAVENOUS CORTICOSTEROIDS AND AIRWAY MANAGEMENT INCLUDING INTUBATION SHOULD ALSO BE ADMINISTERED AS NECESSARY.

PRECAUTIONS: General. While PIPRACIL possesses the characteristic low toxicity of the penicillin group of antibiotics, periodic assessment of organ system functions including renal, hepatic, and hematopoietic during prolonged therapy is advisable. Bleeding manifestations have occurred in some patients receiving β-lactam antibiotics including piperacillin. These reactions have sometimes been associated with abnormalities of coagulation tests such as clotting time, platelet aggregation, and prothrombin time and are more likely to occur in patients with renal failure. If bleeding manifestations occur, the antibiotic should be discontinued and appropriate therapy instituted.

The possibility of the emergence of resistant organisms which might cause superinfections should be kept in mind, particularly during prolonged treatment. If this occurs, appropriate measures should be taken.

As with other penicillins, patients may experience neuromuscular excitability or convulsions if higher than recommended doses are given intravenously.

PIPRACIL is a monosodium compound containing 1.85 milliequivalents of Na^+ per gram. This should be considered when treating patients requiring restricted salt intake. Periodic electrolyte determinations should be made in patients with low potassium reserves, and the possibility of hypokalemia should be kept in mind with patients who have potentially low potassium reserves and who are receiving cytotoxic therapy or diuretics.

Antimicrobials used in high doses for short periods to treat gonorrhea may mask or delay the symptoms of incubating syphilis. Therefore, prior to treatment, patients with gonorrhea should also be evaluated for syphilis. Specimens for darkfield examination should be obtained from patients with any suspected primary lesion and serologic tests should be performed. In all cases where concomitant syphilis is suspected, monthly serological tests should be made for a minimum of four months.

As with other semisynthetic penicillins, PIPRACIL therapy has been associated with an increased incidence of fever and rash in cystic fibrosis patients.

Drug Interactions. The mixing of PIPRACIL with an aminoglycoside *in vitro* can result in substantial inactivation of the aminoglycosides.

Pregnancy—Pregnancy Category B. Although reproduction studies in mice and rats performed at doses up to four times the human dose have shown no evidence of impaired fertility or harm to the fetus, safety of PIPRACIL use in pregnant women has not been determined by adequate and well-controlled studies. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. It has been found to cross the placenta in rats.

Nursing Mothers. Caution should be exercised when PIPRACIL is administered to nursing mothers. It is excreted in low concentrations in milk.

Pediatric Use. Dosages for children under the age of 12 have not been established. The safety of PIPRACIL in neonates is not known. In dog neonates dilated renal tubules and peritubular hyalinization occurred following administration of PIPRACIL.

ADVERSE EFFECTS: PIPRACIL is generally well tolerated. The most common adverse reactions have been local in nature, following intravenous or intramuscular injection. The following adverse reactions may occur:

Local Reactions. Thrombophlebitis (4%), pain, erythema, and/or induration at the injection site (2%) and, less frequently, ecchymosis, deep vein thrombosis, hematomas.

Gastrointestinal. Diarrhea and loose stools (2%); less frequently, vomiting, nausea, increases in liver enzymes (LDH, SGOT, SGPT), hyperbilirubinemia, cholestatic hepatitis, bloody diarrhea, and, rarely, pseudomembranous colitis.

Hypersensitivity Reactions. Anaphylactoid Reactions (see WARNINGS). Rash (1%); less frequently, pruritus, vesicular eruptions, positive Coombs tests.

Renal. Elevations of creatinine or BUN and, rarely, interstitial nephritis.

Central Nervous System. Headache, dizziness, fatigue.

Hemic and Lymphatic. Reversible leukopenia, neutropenia, thrombocytopenia, and/or eosinophilia have been reported. As with other β-lactam antibiotics, reversible leukopenia (neutropenia) is more apt to occur in patients receiving prolonged therapy at high dosages or in association with drugs known to cause this reaction.

Serum Electrolytes. Individuals with liver disease, or individuals receiving cytotoxic therapy or diuretics, were reported rarely to demonstrate a decrease in serum potassium concentrations with high doses of piperacillin.

Skeletal. Rarely, prolonged muscle relaxation.

Other. Superinfection, including candidiasis.
Hemorrhagic manifestations.

Estimation of Oxygen Utilization by Dual Oximetry

JUKKA RÄSÄNEN, M.D., JOHN B. DOWNS, M.D., DONALD J. MALEC, PH.D.,
BRYAN DEHAVEN, R.R.T., and PEGGY SEIDMAN, M.D.

Total body oxygen utilization coefficient was estimated using continuous pulse and pulmonary artery oximetry (dual oximetry) in 17 patients with respiratory failure. Change in arterial and mixed venous oxygen saturations was induced by altering airway pressure. Continuous measurement of mixed venous oxygen saturation provided an accurate and linear estimate of oxygen utilization coefficient ($r = -0.92$), the true values being overestimated by 0.05 ± 0.06 (mean ± SD). Addition of pulse oximetry improved the correlation ($r = 0.93$) and decreased the difference between absolute values (0.02 ± 0.06). Oxygen utilization coefficient can be estimated reliably in an online fashion using pulmonary artery oximetry. However, the use of dual oximetry will further improve the estimate.

THE ULTIMATE GOAL of cardiopulmonary support is restoration and maintenance of adequate peripheral tissue oxygenation. However, little attention has been directed to monitoring of oxygen use. Most currently used indices of tissue oxygenation, such as mixed venous oxygen tension, arteriovenous oxygen content difference, and oxygen utilization coefficient, involve a time delay associated with blood sampling and, therefore, do not reveal rapid changes in the patient's physical status. Measurement of mixed venous blood oxyhemoglobin saturation ($S\bar{v}O_2$) with pulmonary artery oximetry recently was shown to correlate well with oxygen use coefficient (O_2UC).[1] The use of $S\bar{v}O_2$ alone to estimate O_2UC requires the assumption that the majority of change in blood oxygen content is reflected by oxyhemoglobin saturation and that arterial blood is fully saturated with oxygen. $S\bar{v}O_2$ is inversely related to O_2UC and represents the fractional amount of oxyhemoglobin that remains after blood has traversed the tissues.

From the Department of Anesthesiology, The Ohio State University College of Medicine, Columbus, Ohio

Assumption of 100% saturation of arterial blood oxyhemoglobin is unnecessary if pulse oximetry is applied. This investigation determines the accuracy with which O_2UC can be estimated using mixed venous oximetry and an oxygen extraction index (O_2EI) obtained by simultaneous pulse and pulmonary artery oximetry (dual oximetry).

Patients and Methods

The study protocol was approved by the Human Subjects Review Committee of the Ohio State University. Informed consent was obtained from the families of 17 patients who were treated in the Surgical Intensive Care Unit. All patients had acute lung injury that responded to alteration of continuous positive airway pressure (CPAP) with a change in SaO_2. No patient was actively bleeding during the study, nor was any patient receiving blood transfusion or rapid fluid infusions. Variables reflecting the cardiopulmonary function of the patients at the time of data collection are summarized in Table 1.

All patients' tracheas had been intubated before the study and they were receiving at least 5 cmH_2O expiratory airway pressure, either with a ventilator or with a venturi powered CPAP apparatus, as part of their treatment. Patients had indwelling arterial catheters for blood sampling and for measurement of systemic blood pressure. A pulmonary artery catheter equipped with a fiberoptic cable (American Edwards Laboratories, Santa Ana, CA) was inserted and connected to a mixed venous saturation monitor (Sat-1, American Edwards Laboratories), which also was used for thermodilution cardiac output measurements. The saturation monitor was calibrated *in vivo* using a technique suggested by the manu-

---

Submitted for publication: February 23, 1987.

TABLE 1. *Variables Reflecting Cardiorespiratory Function in 17 Patients with Respiratory Failure*

Variable	Mean ± SD	Range
CPAP (cmH_2O)	14 ± 5	5–20
F_IO_2	0.38 ± 0.08	0.30–0.60
PaO_2 (mmHg)	78 ± 18	54–114
$PaCO_2$ (mmHg)	37 ± 6	30–50
Qs/Qt (%)	24 ± 10	8–45
pHa	7.42 ± 0.05	7.30–7.52
Cardiac output (L/min)	6.9 ± 2.4	2.7–11.4
$C(a - \bar{v})O_2$ (mL/dL)	4.0 ± 1.3	2.4–6.8
$S\bar{v}O_2$ (%)	69 ± 9	56–83

facturer. A pulse oximeter probe (Nellcor, Inc., Hayward, CA) was attached to the patient's finger.

After instrumentation, CPAP was changed in steps of 2.5 cmH_2O to produce a change in arterial and mixed venous blood oxygen content. Inspired oxygen concentration initially was adjusted to produce arterial blood oxygen saturation between 94 and 96% and was not changed during data collection. After 5 minutes of equilibration at each level of CPAP, cardiac output, heart rate, respiratory rate, pulmonary artery temperature, and oximeter readings were obtained. Immediately after recording the oximetric saturations, arterial and mixed venous blood were sampled. Progressive change in CPAP in a given direction was discontinued if any of the following conditions were met: an SaO_2 less than 90% or greater than 99%, an increase in $PaCO_2$ by 15%, a spontaneous respiratory rate greater than 35 cycles/min, or a decrease in left ventricular stroke volume by 15%. Arterial and mixed venous blood samples were analyzed for blood gases and pH within 5 minutes of sampling. Oxygen saturations and oxygen contents (CaO_2, $C\bar{v}O_2$) were calculated using a computer program.[2] Then, oxygen utilization coefficient was calculated using the formula:

$$O_2UC = CaO_2 - C\bar{v}O_2/CaO_2$$

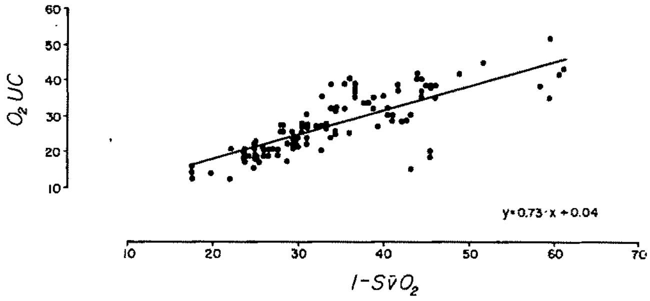

FIG. 1. Relationship between oxygen utilization coefficient (O_2UC) and 1-$S\bar{v}O_2$ in 17 patients with respiratory failure.

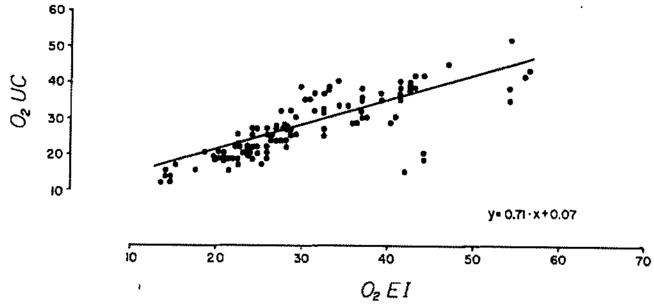

FIG. 2. Relationship between oxygen utilization coefficient (O_2UC) and oxygen extraction index (O_2EI) in 17 patients with respiratory failure.

Oxygen extraction index was calculated from arterial and mixed venous oxygen saturations obtained by dual oximetry using the formula:

$$O_2EI = SaO_2 - S\bar{v}O_2/SaO_2$$

For comparison of O_2EI and SvO_2 as estimates of O_2UC, mixed venous oximetry data were transformed by calculating $1 - S\bar{v}O_2$.

Statistical Analysis

Pearson's correlation coefficients were calculated using a randomly selected value obtained from each patient to assess the intersubject correlations between O_2UC, O_2EI, and $S\bar{v}O_2$. A repeated measures linear regression analysis was used to test how well the relationships between O_2UC and its estimates fit to a linear model.[3] This procedure permits the use of the multiple observations collected for each patient. The logarithm of the distribution function (LogL) was used to assess the relative goodness of fit of the linear relationship between the variables. The larger the value of LogL, the better the fit.[4] Homogeneity of variances was assessed using the Bartlett test.

Results

The study group consisted of 11 men and six women with a mean age of 57 ± 15 years (mean ± SD). Eight patients had acute respiratory failure associated with abdominal sepsis, one had fat embolism syndrome, one had pulmonary contusion, and seven patients had postoperative pulmonary failure without apparent systemic cause. Seven levels of CPAP were studied in 11 patients, six levels in two, five levels in three, and nine levels in one patient, for a total of 113 data points.

The data covered an SaO_2 range from 89 to 99% (95 ± 2%; mean ± SD) and an O_2UC range from 0.13 to 0.54 (0.29 ± 0.09). Correlation between O_2UC and O_2EI was slightly higher ($r = 0.93$; $p < 0.0001$) than that between O_2UC and $1 - S\bar{v}O_2$ ($r = 0.92$; $p < 0.0001$). Both O_2EI (LogL = 293) and $1 - S\bar{v}O_2$ (LogL = 285) fit well to a linear relationship with O_2UC in the repeated measures linear regression analysis (Figs. 1 and 2). The differences between O_2EI and O_2UC averaged 0.02 ±

0.06, while the difference between 1 − $S\bar{v}O_2$ and O_2UC was 0.05 ± 0.06. The difference between 1 − $S\bar{v}O_2$ and O_2EI averaged 0.04 ± 0.02 and ranged from 0.01 to 0.09. It correlated inversely with SaO_2 ($r = -0.90$; $p < 0.0001$). There was a fair correlation between O_2UC and cardiac output ($r = -0.55$; $p < 0.05$) and between O_2UC and tissue oxygen delivery ($r = -0.64$; $p < 0.01$), but no significant correlation between O_2UC and PaO_2, CaO_2, or oxygen consumption.

Discussion

This investigation was designed to determine whether continuous measurement of arterial and mixed venous oxygen saturations would be useful in estimating total body oxygen use. We found that mixed venous oximetry alone provided a clinically useful, linear estimate of O_2UC. The addition of pulse oximetry further improved the accuracy of the estimate.

Since methods that directly measure tissue oxygen dynamics are unavailable for clinical use, changes in oxygen balance must be evaluated from calculations of total body oxygen use. The ratio of oxygen consumption and oxygen delivery, the oxygen utilization coefficient, currently is the most accurate method available for routine assessment of tissue oxygen balance. Alterations in O_2UC reflect changes in both oxygen delivery and oxygen consumption. Therefore, measurement of O_2UC cannot be replaced by separate assessment of oxygen delivery, oxygen consumption, or their components. This fact is reflected in the results of the current study: O_2UC did not correlate well with oxygen delivery or oxygen consumption. Similar results were obtained by Nelson for SvO_2, an estimate of O_2UC.[1]

If arterial blood oxygen content remains constant, change in O_2UC is reflected directly in mixed venous oxygen content. Since oxygen content is determined primarily by oxyhemoglobin saturation, changes in O_2UC also will be reflected by alteration in SvO_2. Nelson found O_2UC to be the variable with which oximetrically measured SvO_2 is related most consistently ($r = -0.92$).[1] Our results show a similar high correlation between O_2UC and $S\bar{v}O_2$ ($r = -0.92$). These results indicate that $S\bar{v}O_2$ can be used to estimate peripheral oxygen use. In addition, it can be measured continuously without blood sampling.

Assumption of constant and complete saturation of arterial blood oxyhemoglobin results in progressive overestimation of O_2UC from SvO_2 as SaO_2 decreases. Therefore, accuracy of estimation of O_2UC will be increased by measuring arterial blood oxyhemoglobin saturation with pulse oximetry, particularly in patients with low and variable SaO_2. In this study, the variation in O_2UC explained by the estimate (r^2) remained similar (84% *vs.* 87%) when pulse oximetry was added, but the difference in absolute values decreased. Use of measured, rather than calculated, saturations could have improved our results slightly. However, the large explained variation (87%) indicates a strong likelihood that calculated saturations were fairly accurate. Certainly they are of greater clinical utility.

Even though pulmonary artery oximetry alone can be used to estimate O_2UC with a small and clinically acceptable error, the noninvasive nature of pulse oximetry warrants the use of dual oximetry for monitoring peripheral oxygen use in most patients who require pulmonary artery oximetry.

Magnetic Resonance Imaging for Detection of Arterial and Venous Occlusion in Canine Muscle Flaps and Bowel Segments

DIANA L. ELIAS, M.D.,* RENDON C. NELSON, M.D.,† MARK D. HERBST, M.D., PH.D.,† and VINCENT N. ZUBOWICZ, M.D.*

Magnetic resonance imaging (MRI) was performed on 16 muscle flaps and eight jejunal segments in dogs to assess its usefulness in detecting vascular occlusion. Arterial or venous occlusion was carried out in 11 muscles and six bowel segments, with the remaining sham flaps serving as controls. Imaging was performed over 2 hours using a spin echo pulse sequence with T2 weighting. Arterial occlusions in muscles resulted in T2 values 15–30% higher than controls, while venous occlusion produced T2 values 55–75% higher than controls. Differences became significant ($p < 0.05$) at 10 minutes after venous occlusion and at 35 minutes after arterial occlusion. Differences between occluded and control bowel segments, although demonstrating a similar trend, failed to reach statistical significance in this preliminary study. The authors conclude that magnetic resonance imaging may be a valuable method for early detection of venous and arterial occlusion in muscle flaps. Further study may also demonstrate this technique to be useful in the diagnosis of ischemic bowel.

FREE TRANSFER OF myocutaneous flaps and jejunal grafts is an integral component in reconstruction of defects caused by trauma, infection, radiation, congenital defects, and radical tumor surgery.[1] The literature reports a failure rate of 5–20% due to thrombosis,[2–4] with successful reexploration in only 50%.[5] This may be due to irreversible cellular damage occurring after approximately 12 hours of ischemia that is referred to as the "no reflow" phenomenon.[4,6–10] No single method of detecting vascular occlusion has gained widespread acceptance, and clinicians rely primarily on visual changes in graft perfusion to assess anastomotic patency. A rapid noninvasive method of confirming a suspected thrombosis is needed.[11]

Magnetic resonance imaging (MRI) measures changes in total water and water distribution in tissues.[12,13] Studies have demonstrated its sensitivity in detecting vascular occlusion in myocardium,[14–17] striated muscle,[11] and renal parenchyma.[18,19]

From the Departments of Surgery and Radiology† at the Emory University School of Medicine, Atlanta, Georgia*

This study was undertaken to evaluate MRI as a means of detecting arterial and venous occlusion in muscle flaps and jejunal grafts.

Materials and Methods

Experimental Preparation

Five mongrel dogs weighing over 30 pounds were anesthetized using sodium pentobarbital (35 mg/kg) and allowed to breathe spontaneously through an endotracheal tube. Gracilis and rectus femoris flaps were developed with isolation of the major vascular pedicle. Two dogs underwent additional celiotomy through a vertical midline incision for isolation of jejunal segments measuring 6–8 cm. A single vascular arcade was isolated and the segments were divided from the adjacent bowel after visual confirmation of adequate perfusion and then placed on the abdominal wall. Baseline imaging was performed on all muscle flaps and bowel loops. Arterial or venous occlusion was carried out in a random fashion, and imaging was repeated at approximate 10–20 minute intervals over 130 minutes. Investigators performing the actual MRI measurements were blinded to the type of occlusion performed. All animals were killed at the end of the study.

Magnetic Resonance Imaging

Magnetic resonance imaging was performed using a Phillips Gyroscan (Phillips Medical Services, Eindhoven, The Netherlands), a 1.5 Tesla superconducting magnet operating at 0.5 Tesla (proton magnetic resonance 21.3 MHz). A spin echo (SE) pulse sequence was used with echo times (TE) of 30 and 60 msec, and repetition time (TR) of 2000 msec. A multislice acquisition

was used with a 5-mm slice thickness at 10-mm intervals. A 256 × 256 matrix was used on the first dog and a 128 × 256 matrix for the succeeding dogs. All images were acquired with the body coil and with two averages. At least three intensity measurements from two echoes were obtained from each muscle flap and bowel segment. T2 values were calculated using the equation:

$$T2 = (t_2 - t_1)/\ln(I_{t_1}/I_{t_2})$$

where t_1 and t_2 represent spin echo times (TE) and I_{t_1} and I_{t_2} represent peak signal intensity at time t.

Statistics

T2 values from all similarly developed flaps were averaged and a standard deviation calculated. Comparison between groups was made with the Student's two-tail t-test. Differences were considered significant if $p < 0.05$.

Results

T2 relaxation times ± SD for control and occluded muscle flaps are shown in Table 1. Measurements taken at time 0 represent baseline values prior to vascular ligation. Average T2 for control muscles over 130 minutes was 38.0 ± 2.0. Arterial ligation produced a 15–30% increase in mean T2 values above controls. This difference was apparent by 10 minutes after occlusion but did not reach statistical significance ($p < 0.05$) until 35 minutes after ligation. Average T2 after 35 minutes was 47.6 ± 2.7. Results of venous occlusion in muscle flaps became significant ($p < 0.05$) by 10 minutes due to markedly elevated T2s. These ranged 55–75% higher than controls. Average T2 after 10 minutes was 63.4 ± 4.7.

Results of arterial and venous ligation in isolated bowel loops are shown in Table 2. Average T2 for controls over 130 minutes was 67.0 ± 6.6. T2 values for arterial and venous occlusion in bowel averaged 78.0 ± 4.3 and 91.1 ± 4.0, respectively. Although a trend was definitely suggested, these data failed to reach statistical significance in this pilot study.

Comparisons of control and occluded muscle flaps and bowel segments are depicted in Figures 1 and 2.

Discussion

Free transfers of muscle for coverage of soft tissue defects, and of jejunum for cervical esophageal replacement are important new advances in plastic surgical technique practiced in most major centers.[1,2,6,20] These procedures are complicated by an overall 5–20% failure rate due to thrombosis,[2–4] with a successful reexploration rate of only 50%.[5] Thrombosis appears to occur within 48 hours of anastomosis[6,9] and revascularization must be performed within 12 hours of occlusion. Delay results in the "no reflow" phenomenon, probably due to irreversible cellular damage.[4,6–10] This may be reflected by decreased ATP and cAMP and increased levels of lactate, as seen in dying skin flaps.[21]

No single technique for detecting early vascular occlusion in flaps has attained widespread acceptance, as

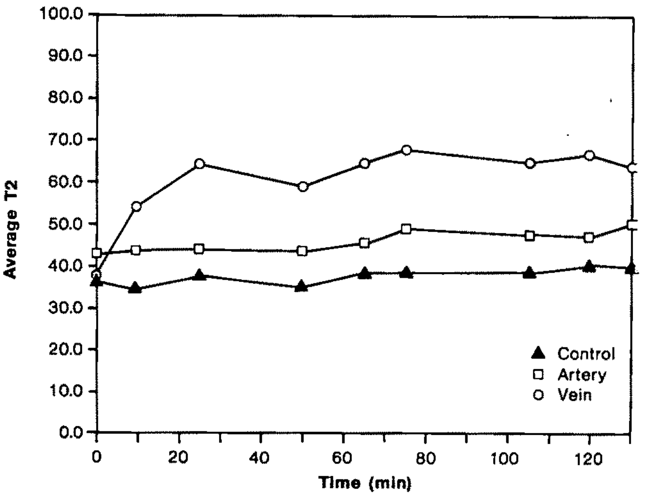

FIG. 1. T2 *versus* time for muscle flaps. Comparison of relaxation times in control and occluded muscle flaps over time. T2 values expressed in msec. Measurements at time 0 represent preligation baseline T2s.

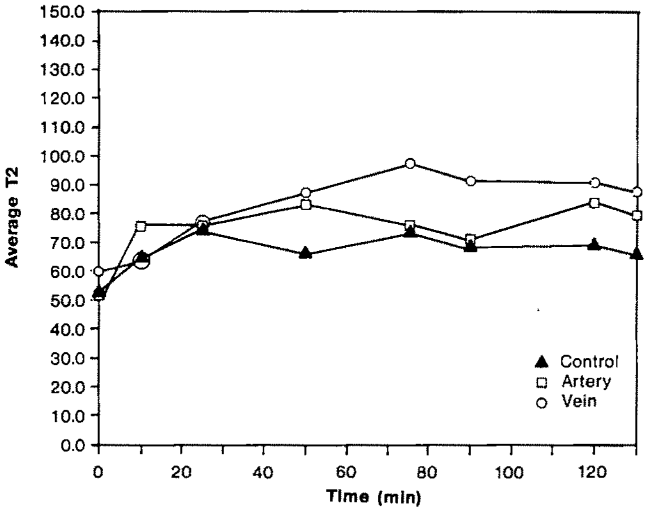

FIG. 2. T2 *versus* time for bowel segments. Comparison of relaxation times in control and occluded bowel segments over time. T2 values expressed in msec. Measurements at time 0 represent preligation baseline T2s.

evidenced by the abundance of publications on this subject. It is generally agreed that the method should be safe, noninvasive, accurate, and simple.[3,9,10,22-25] In addition, the problem of monitoring buried flaps must be addressed.[4,23]

Existing techniques to assess flap viability are based on physiologic or blood flow measurements, yielding either qualitative or quantitative results.

Qualitative methods all measure flap blood flow, either at the pedicle or in the muscle itself. Staining with fluorescein or sulfan blue is unreliable and nonrepeatable.[23,25-27] Stereomicroscopy of surface vessels is impractical and highly subjective.[28] Clearance of radioisotopes is inconsistent, nonrepeatable, and requires radiation exposure.[6,9,23,26] Doppler ultrasound, although promising in some studies, demands precise probe placement directly on the vessels and is not useful in end-to-side anastomoses.[6,9,23,25,26,29,30]

Quantitative methods may measure blood flow or physiologic parameters to assess flap viability. The physiologically oriented techniques include transcutaneous O_2 and CO_2 sensors, surface thermometers, pH monitors, and electrical impulse detectors. Transcutaneous gas sensors have produced inconsistent results and can be associated with burns to the skin. In addition, anesthetic gases may interfere with transcutaneous O_2 readings.[5,6,8,26,31-33] Surface thermometry responds too slowly to changes in perfusion to be clinically useful.[6,23,25] pH probe studies have been encouraging, but results may be misleading due to systemic perfusion alterations.[26,34] Evoked M waves are sensitive indicators of muscle contractility according to one study, but the technique is complex and cumbersome.[4]

Quantitative blood flow measurements are the most accurate methods of flap monitoring. These include reflection photoplethysmography, laser Doppler flowmetry, and electromagnetic flowmetry. Photoplethysmography is only useful in flaps with a skin surface and cannot be used for denuded or buried grafts.[6,9,23,25,26,35] Doppler and electromagnetic flowmeters require precise placement of probes directly on the vascular pedicle and interpretation of complex wave forms.[6,23,25,30,36-38]

All of the methods mentioned have advantages and disadvantages. Shortcomings include inability to monitor buried flaps and difficulty distinguishing arterial from venous occlusion. A method capable of detecting occlusion under these circumstances would be most useful.

Magnetic resonance imaging is a relatively new technique undergoing vigorous investigation in a variety of settings.[11-13,15-19,39] MRI is a form of spectroscopy based on magnetic and spin properties of nuclides. When placed in a magnetic field and pulsed with a specific radiofrequency, these nuclides absorb energy. When the pulse is terminated, the nuclides relax to their ground state. The characteristic relaxation is defined as the average time required for a nuclide to reach its ground state.[11,12,13,40] Hydrogen magnetic resonance has been used extensively to study the "state" of water in living tissues. These molecules exist in bound and unbound fractions, which characteristically relax at different rates, and their ratio is influenced by protein and ion concentrations.[17-19] This technique can therefore be used to study tissue physiology at the molecular level. Several investigators have demonstrated increased relaxation times of hydrogen protons in infarcted skeletal muscle in rats,[11] and infarcted myocardium in dogs that paralleled increases in total water content.[14-17] Recently, MRI methods have been used to detect arterial and venous occlusion in rabbit kidneys.[18,19]

Our study demonstrates an unequivocal increase in relaxation time (T2) with venous occlusion of both muscle and bowel grafts. In contrast, arterial occlusion produced only slight increases in T2. Ischemia, due to arterial or venous occlusion, is known to result in loss of cell membrane integrity with resultant increase in intracellular water and shift in ion concentrations, which produce alterations in the ratio of bound to free water.[7,15-19,41] Venous occlusion also results in a marked increase in the total water content. The latter mechanism is probably responsible for the larger increase in T2 noted in our venous as compared to our arterial occlusions. Intracellular water shifts probably contribute to the increased T2 in our venous occlusions and are most likely responsible for the slight increase in T2 noted in our arterial occlusions. Interestingly, our bowel experiments yielded control values for T2 significantly higher than those in muscle (67.0 *vs.* 38.0 msec). This may reflect an inherent difference in relaxation time of bowel, or may be due to ischemia induced by ligation of adjacent vascular collateral arcades.

This study confirms the ability of MRI to detect venous occlusion. Changes in T2 during arterial occlusion, however, may be too subtle for clinical application. Addition of paramagnetic contrast agents may solve this dilemma. These compounds decrease the relaxation time of water in tissues.[13,17,19] Experiments in rabbit kidneys with infusions of manganese, a paramagnetic ion, have demonstrated no change in T2 values of arterially occluded kidneys, but a significant decrease in T2s of normally perfused kidneys.[19] Use of these paramagnetic ions may enhance detection of arterial occlusion in grafts. Further research in this area is needed.

A Prospective Study of Vein Patch Angioplasty During Carotid Endarterectomy

Three-year Results for 801 Patients and 917 Operations

NORMAN R. HERTZER, M.D., EDWIN G. BEVEN, M.D., PATRICK J. O'HARA, M.D., and LEONARD P. KRAJEWSKI, M.D.

From 1983 through 1985, 801 consecutive patients (mean age: 66 years) underwent 917 primary carotid endarterectomies at the Cleveland Clinic. Conventional arteriotomy closure was performed during 483 operations, while patch angioplasty using a distal segment of saphenous vein was employed in 434. Preoperative risk factors, surgical management, and antiplatelet therapy were equivalent in the vein patch (VP) and nonpatch (NP) groups. Early results were evaluated by intravenous angiography (DSA) in 715 patients (89%), and 332 reconstructions (36%) have been reassessed by objective imaging during a mean follow-up interval of 21 months. Ischemic strokes occurred after 18 (1.9%) of the 917 procedures (0.7% VP, 3.1% NP; $p = 0.0084$), and symptomatic ($N = 9$) or unsuspected ($N = 8$) thrombosis of the internal carotid artery was confirmed by neck exploration or routine DSA after 1.9% of all operations (0.5% VP, 3.1% NP; $p = 0.0027$). Only ten patients (1.2%) have required reoperations for severe recurrent lesions, but the cumulative 3-year incidence of new defects ($\geq$30% stenosis) documented by objective studies in the VP and NP groups was 9% and 31%, respectively ($p = 0.0066$). These results strongly suggest that VP angioplasty enhances the safety and durability of carotid endarterectomy.

CONTROVERSY CONCERNING CEREBROVASCULAR surgery was abruptly intensified in 1985, when the EC/IC Bypass Study Group concluded that medical therapy was as effective as middle cerebral revascularization in the treatment of intracranial arterial disease.[1] In response to this investigation as well as to the fact that carotid endarterectomy has become one of the most common vascular procedures performed in the United States, influential neurologists have suggested that even extracranial reconstruction may no longer be justified outside the framework of prospectively randomized clinical trials.[2-4] Without exception, these criticisms were supported by the high operative stroke and/or death rates reported several years ago by Easton and Sherman[5] in southern Illinois (21%), and more recently by Brott et al.[6,7] in Cincinnati (6.5–9.5%).

Excessive surgical complications obviously have a legitimate influence on medical opinion. For example, Chambers and Norris[4] calculated in 1984 that asymptomatic carotid bifurcation lesions should be corrected only if a subset of patients could be identified in which the annual incidence of stroke without operation was 5% or more. The same authors found in 1986 that the spontaneous risk of severe stenosis (>75% by Doppler ultrasonography) actually exceeded this figure (5.5%), yet they again discouraged elective intervention because four (13%) of the 30 patients in their series who underwent carotid endarterectomy had perioperative strokes.[8] Countless other studies have demonstrated that the composite morbidity and mortality of carotid endarterectomy is less than 3% at many centers, but it is inevitable that the merit of this operation will be open to speculation until its safety is universal.

Dependable technical results are essential to the success of carotid endarterectomy. The bifurcation must be widely patent and relatively resistant to platelet aggregation in order to prevent thrombosis or microembolization, but in each of these respects, routine arteriotomy closure occasionally may be inadequate. Turnipseed et al.[9] and Ortega et al.[10] have documented postoperative internal carotid occlusions in 3–5% of patients evaluated by noninvasive methods, whereas others using intraoperative ultrasound have consistently discovered residual intraluminal defects in 7–8% of their series.[11-13] Early thrombosis has been recognized after approximately 2% of the carotid endarterectomies performed at the Cleveland Clinic, and neurologic deficits occurred with fewer than half of these events.[14,15] In 1983, however, we ini-

tiated a prospective study of vein patch (VP) angioplasty in an attempt to eliminate, if possible, all serious complications of an operation for which perfection appears to be the only acceptable standard. This report is a summary of the first 3 years of our experience with carotid patching.

Materials and Methods

Patch angioplasty previously had been performed on a selective basis in approximately 7% of patients who required carotid endarterectomy at the Cleveland Clinic, but one of us (N.R.H.) decided early in 1983 to apply a routine patch of saphenous vein harvested from the ankle to determine whether this precaution might influence the perioperative complication rate and/or the incidence of recurrent stenosis. Excluding late reoperations and any procedures that were limited to the external carotid artery, 801 patients underwent a total of 917 conventional bifurcation endarterectomies within the subsequent 32 months of the investigation. The remaining authors continued to patch selectively during this time, but Figure 1 illustrates that their preference for primary closure declined throughout the study period. In summary, there were 233 patients (273 operations) in the routine patch group, whereas selective patching was used in another 135 (161 operations). Only 14 entrants (1.7%) received bilateral reconstructions with a patch on one side but not on the other; demographic and survival information for this small subset was included with the non-patched (NP) group (Tables 1 and 4, Fig. 2), but the cumulative neurologic data for these 14 patients were calculated in the VP group as well (Fig. 3).

Patient Information

The VP and NP groups contained 368 and 433 patients, respectively. As indicated by the comparisons in Table 1, these two cohorts had similar clinical features.

Sex and Age

There were 563 men (70%) and 238 women (30%) in the entire series. The men ranged in age from 40 to 84 years (mean: 65 years), whereas the women were 47–87 years of age (mean: 67 years).

Surgical Indications

Unilateral carotid endarterectomy was performed in 685 patients, but 116 (14%) required bilateral procedures during the study period. Previous neurologic events had occurred in 393 patients (49%), including 141 (18%) with completed strokes followed by good functional recovery, 123 (15%) with cortical transient ischemic attacks (TIA), and 129 (16%) with amaurosis

fugax or microembolic retinal infarcts. The remaining 408 patients (51%) had asymptomatic carotid stenosis (N = 385, 48%) or subtotal lesions associated with nonspecific vertebrobasilar symptoms (N = 23, 3%).

Risk Factors and Antiplatelet Therapy

A total of 554 patients (69%) either had hypertension (BP ≥ 180/90 mmHg) or already required antihypertensive management. Diabetes mellitus under treatment with insulin or oral hypoglycemic agents was present in 160 patients (20%). Serum cholesterol values were available for 696 entrants (87%) and ranged from 91 to 995 mg/dL, with a mean of 245 mg/dL (NP, 240 mg/dL; VP, 252 mg/dL). Triglyceride levels were obtained for 206 patients (26%) and ranged from 35 to 4400 mg/dL with a median of 245 mg/dL (NP, 252 mg/dL; VP, 238 mg/dL).

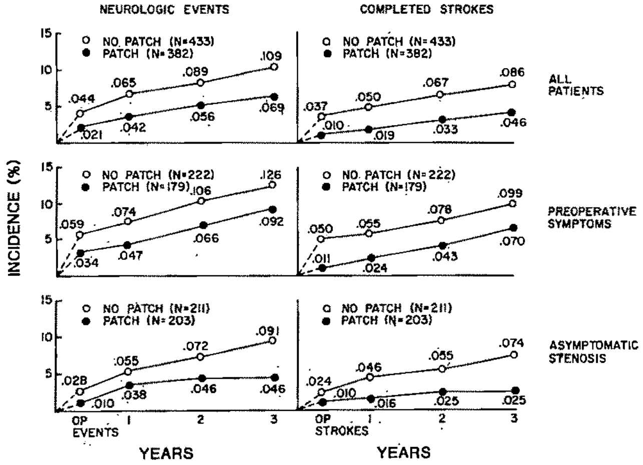

FIG. 3. The cumulative incidence of all ipsilateral neurologic events (left) and completed strokes (right) within the perioperative and late study periods.

Antiplatelet agents (aspirin and/or dipyridamole) were prescribed before surgery for 443 patients (56%), whereas 664 (83%) complied with antiplatelet therapy during the early postoperative course as well as the late follow-up interval. Another 52 patients (6%) received coumadin before their operations, and 27 (3%) have remained on formal anticoagulation after carotid endarterectomy.

Surgical Considerations

All 917 procedures in this series were conducted using general anesthesia, routine carotid shunting, and systemic heparinization that was at least partially reversed with protamine sulfate at the conclusion of each operation. The saphenous patch usually was obtained at the medial malleolus, but it was removed from the upper calf whenever the arterial circulation appeared inadequate to heal a harvesting incision near the foot. There were no wound complications with this approach, and the loss of a segment of vein close to the ankle did not interfere with subsequent *in situ* saphenous grafts in the few patients who already were scheduled for elective lower extremity revascularization at the time their carotid disease was discovered.

The carotid arteriotomy was repaired primarily during 483 operations, whereas patch angioplasty was performed in 434. Additional surgical considerations were comparable in both groups (Table 2).

Associated Procedures

Only nine (1%) of the 917 operations were necessary to correct incidental carotid lesions in patients who originally were evaluated because of other manifestations of peripheral vascular disease. Another 161 procedures (18%), however, were either staged (N = 53, 6%) or combined (N = 108, 12%) with open heart surgery in cardiac patients. Altogether, 122 (26%) of the 464 endarterectomies for asymptomatic carotid stenosis were done in conjunction with myocardial revascularization.

Angiographic Status

Preoperative angiograms demonstrated severe (≥70%) stenosis of the ipsilateral common carotid or internal carotid artery preceding 724 operations (79%). Severe stenosis or occlusion of the contralateral internal carotid was present at the time of 215 procedures (23%), but the incidence of advanced contralateral carotid disease was similar in the VP (25%) and NP cohorts (22%).

Postoperative Assessment

Early technical results were documented by intravenous digital subtraction angiography (DSA) during the same hospital admission in 715 (89%) of the 801 patients. Although 14 operative survivors (1.8%) have been lost, late clinical results were available for the remainder of the series during a maximum follow-up interval of 40 months (mean: 21 months). Within this period, 332 (36%) of the 917 carotid endarterectomies were reassessed by DSA (N = 290, 87%) or Doppler ultrasonography (N = 42, 13%). Long-term objective imaging was obtained for 43% of the VP group and for 30% of the NP group.

Statistical Analysis

Paired data were compared using Fisher's exact test. Life table calculations were performed according to Cutler and Ederer[16] and were evaluated with the method described by Lee and Desu.[17]

Results

Early Results

A summary of perioperative complications for all 917 operations in the series is presented in Table 3.

Operative mortality. Although 14 patients (1.7%) died as the result of cardiac or other peripheral vascular procedures that were performed within the first month after carotid endarterectomy, only four fatal complications (0.5%) were related directly to extracranial reconstruction. Two of these patients (1 VP, 1 NP) had delayed cerebral hemorrhage and another sustained a myocardial infarction following endarterectomy alone. The fourth patient experienced a brainstem stroke during simultaneous coronary and carotid revascularization and eventually developed irreversible multisystem failure. Nevertheless, early mortality was identical irrespective of whether patch angioplasty had been employed.

Ischemic neurologic deficits. Seven transient neurologic deficits (0.8%) were evenly distributed (4 VP, 0.9%; 3 NP, 0.6%) and disappeared completely within hours after recovery from general anesthesia. Ischemic strokes with persistent functional impairment occurred in conjunction with 18 operations (1.9%), and all involved the ipsilateral cerebral hemisphere. The difference between early stroke rates in the VP (0.7%) and NP groups (3.1%) was statistically significant (p = 0.0084).

Internal carotid occlusion. Postendarterectomy thrombosis of the internal carotid artery was documented by immediate neck exploration or angiography in nine of the 15 patients who experienced perioperative strokes in the NP cohort, and all nine of these patients underwent urgent thrombectomy with secondary patch angioplasty. In comparison, symptomatic thrombosis did not occur in the primary patch group (p = 0.0041). Eight other patients (1%) were found to have asymptomatic internal carotid occlusions during routine postoperative DSA studies performed before their discharge from the hospital (2 VP, 0.5%; 6 NP, 1.2%). Thus, a total of 15 early occlusions (3.1%) were associated with standard arteriotomy closure, whereas only two clinically silent events (0.5%) were identified in the patch group (p = 0.0027).

Patch disruption. Semielective evacuation of simple cervical hematomas was necessary after 14 (1.5%) of the 917 procedures (7 VP, 1.6%; 7 NP, 1.4%). Another three patients (0.7%) in the patch group, however, developed acute false aneurysms during the early postoperative period and underwent urgent reoperations to correct this serious complication. One patient was found to have an unexplained rent in the center of the patch and awakened after its replacement with a contralateral monoparesis that resolved within the following week. The remaining two patients had anastomotic disruptions. One was repaired successfully but the other recurred because of infection 1 month later and required carotid ligation. Neither of these patients sustained neurologic deficits.

Clinical Correlations. The risk of early stroke or thrombosis is correlated with selected clinical features in Table 4. The results of patch angioplasty were measurably superior only with respect to the stroke rate among patients with patent contralateral internal carotid arteries (0.3% VP, 3.2% NP; $p = 0.0085$) and the incidence of postendarterectomy occlusion among men (0.4% VP, 4.1% NP; $p = 0.005$). Nevertheless, these data also suggested several other trends even though they could not be fully confirmed by statistical testing. Patch closure was associated with three to five times fewer perioperative strokes in women and in patients with previous neurologic symptoms. Moreover, patching appeared to discourage carotid thrombosis irrespective of whether antiplatelet agents had been administered before surgery ($0.05 < p < 0.1$). Considering all complications (death, stroke, thrombosis, patch disruption) and counting no patient twice, the combined surgical morbidity and mortality rate was 2.4% (9/368) when patches were applied and 6.0% (26/433) when they were not ($p = 0.015$).

Late Results

Survival. Cumulative survival and the number of eligible patients at each follow-up interval are illustrated in Figure 2. A total of 294 entrants were available for consideration during the third postoperative year, and the survival rates for the VP and NP cohorts at the conclusion of the study period were 80 and 87%, respectively. Attrition was comparable among symptomatic and asymptomatic surgical candidates, and none of the actuarial differences was statistically significant. Of 81 late deaths, 28 (35%) were attributed to cardiac disease, 11 (14%) to cancer, and nine (11%) to cerebrovascular events. Fatal strokes have occurred in only 1.1% of each treatment group (4 VP, 5 NP).

Neurologic events. There were 31 perioperative TIAs, strokes or deaths. Of the remaining 770 patients, 42 (5.4%) have experienced subsequent neurologic symptoms involving the ipsilateral (N = 27, 3.5%) or contralateral cerebral hemisphere (N = 15, 1.9%) during a mean follow-up interval of 20 months. Completed strokes have occurred on the same side as previous carotid endarterectomy in 11 (2.7%) of the 412 patients in the NP group and in seven (2.0%) of the 358 who received patch angioplasty. Figure 3 illustrates the cumulative incidence of all ipsilateral neurologic events in the entire series. None of the observed differences was statistically valid beyond the early postoperative period. Therefore, patching did not appear to influence the late stroke rate.

Recurrent stenosis. There were 21 perioperative deaths or internal carotid occlusions. Only ten (1.1%) of the remaining 896 endarterectomies (3 VP, 0.7%; 7 NP, 1.5%) have required reoperations for recurrent stenosis during the follow-up period (Fig. 4). As indicated in Table 5, however, objective reassessment has been obtained for just 332 arteries (37%) despite the fact that all patients were encouraged to schedule annual DSA or Doppler ultrasound examinations for at least 3 years after their original procedures. Recurrent lesions (≥30% of lumen diameter) have been documented with this approach in 4.8% of the VP group and in 14% of the NP group ($p = 0.0137$). Furthermore, the cumulative recurrence rate (Fig. 5) was 9% and 31%, respectively ($p = 0.0066$). The actuarial difference between the VP and NP cohorts (3.7% VP, 39% NP) was especially significant ($p = 0.0019$) when asymptomatic carotid stenosis had been the initial indication for surgical treatment.

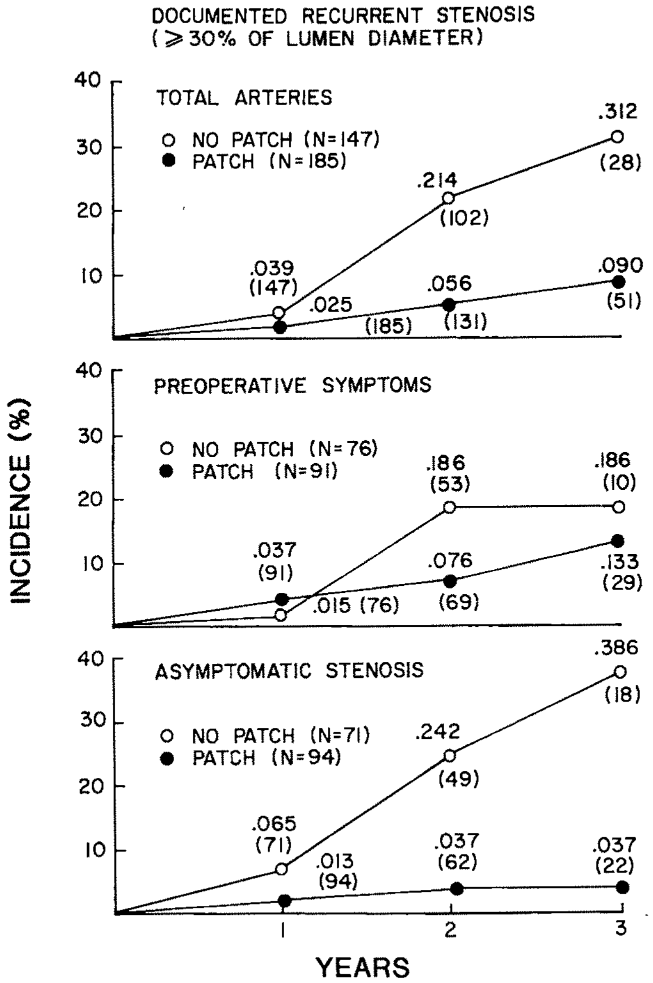

FIG. 5. The cumulative incidence of recurrent lesions (≥30% stenosis) in 332 arteries documented by objective carotid imaging. The number of vessels under consideration at each interval is enclosed in parentheses.

Discussion

Despite lingering controversy concerning its perceived overuse, countless studies have established that carotid endarterectomy is an exceedingly effective approach to stroke prevention in selected patients, provided its immediate risk meets acceptable standards. Previous reports from the Cleveland Clinic indicated that surgical treatment should be a serious consideration for either symptomatic or asymptomatic patients who have severe (≥70%) carotid stenosis or advanced, bilateral bifurcation disease.[18-20] Moore et al.[21,22] have presented similar data, but the fact remains that long-term benefit in appropriate candidates is greatly compromised by excessive complication rates at the centers in which their procedures are to be performed. Since acute or unstable strokes and chronic hemiplegic deficits now are universally accepted as contraindications to surgical intervention, poor results after extracranial reconstruction generally reflect imperfect surgical technique. There is abundant evidence that carotid endarterectomy *can* be done safely, and if surgeons are to respond effectively to their critics, it *must* be done safely.

In addition to reservations about its early risk, there currently is speculation concerning the durability of carotid endarterectomy. Although large, retrospective in-

* Operative deaths and early occlusions have been omitted.

vestigations have suggested that the incidence of recurrent stenosis warranting reoperation is 3% or less, this conclusion necessarily was based on incomplete follow-up and imprecise criteria (new symptoms or cervical bruits) for diagnostic angiography.[23-27] Since the introduction of noninvasive hemodynamic testing and carotid imaging, however, recurrence rates have been reported to be substantially higher than expected in small series of patients who were evaluated prospectively. According to several of these studies, recurrent stenosis exceeding 50% of lumen diameter occurred in 9–19% of patients within 2–5 years after conventional endarterectomy.[28-32] The vast majority of these lesions were caused by myointimal hyperplasia, and this complication appeared to be especially common in women and in cigarette smokers.[33,34] Even if the perioperative risks of carotid endarterectomy were negligible, an unacceptable incidence of early hyperplastic recurrence undoubtedly would be cited as sufficient reason not to correct primary asymptomatic stenosis irrespective of its severity.

Sundt,[35] Imparato,[36] and their associates have long maintained that patch angioplasty was singularly important in the reduction of early morbidity and late recurrence throughout their extensive experience with carotid reconstruction. Archie[37] also found that vein patching eliminated neurologic complications and recurrent hyperplastic stenosis in his series of 200 prospectively randomized operations, and Deriu et al.[38] described similar success with prosthetic patch material following 86 procedures. In our study of over 900 endarterectomies, saphenous patch angioplasty was associated with perioperative strokes in 0.7% and internal carotid thrombosis in 0.5%. In comparison, early strokes ($p = 0.0084$) or occlusions ($p = 0.0027$) each occurred after 3.1% of routine arteriotomy closures. Although their clinical importance is not yet known, recurrent defects were objectively documented in only 4.8% of the patch group during the first 3 postoperative years, compared with 14% of the NP group ($p = 0.0137$).

This investigation has at least two unique features. First, it contains a sufficient number of patients and operations that its conclusions should be reliable. Second, neither treatment cohort was prejudiced by poor results. If VP angioplasty can make good results even better at our center, then it could substantially enhance the mediocre outcome that apparently is encountered at many others. The success of the saphenous patch probably is related to several factors. Clearly, it alters the configuration of the carotid bulb by making it larger.[36] In addition, its intimal surface may prevent early microembolic strokes and carotid thrombosis by discouraging platelet aggregation at the endarterectomy site. Finally, it may reduce the incidence of myointimal hyperplasia by promoting rapid endothelial coverage of the bifurcation.

The adjunctive use of a shunt is a logical consideration simply because patch angioplasty takes more time than primary closure. Accordingly, surgeons who ordinarily prefer not to shunt might choose to restrict patching to specific subsets of patients who seem to have the most to gain from this precaution. Women comprise one such group because of the small size of their carotid arteries and their propensity for hyperplastic recurrence, and patients with contralateral internal carotid occlusions are another because their risk for perioperative stroke is relatively high under any circumstances.[39,40] Whatever the criteria for its use, our experience suggests that patch angioplasty helps to fulfill the high expectations that surgeons, patients, and critics alike have established for carotid endarterectomy: the early results must be perfect, and the late results have to stay that way.

Acknowledgment

B. Michele Melia, Sc.M., Department of Biostatistics and Epidemiology, and Geri Locker, Research Division, performed the statistical analysis. Becky Roberts and Frances Federico assisted in data retrieval and preparation of the manuscript.

Effect of Optimization of Hemodynamics on Fibrinolytic Activity and Antithrombotic Efficacy of External Pneumatic Calf Compression

EDWIN W. SALZMAN, M.D., GERALD P. McMANAMA, M.D., ASCHER H. SHAPIRO, Sc.D., LINDA K. ROBERTSON, R.N., ANN S. DONOVAN, R.N., HOWARD W. BLUME, M.D., JUDY SWEENEY, R.N., ROGER D. KAMM, PH.D., MARK C. JOHNSON, S.M., and PETER McL. BLACK, M.D.

External pneumatic calf compression is effective but imperfect for antithrombotic prophylaxis in surgical patients. In preliminary studies, sequential filling of multisegmented leggings with graded pressure decreasing from ankle to knee increased venous flow velocity and wall shear stress, decreased residual venous volume, and enhanced postoperative fibrinolysis more than uniform compression. To determine if improved hemodynamics also increased antithrombotic activity, we performed a prospective randomized trial in neurosurgical patients comparing sequential application of graded pressure with uniform pressure applied to either a segmented bladder or to a single bladder. Deep vein thrombosis was diagnosed by leg scanning and impedance plethysmography and confirmed by phlebography. Venous thrombosis developed in 3 of 45 patients with graded-sequential filling, 6 of 50 with uniform compression-multiple compartments, and 3 of 41 with uniform pressure single bladder (differences not significant). These results suggest either that uniform compression offers all that can be expected of external pneumatic calf compression in prevention of venous thrombosis, or that even if a study with greater statistical power showed graded-sequential filling to be superior, the benefit/cost ratio of the more complex latter system is not likely to be large.

From the Department of Surgery, Beth Israel Hospital, and the Charles A. Dana Research Laboratories, Harvard Medical School, Boston, Massachusetts, and the Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

ALTHOUGH THE INCIDENCE of deep vein thrombosis in postoperative patients can be reduced by prophylactic administration of antithrombotic drugs, such preventive measures have not been universally adopted into practice. Several surveys[1-3] have reported that many practitioners use prophylactic antithrombotic drugs only in their highest risk patients, if they use them at all. The efficacy of prophylactic administration of anticoagulants and antiplatelet agents is disputed, and is certainly not absolute; failures do occur. The requirement for laboratory control, at least with warfarin, is also a deterrent. The most prominent obstacle to wider adoption of antithrombotic prophylaxis, however, has been the fear of bleeding complications, which inevitably to some degree attend the use of antithrombotic drugs in surgical patients.

An alternative approach, attractive because of its freedom from hemorrhagic side effects, is the use of physical methods to reduce pooling of venous blood in the lower extremities and to increase the velocity of venous blood flow. Such physical techniques include elastic stockings, passive leg exercises, electrical calf stimulation, and external pneumatic compression of the legs. The latter has been most extensively studied and appears to be most effective among the physical methods available.

A substantial literature has developed regarding the use of external pneumatic compression boots or leggings in patients at risk of venous thromboembolism, including patients undergoing neurologic operations,[4-6] urologic surgery,[7,8] general surgical procedures for malignant or benign disease,[9,10] operations for gynecologic malignancy,[11] orthopedic procedures,[12,13] and nonoperative conditions.[14] The mechanism of action of external pneumatic compression in reducing the rate of venous thrombosis in the lower limbs is conjectured to be twofold: a fluid mechanical effect expelling blood from the lower extremities to substitute for the action of the inoperative muscle pump in the recumbent patient, and enhancement of fibrinolytic activity.[15] The relative in-

fluence of these two factors is not certain. External pneumatic compression appears to be associated with no bleeding complications even in patients undergoing extensive surgery.

Although external pneumatic compression of the legs has proven efficacious in reducing the rate of venous thrombosis, there are occasional failures associated with its use, particularly in high risk patients. In our trial of calf compression in neurosurgical patients,[4] for example, 9% of patients who were treated with external pneumatic compression developed deep vein thrombosis (compared with 25% in the control group). As conventionally applied, external pneumatic calf compression may not produce an optimal hemodynamic effect. It is possible that an improvement in the fluid mechanical aspects of the procedure, brought about by modifications in the apparatus, would be reflected in an increase in its antithrombotic effectiveness.

Shapiro and associates have conducted an extensive study of the hydrodynamics of external pneumatic compression, first in theoretical and experimental circulation models[16] and later in human volunteers using gated blood pool scans of the lower extremities.[17] They compared the amount and rate of blood expelled when different modes of intermittent external pneumatic compression were applied to the lower extremities. Scintillation camera imaging of the labelled red cell pool synchronized to the pressurization cycle provided data on the time course of changes in regional blood volumes in the leg. They calculated regional values of the fraction of blood ejected as well as comparative indices proportional to flow rate, blood velocity, and wall shear stress, all of which might reasonably be regarded as figures of merit to be maximized in an attempt to obtain optimal prophylaxis against deep vein thrombosis. Using a four-compartment cuff, they studied compression modes with different intercompartmental pressure gradations and different intercompartmental intervals to the onset of pressurization. The most effective system hemodynamically was found to be a four-compartment legging in which the bladders filled in sequence beginning at the ankle with graded pressures decreasing from ankle to knee. The optimal values for a four-compartment system were approximately 60, 50, 40, and 30 mmHg, decreasing from ankle to knee, with about 0.25 sec between pressurizations of successive segments, a pressure rise time of less than 0.5 sec, each segment held at full pressure for about 10 sec, and a period of about 50 sec with pressure relieved before the next cycle. No commercially available system is hemodynamically optimal or conforms to these features.

We tested the hypothesis that an external pneumatic compression device with these characteristics would improve antithrombotic efficacy in patients undergoing neurosurgical operations, a high-risk group that cannot safely be given antithrombotic drugs because of the hazard of intracranial bleeding complications. A corollary of this hypothesis would be that graded-sequential filling of such a specially designed apparatus would have sufficiently improved antithrombotic properties to justify its increased cost and complexity. We also studied the effect of different modes of calf compression on whole blood fibrinolytic activity to explore further the mechanism of the antithrombotic action of external pneumatic compression.

Methods

The trial was initiated as a two-armed clinical study with randomization afforded by a series of sealed envelopes. Patients were assigned either to receive uniform compression delivered by a four-compartment system applied to the calf (Group II), with all compartments filled simultaneously to the same pressure, or to have sequential filling of the same system from ankle to knee with graduated pressure decreasing from ankle to knee (Group I) according to specifications derived from the studies of Kamm et al.[17] with pressure and timing values as stated above. The apparatus was furnished by Gaymar Industries, Inc., Orchard Park, NY. The four-segment cuffs had "wavy" boundaries between segments, a configuration that effectively eliminated the pooling of blood that, in the scintillation studies of Kamm et al., had been observed to occur between segments of more conventional four-segment cuffs.

The study was conducted in patients undergoing neurosurgical operations at the Beth Israel Hospital. A description of the patient population is presented in Table 1. External pneumatic compression was applied during the induction of anesthesia, except for two patients (1 in Group I and 1 in Group II) in whom confinement to bed before operation suggested the need for earlier prophylaxis. In these cases the external pneumatic compression device was applied as soon as the patient came to the attention of the investigators.

Diagnosis of deep vein thrombosis was made by ^{125}I-fibrinogen scanning,[18] which was begun on the first postoperative day, impedence plethysmography (IPG)[19] every second day, and ascending phlebography by the technique of Rabinov and Paulin[20] in patients who had positive fibrinogen scans or IPGs. In addition, blood was drawn before operation and at intervals in the postoperative period for determination of fibrinolytic activity in heparinized whole blood by a radioactive clot lysis technique modified by Coppe et al.[21] from the method of Moroz.[22] General surgical patients undergoing operations for nonthrombotic conditions were also studied as controls for the fibrinolysis assay. Patients were main-

tained on external pneumatic compression until they became ambulatory or for a maximum of the period spanned by three injections of labelled fibrinogen, roughly 3 weeks.

After 43 patients had been entered into the trial, Group III, receiving uniform compression with a single bladder system (Venodyne, Lyne-Nicholson, Inc.), was added to provide a realistic comparison of graded-sequential filling *versus* a commercially available system having uniform pressurization. The randomization was adjusted to balance the three patient groups. It should be noted that the Venodyne system has a substantially longer pressure rise time than do the other systems studied.

For ethical reasons no unprotected control group was included in this study, which instead compared a technique of established effectiveness *versus* another form of treatment that was potentially superior. This protocol was approved by the Institutional Review Board at the Beth Israel Hospital.

Results

One hundred fifty-eight subjects were enrolled in the study, but 22 were dropped prior to its completion because of nonadherence to the study protocol in 13 patients, including two who refused the procedure because of discomfort, nonoperative therapy (5 patients), or failure of the apparatus (4 patients). Forty-five of the remaining 137 patients were in Group I, 50 in Group II, and 41 in Group III. The surgical procedures, age, sex, and other relevant clinical details are shown in Table 1. The groups appeared to be comparable in all important respects, except that patients in Group I had a somewhat higher prevalence of risk factors for venous thrombosis.

Compression of the limbs is known to enhance systemic fibrinolytic activity, which might augment the antithrombotic action of external pneumatic compression. We studied whole blood fibrinolytic activity in the first 75 patients. A fall in fibrinolytic activity is characteristic of postoperative patients, beginning in the first 24 hours after operation and reaching its nadir by the third postoperative day.[23,24] Such a reduction in fibrinolytic activity was exhibited by the group of general surgical patients studied as controls (Fig. 1; $p < 0.01$ preop *vs.* postop day 1, Friedman's rank sum test). Patients who received external pneumatic compression of the limbs with a uniform compression device, either in Group II or Group III, failed to display this expected fall in fibrinolytic activity in the postoperative period and, in fact, 9 of 16 patients (56%) with the single bladder system and 21 of 35 (60%) with the four-compartment uniform compression system showed an *increase* in the fibrinolytic index on the first postoperative day (Figs. 1 and 2).

Patients in Group I had an average increase in fibrinolytic activity that was significantly greater in magnitude than for those in Groups II and III (mean fibrinolytic index on first postop day 1.45 for graded sequential group *vs.* 1.06 for single bladder system and 1.12 for multiple bladder system with uniform compression; $p < 0.02$ by Dunnett's test or Kruskal-Wallis test), and 23 of 25 patients (92%) with graded sequential filling had a rise in activity. Thus the effect on fibrinolytic activity was correlated with the hemodynamic effectiveness of the external pneumatic compression systems. Patients who failed to be protected by external pneumatic compression, and who developed venous thrombosis despite its use, typically also failed to develop enhanced fibrinolytic activity as a result of the application of external pneumatic compression after operation. Six of the eight such patients whose fibrinolytic index was assessed on the first postop day had values below their group mean (Fig. 2). Patients whose level of fibrinolytic activity was increased did not exhibit any clinically obvious bleeding tendency as a result, but blood loss was not measured and this issue was not rigorously appraised.

The effect of the treatments on the incidence of deep venous thrombosis is shown in Table 2. All patients who developed a positive fibrinogen scan or IPG were requested to have a phlebogram to confirm the diagnosis of venous thrombosis, but five refused. Fifteen patients developed a positive fibrinogen scan; ten of these had a phlebogram, three of which proved to be negative. These three patients are regarded as "false positives," although the positive scan may have been related to venous thrombosis in a muscular tributary of the deep venous system that was not visible on phlebography. For purposes of analysis, "positive" patients are considered to be those who have a positive scan with a positive (confirmatory) phlebogram plus those who had a positive scan but did not have a phlebogram.[4] The results of such an analysis suggest a trend toward a greater antithrombotic effect for graded sequential filling than for the uniform pressure four-compartment system, but no difference from the single bladder uniform compression system. The differences are not statistically significant. The 95% confidence interval for the difference between graded sequential compression and uniform compression with multiple segments is from −16.9% to 6.3%, and for the difference between graded sequential compression and uniform compression with a single bladder it is from −11.4% to 10.2%. The fact that these intervals include zero is consistent with the lack of statistical significance.[25]

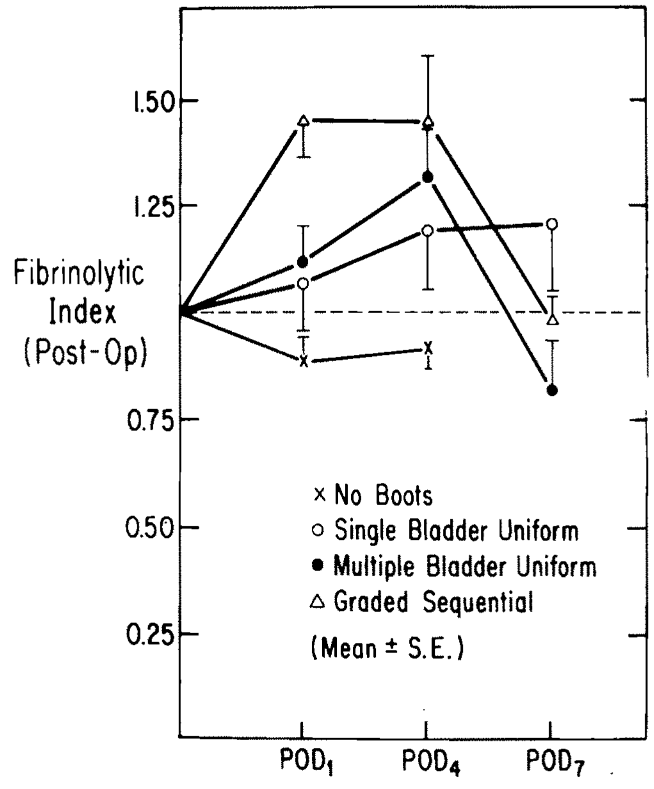

FIG. 1. Fibrinolytic activity in the three patient groups on the first, fourth, and seventh postoperative days. Analogous values are also shown for general surgical patients undergoing operations of comparable severity ("no boots"). Results are expressed as a "fibrinolytic index" (cpm released into supernatant divided by cpm originally contained in radioactive clot) and are normalized to preoperative values for each patient.

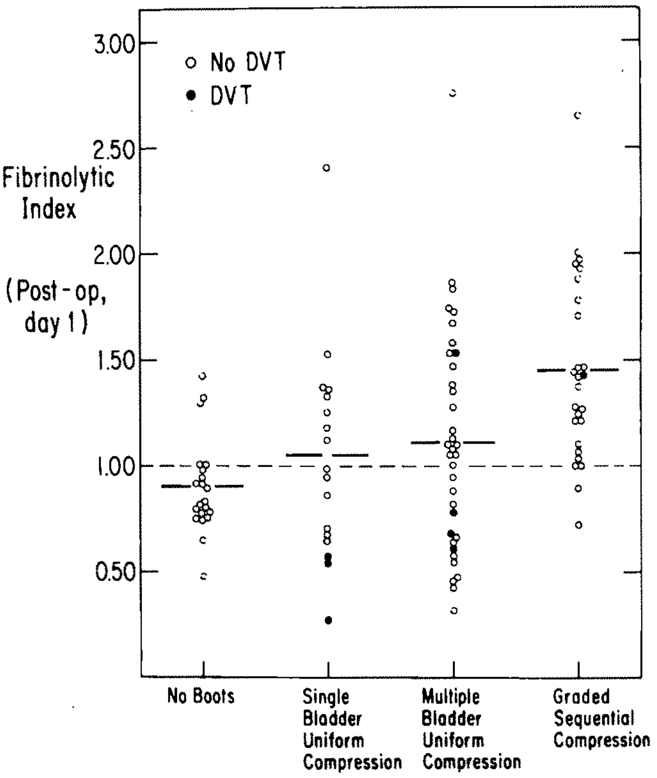

FIG. 2. Fibrinolytic index on the first postoperative day in the four patient groups. Horizontal bars indicate mean values. Closed circles indicate patients who subsequently developed deep vein thrombosis.

The same conclusion will be reached if one considers as "positive" only those patients who had a positive scan with a positive (confirmatory) phlebogram or if one includes as positive all patients with a positive scan regardless of the phlebogram.

We calculated that if the present rate of venous thrombotic complications were maintained, approximately 500 patients in each group would be required to show a statistically significant difference between Group I and the other groups with an alpha error <0.05 and a beta error of 0.20.[26] Because this was considered impractical the study was terminated at this time.

Discussion

External pneumatic compression is an established form of prophylaxis for prevention of venous thrombosis in postoperative patients. The relative importance of enhanced fibrinolysis and of physical dispersion of the components of a thrombus by hemodynamic factors in calf compression is not known. In this study they tended to vary together. The failure of fibrinolytic activity to be enhanced by pneumatic compression in patients who subsequently developed venous thrombosis was predictable. The association of long whole blood clot lysis times with subsequent venous thrombosis in surgical patients

was observed by Comp and associates,[27] and Clayton et al.[28] found low levels of fibrinolytic activity to be a sensitive predictor of venous thrombosis in patients undergoing gynecologic operations.

The evidence for the efficacy of pneumatic compression is persuasive, but calf compression might be even more effective if its hemodynamic effects were optimized. Among the four fluid mechanical parameters influenced by external pneumatic compression (flow velocity, volume flow rate, shear stress, and residual volume of blood in the limbs), it is not yet possible to decide which is most important for antithrombotic effectiveness of the system; however, since under normal circumstances they all tend to vary together, this point may be moot. It is clear that commercially available systems for applying external pneumatic compression to the lower limbs are not optimized in these respects.

We found that a system for external pneumatic compression in which the pressure was applied in a graded fashion, milking the blood from ankle to knee, was more effective hemodynamically, and in the clinical trial it proved to be more effective in enhancement of fibrinolytic activity than uniform compression applied to the leg either in a multiple bladder system or in a single bladder. Nicolaides et al.[29] have previously reported that a multiple bladder system involving sequential filling from ankle to thigh but with uniform pressure was more effective in accelerating femoral venous flow and was superior to a single bladder system in preventing proximal venous thrombosis in patients undergoing abdominal operations; however, there was no significant difference in the rate of calf thrombi. Since the sequentially filled device in their trial had thigh cuffs as well as calf cuffs and the single bladder system had only calf compression, it is not certain that the difference in the frequency of proximal (thigh) thrombi was attributable to the sequential filling. In a subsequent study, Nicolaides et al.[30] compared the sequentially filled device applied for at least 3 days and followed by elastic stockings *versus* electrical calf stimulation *versus* low-dose heparin, and they found the results of external pneumatic compression and heparin to be roughly equivalent. In the system employed by Nicolaides et al., the filling pressures, rise time, duration of filling, and interval beteen successively filled bladders were different from the corresponding values employed in the optimized device we have studied, which is not duplicated by any commercial unit now available.

Despite the improved hemodynamic effectiveness of the graded compression sequentially filled system and the superior biologic effects reflected by enhanced fibrinolytic activity, we were unable to show greater antithrombotic effectiveness for this device. There were no significant differences in the frequency of venous thrombosis in the three patient groups. Two possible explanations are: (1) regardless of the difference in hemodynamic effects, the difference in antithrombotic effectiveness among the three modes of external pneumatic compression is negligible, and the uniform compression system accomplishes all that can be expected of external pneumatic compression in respect to prevention of venous thrombosis, or (2) a real difference exists, with graded sequential compression being superior to uniform compression, but because of the limited number of patients or for other reasons, the study was insufficient in statistical power to show the difference (*i.e.*, there is a possibility of a beta error).[31] Even if the latter is true, however, the difference in efficacy of the three forms of calf compression is probably not large, and one must question whether the increment in clinical benefit would be worth the additional cost and complexity of engineering and producing the graded sequential filling system.

It remains possible that, in a population at even higher risk than the neurosurgical patients (such as those with reconstructive operations on the hip), a hemodynamically superior system applying graded pressure with sequential filling might have demonstrably better antithrombotic efficacy than systems in which fluid mechanical features are not optimized.

Pulmonary Hypertension and Leukosequestration after Lower Torso Ischemia

HAIM ANNER, M.D., RONALD P. KAUFMAN, JR., M.D., LESTER KOBZIK, M.D., C. ROBERT VALERI, M.D.,*
DAVID SHEPRO, PH.D.,† and HERBERT B. HECHTMAN, M.D.

Ischemia stimulates thromboxane (Tx) synthesis. This study tests the hypothesis that the cardiopulmonary dysfunction that may follow aortic declamping is related to Tx. Anesthetized dogs ($N = 15$) were subjected to 4 hours of infrarenal aortic cross-clamping. In untreated control animals ($N = 7$), plasma levels of TxB_2 rose from 654 ± 74 pg/mL to 1238 ± 585 pg/mL at 5 min ($p < 0.05$), and to 3174 ± 912 pg/mL 3 hours after declamping ($p < 0.05$). Mean pulmonary artery pressure (MPAP) rose 5 min after declamping from 13 ± 2 mmHg to 21 ± 2 mmHg ($p < 0.05$). Cardiac Index (CI) declined during ischemia from 181 ± 30 mL/kg · min to 128 ± 16 mL/min · kg ($p < 0.05$), and to 80 ± 8 mL/min · kg after 4 hours of reperfusion ($p < 0.05$). Platelet counts declined but platelets labeled with In-111 did not accumulate in the lungs, whereas quantitative counts of polymorphonuclear leukocytes (PMN) in the lungs 4 hours after declamping yielded 213 ± 33 PMN/25 high power fields (HPF) in dependent areas of the lung and 153 ± 26 PMN/25 HPF in nondependent areas. The wet/dry weight ratio of the lungs was not elevated, although foci of proteinaceous exudate and PMNs in alveoli were noted. Another group of dogs ($N = 8$) were pretreated by random choice with the Tx synthase inhibitor OKY-046 2 mg/kg IV every 2 hours, which led to: lower TxB_2 levels at baseline 95 ± 35 pg/mL ($p < 0.05$), 5 min after ischemia 140 ± 93 pg/mL and after 3 hours of reperfusion 122 ± 36 ($p < 0.05$); lower MPAP, 16 ± 2 mmHg ($p < 0.05$); higher CI throughout ($p < 0.05$); normal histology and reduced pulmonary PMN sequestration both in dependent 127 ± 15 PMN/25 HPF and nondependent areas of the lungs 95 ± 11 PMN/25 HPF ($p < 0.05$). In animals undergoing sham ischemia ($N = 3$), levels of TxB_2 and cardiopulmonary function remained unchanged from baseline. There were 150 PMN/25 HPF in dependent and 85 PMN/25 HPF in nondependent lung areas. The results indicate that ischemia-generated Tx mediates a rise in MPAP, a fall in CI, and PMN entrapment in the lungs.

THE CARDIOPULMONARY DYSFUNCTION that occasionally accompanies abdominal aortic aneurysm surgery is thought to be due to microaggregates released from the ischemic lower torso.[1-3] Experimental work has documented intrapulmonary clot formation as well as platelet and neutrophil accumulations in the lungs following release of an occluding aortic clamp. The associated decline in cardiac output and increase in pulmonary microvascular permeability has been theorized to be related to activation of circulating blood cells (*i.e.*, platelets and polymorphonuclear leukocytes). Products of these cells, such as proteases and oxygen-free radicals, are thought to be the direct mechanism of injury.

Ischemia of a limb is a stimulus to the synthesis of TxA_2.[4] A rise in plasma and hind limb lymph Tx levels were noted during the period of postischemic reperfusion.[5] This vasoactive proaggregatory prostenoid may be partially responsible for the activation and accumulation in the lungs of circulating blood cells. This study was designed to test the thesis that blood cell accumulations in the lungs following lower torso ischemia are related to TxA_2.

Methods

Eighteen female greyhound dogs weighing 22–30 kg were anesthetized with pentobarbital sodium, 15–20 mg/kg IV and paralyzed with 2 mg pancuronium bromide. The dogs were intubated and ventilated with room air at a tidal volume of 15 mL/kg and rate of 12 to

Submitted for publication: March 13, 1987.

15 cycles/minute to achieve an arterial PCO_2 of 30–35 mmHg. The state of anesthesia and paralysis were maintained by a continuous infusion of pentobarbital (0.1 mg/kg • min) and pancuronium (30 μg/kg • min). The animals were placed supine and catheters passed into the aorta *via* the right carotid artery and into the right atrium *via* the right jugular vein. A 7 French thermistor-tipped pulmonary arterial catheter (Electro-Catheter Corp., Rahway, NJ) was introduced through the left jugular vein, and a Foley catheter placed into the urinary bladder.

In 15 dogs the infrarenal aorta was mobilized through a midline laparotomy. All distal branches were ligated and transected, including the internal iliac and the median caudal arteries. The aorta was occluded with a pediatric vascular clamp just below the renal arteries and the abdomen loosely closed. After 4 hours the abdomen was reopened and the aortic clamp removed. Three animals underwent laparotomy without aortic clamping and served as a sham group. Lactated Ringer's solution was administered to maintain a pulmonary arterial wedge pressure of 4 mmHg. External heat was used to stabilize body temperature between 36 to 37 C. Strain gauge transducers (Model D-240, Benley Laboratories, Inc., Irvine, CA) were used to measure the following pressures: mean arterial (MAP), mean pulmonary arterial (MPAP), and pulmonary arterial wedge (PAWP). Cardiac output, determined by thermodilution (Model 801, Instrumentation Laboratory, Lexington, MA) was performed in triplicate and divided by body weight to obtain cardiac index (CI).

Blood gases, pH, oxygen saturation, and hemoglobin of arterial and mixed venous blood were measured with Clark and Severinghaus electrodes and by spectrophotometry using extinction coefficients specific for dog blood (Instrumentation Laboratory, Model 813 and 282). Physiologic shunting ($\dot{Q}S/\dot{Q}T$), the per cent of blood exiting the lungs with the same oxygen content as mixed venous blood, was calculated from the Berggren equation:[6]

$$\frac{\dot{Q}S}{\dot{Q}T} = \frac{CcO_2 - CaO_2}{CcO_2 - C\bar{v}O_2} \times 100$$

where $\dot{Q}S$ is shunt flow, $\dot{Q}T$ is total flow, CaO_2 and $C\bar{v}O_2$ are oxygen contents in arterial (a) and pulmonary arterial ($\bar{v}$) blood. CcO_2 is the oxygen content in capillary blood derived from the alveolar gas equation assuming a respiratory quotient of one. Platelets and leukocytes were counted by means of phase microscopy. Plasma concentrations of thromboxane (Tx) B_2 and 6-keto-$PGF_{1\alpha}$, the stable hydrolysis products of TxA_2 and prostacyclin, respectively, were measured by use of a double antibody radioimmunoassay.[7–9] Blood was drawn into tubes containing ethylene diamine tetracetic acid (EDTA) anticoagulant and aspirin. The blood was centrifuged at 1500 × g for 20 minutes and the plasma separated and stored at −20 C until assayed.

To assess pulmonary entrapment of circulating blood cells, surface counting of In-111-labeled autologous platelets was done in three animals while quantitative histology was done to assess leukocyte sequestration. White blood cell separation and labeling was not done because of our past experience, which indicated that the method itself would activate these cells and lead to their pulmonary entrapment. Just after anesthesia, 200 mL blood was drawn in acid-citrate dextrose solution and replaced with 300 mL of Ringer's Lactate. Platelet concentrates were isolated from the blood in a 22 C refrigerated centrifuge (International Equipment Co, Needham Heights, MA). The blood was spun at 3200 × g for 4 minutes. Platelet-rich plasma (PRP) was removed and the concentrated red blood cells were returned to the animal. The PRP was centrifuged at 5500 × g for 5 minutes and the supernatant decanted. The PRP was washed with 100 mL of 0.9% sodium chloride, spun, and after the supernatant was decanted, 50 mL of 0.9% sodium chloride was used to resuspend the platelets. One mCi of In-111-oxine (New England Nuclear, Boston, MA) was added and, after a 30-minute incubation in a 37 C water bath, the platelets were washed and resuspended in 50 mL of platelet-poor plasma prior to transfusion.

In order to minimize entrapment in the surgical wound, the labeled platelets were infused following the operative procedure, which was 10 minutes prior to aortic clamping. One-inch collimated sodium iodide crystals were mounted over both lung fields as well as the upper and lower extremities. Location of the external detectors was maintained constant throughout the experiment. Counts were collected 10 minutes after platelet infusion, just prior to arotic clamping, and thereafter at 30-minute intervals.

Animals were pretreated with saline placebo (N = 7) or the Tx synthase inhibitor OKY-046 2 mg/kg (N = 8) IV, every 2 hours, starting 30 minutes prior to surgery. Sham animals (N = 3) were treated with saline. Monitoring was continued for 8 hours, that is 4 hours of aortic clamping and 4 hours of reperfusion. The dogs were then killed with an overdose of IV potassium. The lower lobe of one lung was removed and the wet to dry ratio of the bloodless lung determined. Gluteraldehyde introduced *via* the endotracheal tube was then used to inflate the lungs for 20 minutes at a constant pressure equivalent to a 25-cm column of water. The trachea was then ligated and the lungs removed and bathed in gluteraldehyde for 24 hours. Specimens of lung were taken from dependent (posterior) and nondependent (anterior) regions. After hematoxilin and eosin staining, polymor-

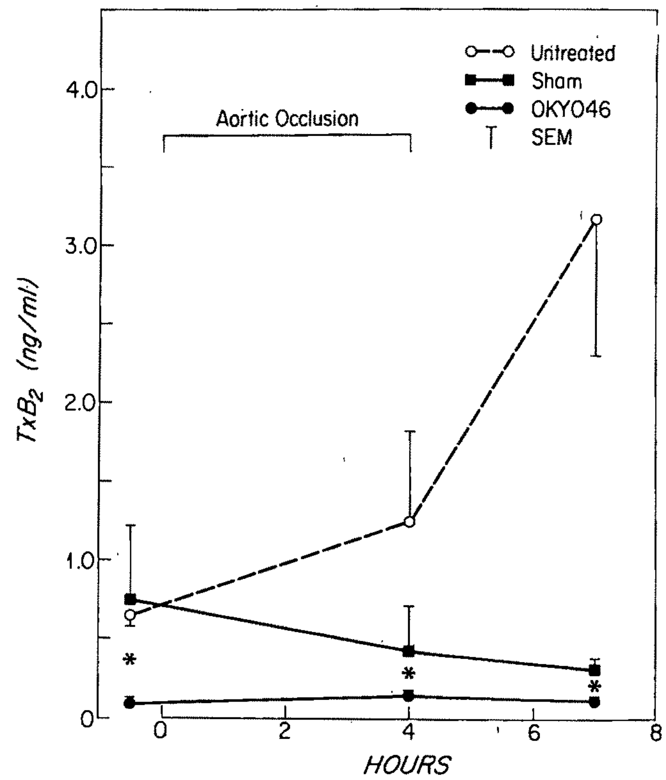

FIG. 1. Four hours of infrarenal aortic occlusion led to a rise in plasma TxB_2 5 minutes after clamp release. Synthesis of Tx was most prominent later during reperfusion. Pretreatment with OKY-046 prevented TxB_2 synthesis. Asterisks refer to significant differences between OKY-046 and placebo-treated groups.

phonuclear leukocytes (PMN) were counted in 25 high powered fields (HPF) from each region. All data are presented in text and figures as mean ± standard error. Statistics are based on a two-way analysis of variance, paired and nonpaired t-test. Significance was accepted if $p < 0.05$.

Animals used in this study were maintained in accordance with the guidelines of the Committee on Animals of the Harvard Medical School and those prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animals Resources, National Research Council (DHEW publication No. (NIH) 78-23, revised 1978).

Results

Aortic cross-clamping in placebo-treated animals resulted in a rise of TxB2 levels in mixed venous blood from a baseline level of 654 ± 74 pg/mL to 1238 ± 585 pg/mL ($p < 0.05$) at 5 minutes and 3174 ± 912 pg/mL after 3 hours of reperfusion ($p < 0.05$) (Fig. 1). Mean pulmonary arterial pressure rose from a value of 13 ± 2 mmHg prior to ischemia to 21 ± 2 mmHg, 5 minutes after reperfusion ($p < 0.05$). Ninty minutes after reperfusion, MPAP levels had returned to baseline (Fig. 2). The CI declined from 181 ± 30 mL/kg • min at baseline to 128 ± 16 mL/min • kg ($p < 0.05$) at the end of ischemia and to 80 ± 30 mL/min • kg ($p < 0.05$) at the end of the 8-hour monitoring period (Fig. 3). Pulmonary arterial wedge pressure was maintained at baseline levels of 4 mmHg. Physiologic shunt remained unchanged from a baseline value of 5 ± 1%.

The platelet count fell progressively from 133,000 ± 11,000/mm^3 to 93,000 ± 14,000/mm^3 after 4 hours of ischemia and to 38,000 ± 13,000/mm^3 after 4 hours of reperfusion ($p < 0.05$) (Fig. 4). There was no change in In-111 activity in the lungs or legs. The wet/dry weight ratio of the lungs was 5.32 ± 0.12, a value similar to the sham group 5.59. Light microscopy of the lungs revealed accumulations of PMNs throughout the lung paren-

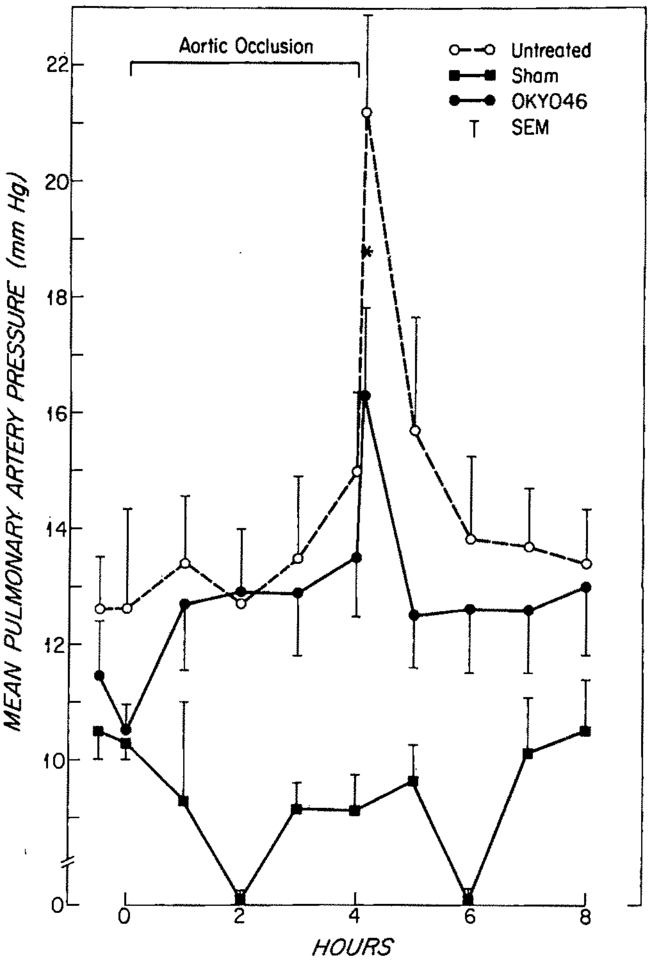

FIG. 2. Release of the aortic clamp led to an immediate rise in MPAP in untreated animals. This increase was blunted by pretreatment with OKY-046. Asterisks (*) refers to significant differences between placebo and OKY-046-treated groups.

chyma (Fig. 5A). Platelet microaggregates were not seen and there was no evidence of vascular congestion. While most leukocytes were seen within vessels, foci of PMNs along with a proteinaceous exudate were present within alveoli. Quantitative PMN counts were 213 ± 34 PMN/25 HPF in dependent and 153 ± 27 PMN/25 HPF in nondependent lung regions (Fig. 6). In contrast, the lungs of sham animals had 100 PMN/25 HPF in dependent and 85 PMN/25 HPF in nondependent regions.

Pretreatment with the Tx inhibitor OKY-046 led to baseline plasma TxB_2 levels of 95 ± 35 pg/mL, a value lower than placebo-treated dogs ($p < 0.05$). In this group there was no ischemia-induced increase in plasma TxB_2 concentration (Fig. 1). The small rise in MPAP from 13 ± 1 mmHg at baseline to 16 ± 2 mmHg after 5 minutes of reperfusion was in contrast to the placebo-treated animals ($p < 0.05$) (Fig. 2). Further, OKY-046 pretreatment led to a higher CI than in the placebo group throughout the 8 hours of monitoring, 216 ± 32 mL/min • kg after 4 hours of ischemia ($p < 0.05$), and 133 ± 40 mL/min • kg ($p < 0.05$) after 4 hours of reperfusion (Fig. 3).

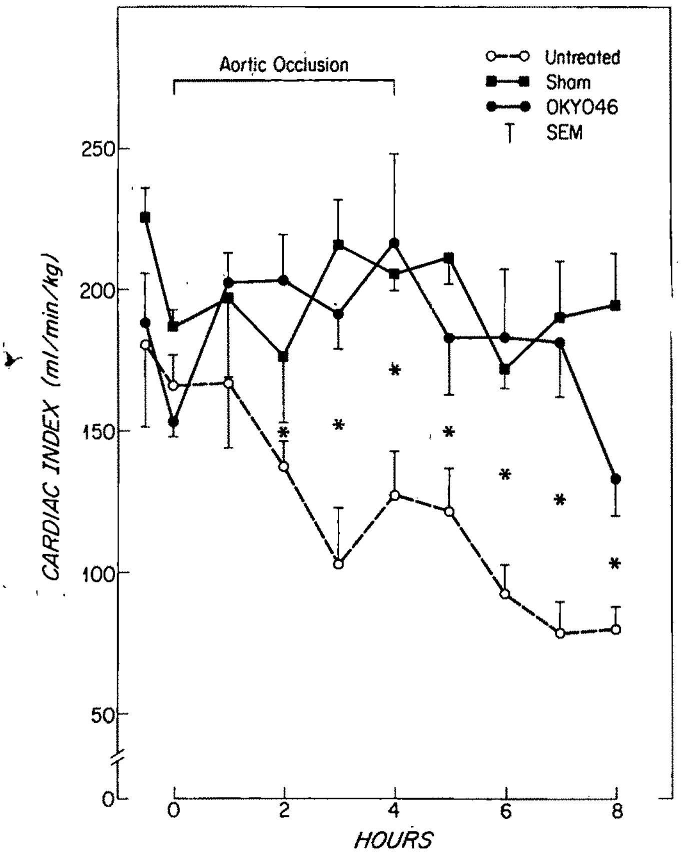

FIG. 3. Cardiac index declined in untreated relative to OKY-046–treated animals. Asterisks (*) refer to significant differences between placebo and OKY-046 treated groups.

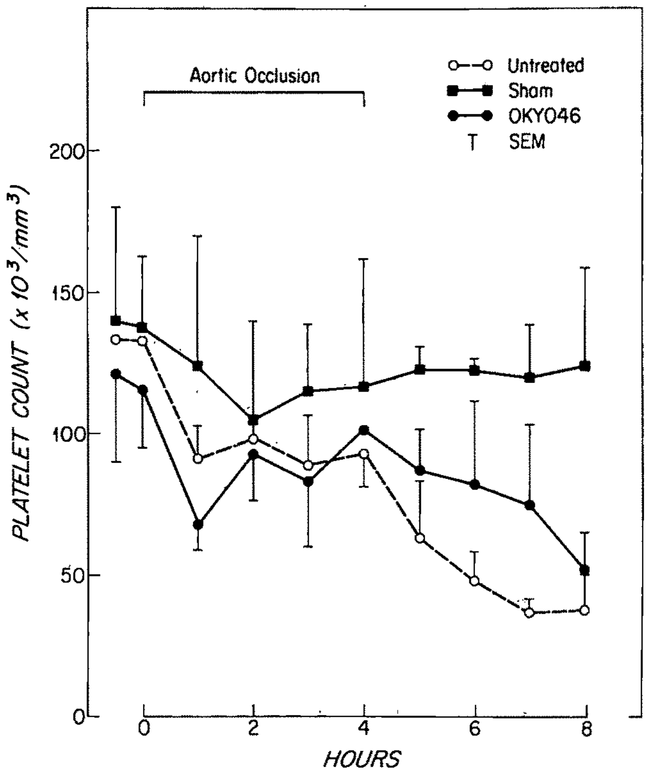

FIG. 4. Platelet counts fell both in untreated and OKY-046–treated groups.

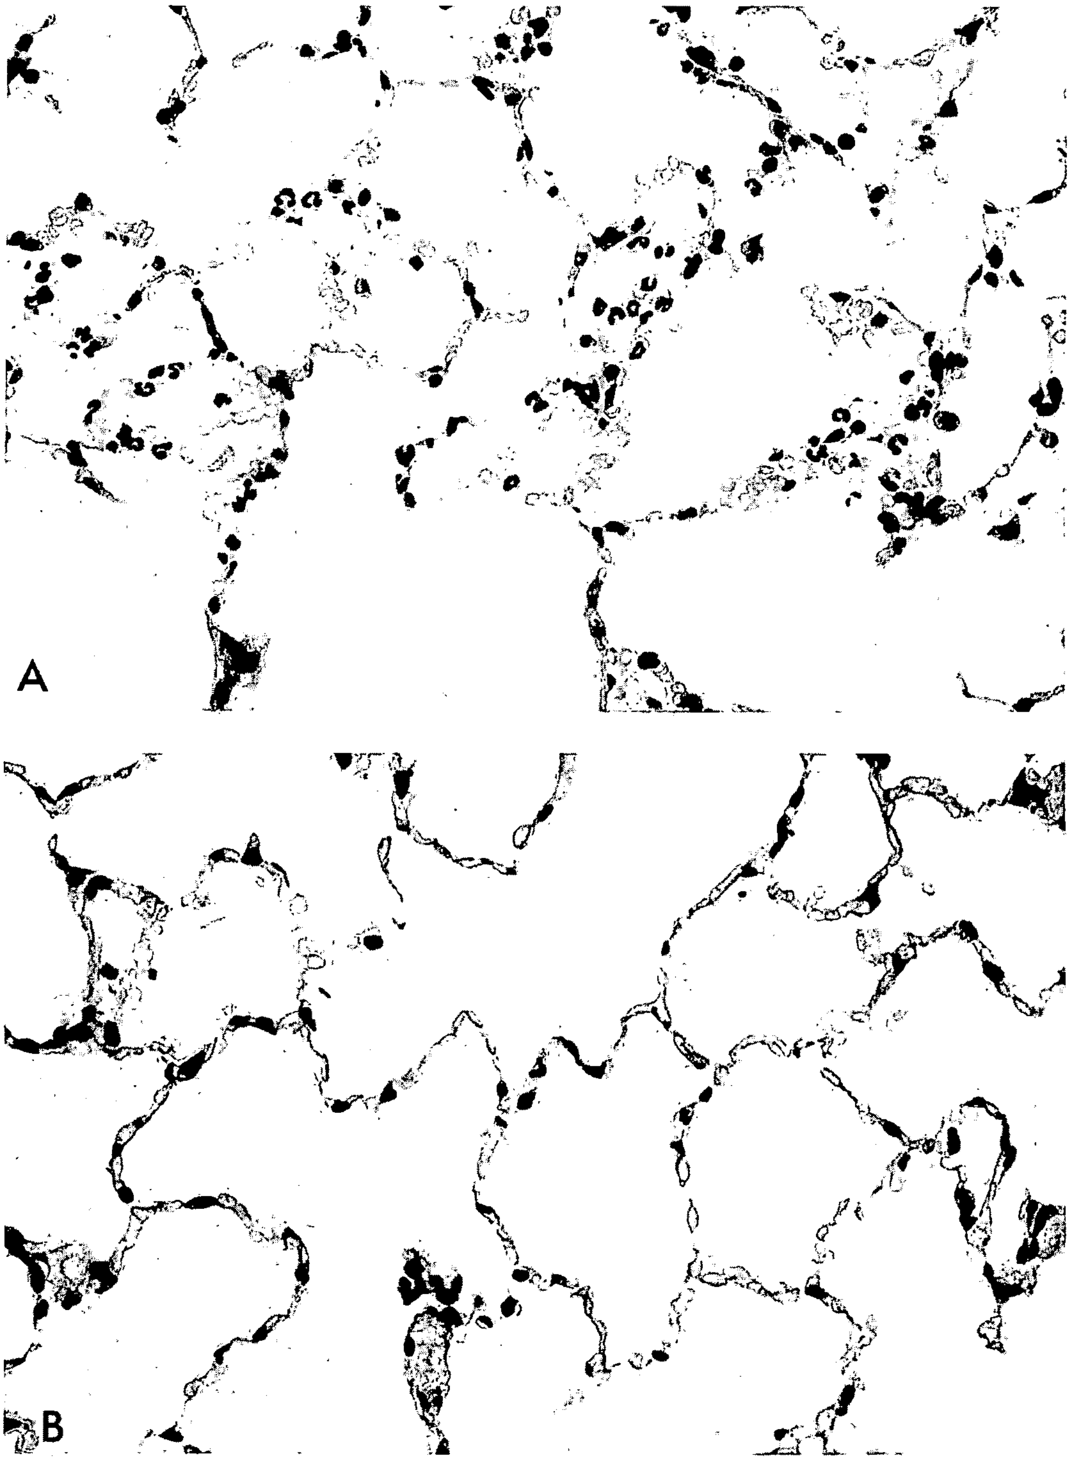
There were no pathologic changes on microscopic examination in OKY-046 pretreatment animals (Fig. 5B). Pulmonary leukocyte counts were lower than placebo-treated animals 127 ± 15 PMN/25 HPF in dependent areas of the lung ($p < 0.05$) and 95 ± 11 PMN/25 HPF in nondependent areas ($p < 0.05$) (Fig. 6). The decline in circulating platelet counts was similar to untreated animals, 121,000 ± 22,000/mm^3 at the end of the ischemic period and 51,000 ± 14,000/mm^3 after 4 hours of reperfusion. Physiologic shunt was unchanged from 6 ± 2% at baseline. Ratio of wet to dry lung weight was 5.36 ± 0.09.

Discussion

Four hours of infrarenal aortic clamping led to a rise in levels of plasma TxB_2 beginning 5 minutes after clamp release but becoming most prominent after 3 hours of reperfusion (Fig. 1). On the other hand, the increase in MPAP occurred just after release of the aortic clamp and was restored to baseline after 3 hours of reperfusion (Fig. 2). The fact that inhibition of Tx synthesis significantly limited the pulmonary hypertension



FIGS. 5A and B. Placebo-treated animals (*A*) showed accumulations of PMNs in capillary beds throughout the lung parenchyma. Most neutrophils were within vessels, but in other fields foci of inflammatory cells and proteinaceous exudate within alveolar air spaces were also present. Pretreatment with OKY-046 led to normal histology without PMN accumulations (*B*).

strongly suggests a direct pulmonary arterial constrictive effect of TxA_2. The observation at 3 hours of reperfusion in saline-treated animals that plasma TxB_2 concentrations continued to rise while MPAP fell does not negate the role of TxA_2. A changing and more remote site of TxA_2 synthesis, an agent with a 30-second half-life, could have altered its biological effect.

Depression of cardiac function has been associated with Tx synthesis.[10-12] The mechanism appears to be indirect. A circulating agent in plasma that depresses contractility of a papillary muscle has been shown to be generated as a consequence of Tx synthesis.[4] The ability to prevent the appearance of this circulating negative inotrope and maintain CI has been described in patients treated with cyclooxygenase inhibitors undergoing abdominal aortic aneurysmectomy. The present data confirm the relationship between the synthesis of Tx and depression of cardiac output.

The consequences of lower torso ischemia are not only pulmonary hypertension and depression of cardiac function but also acute respiratory failure. The original hypothesis proposed to explain pulmonary dysfunction involved the release of microemboli from the ischemic lower extremities.[1-3] Our inability to find evidence of pulmonary platelet sequestration either by In-111 labelling or by microscopy does not confirm this original thesis. In other settings where platelet microemboli were believed to play pathophysiologic roles such as hemorrhagic shock, current evidence also denies their importance.[13]

Leukocyte entrapment in the lungs does not appear to be the result of platelet-neutrophil microembolization. If microaggregates accumulated in the lungs and were dependent on Tx synthesis, this would be at variance with the facts that the observed thrombocytopenia was neither related to platelet sequestration in the lungs nor to Tx synthesis. Thromboxane generation in the lower torso should not be selective in causing PMN and not platelet aggregation and mechanical entrapment in the pulmonary microcirculation.

A more attractive postulate to explain PMN accumulations in the lungs is that TxA_2 acts uniquely with respect to PMN in promoting chemoattraction. Classic chemattractants such as leukotriene (LT) B_4 or complement fragment C5a could be released from the lower torso and stimulate leukocytes as well as lung endothelium to synthesize TxA_2. Such chemoattractants, when applied to endothelium grown in culture, will stimulate Tx synthesis.[14] Further, other work has shown that LTB_4 or C5a can cause PMN accumulations by means of a Tx pathway.[15] One hypothesis to explain PMN accumulations in the lungs is that an agent released from the ischemic lower torso leads to Tx synthesis by leukocytes as well as the pulmonary microvasculature which in return results in endothelial-PMN adherence. A second postulate is that TxA_2 directly influences endothelial cell gap junctions by varying stress fiber assembly. Agents such as Tx that decrease the number of actin cables lead to a widening of interendothelial junctions, thereby allowing increased diapedesis of PMN.[16]

The observation that more PMNs are sequestered in dependent than in nondependent lung regions is likely to be a consequence of the gravitational distribution of blood flow, which favors dependent regions (Fig. 6). The putative circulating mediators that determine pulmonary PMN sequestration are also likely to be distributed to the lungs with regard to blood flow distribution.

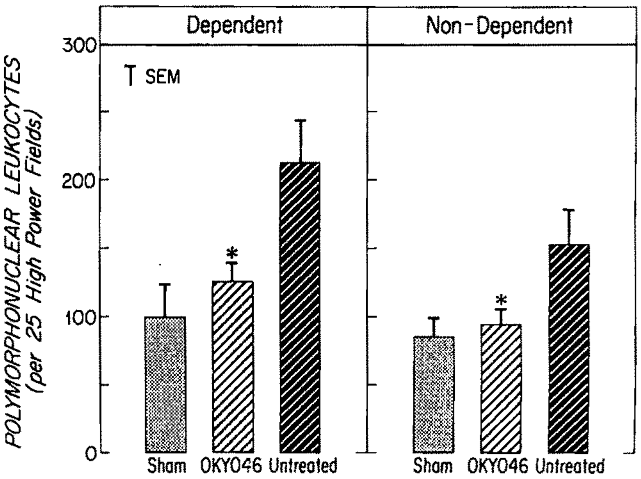


FIG. 6. Leukocytes were unevenly distributed throughout the lung. Increased PMN counts were found in the higher flow-dependent areas compared to the lower flow nondependent areas both in untreated and OKY-046-treated animals. Asterisks indicate significant differences between placebo- and OKY-046-treated groups.

Although pulmonary edema was not documented by an increase in the wet/dry weight ratio of the lungs, there was histologic evidence of early microvascular injury manifest by foci of proteinaceous exudates in alveoli containing inflammatory cells (Fig. 5). These changes were not severe and therefore the maintenance of a low physiologic shunt was not surprising. It is possible that the pulmonary injury would have worsened with time and the passage of more PMNs into the extravascular spaces. It is generally believed that PMNs are the responsible agents for most varieties of acute respiratory failure.[16,17]

In summary, lower torso ischemia led to the generation of TxA_2 which is responsible for the pulmonary hypertension, cardiac depression, and pulmonary PMN accumulations noted following aortic clamp release and reperfusion.

The Selective Use of Antilymphocyte Serum for Cyclosporine Treated Patients with Renal Allograft Dysfunction

FRANCIS L. DELMONICO, M.D., HUGH AUCHINCLOSS, JR., M.D., ROBERT H. RUBIN, M.D., PAUL S. RUSSELL, M.D.,
NINA TOLKOFF-RUBIN, M.D., LESLIE T. FANG, M.D., and A. BENEDICT COSIMI, M.D.

Eighty-seven adult renal allograft recipients were initially treated with cyclosporine-prednisone immunosuppression. Thirty patients experienced no episode of rejection. Antilymphocyte antibody therapy (ALS) was administered to 21 of the 68 recipients of cadaveric donor allografts for either primary allograft dysfunction or acute rejection, and to 6 of 19 recipients of haploidentical, living-related allografts because of steroid-resistant rejection. The cumulative allograft and patient survival for the entire series (follow-up 9–36 months) was 84% and 95%, respectively. This improvement in the rate of successful transplantation can be attributed to the selective addition of ALS therapy to recipients with specific instances of renal allograft dysfunction. In this report, the indications for the use of ALS preparations following prophylactic CsA immunosuppression are reviewed. Experience with the protocols of the ALS administration is also discussed. In selected cases, the administration of either ATG or OKT3 can significantly benefit CsA recipients who experience either primary allograft nonfunction or an epidose of acute rejection.

From the Transplantation Unit of the General Surgical Services, Massachusetts General Hospital, and the Departments of Surgery and Medicine, Harvard Medical School, Boston, Massachusetts

DESPITE THE IMPROVEMENT in renal allograft survival in patients receiving cyclosporine (CsA) immunosuppression, a significant proportion of these recipients still experience rejection episodes, some of which are unresponsive to high-dosage steroids. This is reflected in the current survival statistics, which note a first-year renal allograft loss of approximately 25 to 30% in several CsA multicenter trials.[1–3] At least half of these allograft losses were due to rejection. Whereas the role of additional immunosuppressive therapy such as antilymphocyte serum (ALS) has been well defined for patients receiving azathioprine-prednisone immunosuppression, its proper use in CsA-treated patients has been less certain. Early reports of experimental trials using CsA in combination with ALS in nonhuman primates suggested that unacceptable complications might be experienced in patients receiving CsA and ALS concomitantly.[4] Thus, clinicians have been appropriately cautious about administering CsA and ALS in a combined regimen.

During the past 3 years, CsA has been routinely administered at the Massachusetts General Hospital as the primary immunosuppressive medication for recipients of both cadaveric donor (CD) and haploidentical living-related donor (LRD) renal allografts. Our experience has suggested that the rate of successful renal transplantation reported in the above noted multicenter trials can be improved even further by adding ATG or OKT3 antilymphocyte preparations to CsA protocols for selected instances of renal dysfunction. This report details our experience with the administration of antilymphocyte antibody preparations in CsA-treated renal allograft recipients and our current recommendations for their use in these patients.

Methods

Between January 1984 and April 30, 1986, 87 consecutive adult renal allograft recipients were treated with CsA-prednisone immunosuppression (Table 1). Sixty-eight patients were recipients of CD allografts and 18 received haploidentical LRD allografts. One HLA-identical LRD recipient was treated with CsA-prednisone because he had received a second renal allograft. One patient suffered loss of a CD allograft because of a donor-transmitted bacteroides infection. This patient was included in the statistical failures of CD allografts. No patient was excluded from this retrospective review.

Submitted for publication: January 12, 1987.

TABLE 1. *Characteristics of 87 Consecutive Adult Renal Allograft Recipients*

	LRD	CD
Donor	19	68
Primary transplant	18	60
Secondary transplant	1	8 (10%)
Diabetics	4	9 (15%)
>50 years age	2	21 (26%)
>50% sensitized	—	26 (38%)
+ Historical crossmatch	—	6

The patient population of this series included diabetics (15%), highly sensitized individuals (38%), recipients over age 50 (26%), and recipients who had previously rejected a primary allograft (10%) (Table 1).

The oral preparation of CsA was administered on a twice daily schedule. The first 40 patients were treated with an initial dosage of 15–17 mg/kg/day. Subsequently the starting dosage has been reduced to 12 mg/kg/day. No patient received intravenous CsA. The CsA dosage was gradually tapered, usually beginning on the 6th or 7th post-transplant day, in an attempt to maintain a plasma level of 50–100 ng/mL measured by radioimmunoassay. The CsA-Radioimmunoassay kit was provided by Sandoz Pharmaceuticals, Basle, Switzerland, for the determination of CsA plasma levels twice weekly.

All recipients were treated with the following steroid protocol administered as prednisone orally or methylprednisolone intravenously. An initial divided dose of 200 mg was given on the day of renal transplantation. The daily dosage was then reduced by 40-mg decrements to 20 mg/day by the 5th day following transplantation. Prednisone dosage was tapered to 15 mg/day approximately 6 weeks following transplantation.

Protocol for Renal Allograft with Primary Function Followed by Acute Rejection

When rejection was suspected, the patient was initially treated with intravenous methylprednisolone (500 mg). The CsA dosage was reduced concomitantly if the plasma CsA level was greater than 150 ng/mL. If the creatinine continued to rise after 48 hours, despite a second pulse of steroids, a percutaneous biopsy was performed. The features of acute rejection associated with CsA immunosuppression have been detailed.[5] The most consistent finding of rejection is not only the presence of mononuclear cells within allograft interstitium, but the penetration of lymphocytes into and through vessel walls with some being characteristically attached to the arteriole endothelium. This finding of endothelialitis is the signal feature that distinguishes rejection from CsA nephrotoxicity.[5]

Biopsy confirmation of persistent rejection (that is failure to improve or reverse with at least two doses of methylprednisolone) prompted the initiation of antilymphocyte antibody therapy. Either OKT3 5 mg/day (Orthoclone, Ortho Pharmaceutical Company, Raritan, New Jersey) was administered *via* a peripheral vein for 10 consecutive days, or ATG 15 mg/kg/day (ATGAM, Upjohn Company, Kalamazoo, Michigan) was administered through a central vein or A-V fistula for 10–14 days. In the initial seven CsA patients treated with OKT3, and CsA dosage was maintained at the pre-OKT3 dose throughout the course of OKT3 treatment. However, in more recent patients, the CsA dosage was reduced to 2–3 mg/kg/day during OKT3 therapy. Following completion of OKT3 treatment the CsA dose was increased to 4–6 mg/kg/day. In all of these patients with "steroid-resistant" rejection, azathioprine (2 mg/kg/day) was begun on the 7th day of OKT3 treatment and continued indefinitely. Subsequent rejection episodes following withdrawal of OKT3 therapy were treated initially with methylprednisolone (500 mg IV). If biopsy-confirmed rejection failed to reverse after 2 bolus doses, ATG was then administered daily for 10–14 days. During ATG therapy, CsA dosage was reduced to 2–3 mg/kg/day and azathioprine was reduced to 25–50 mg/day. Allograft failure was defined as return to dialysis or patient death.

Protocol for Renal Allograft with Primary Dysfunction

The CsA dose was reduced to 6–8 mg/kg/day for the first 3 days following transplantation. Patients whose allograft function recovered sufficiently to allow withdrawal of dialysis by this time were then treated as outlined in Figure 1. ATG was added only if dialysis was required beyond this period. Azathioprine (2 mg/kg/day) was substituted for CsA during the period of ATG administration. When diuresis (greater than 1000 mL/day) and a falling creatinine allowed withdrawal of dialysis support, ATG was discontinued and CsA was resumed at a reduced dose (4–6 mg/kg/day). Azathioprine was not discontinued in these patients who then were maintained on triple drug therapy.

Protocol for Conversion of CsA to Azathioprine in Long-term Patients

At 6–12 months following transplantation, recipients of renal allografts during 1985–1986 with stable allograft function were randomized to either CsA withdrawal or to triple drug therapy. Azathioprine (2 mg/kg/day) was added to the regimen of all patients not yet receiving the drug for 1 week without altering the CsA dose. During the subsequent week the CsA dosage was decreased by 50%. CsA was then either discontinued (in half of the patients) or it was continued at the reduced level (in the other randomized half). No changes were made in the prednisone dose during or following CsA alteration.

Results

Comparison to a group of renal allograft recipients treated previously in this unit with azathioprine, prednisone, and ALS immunosuppression emphasizes the improvement that has been achieved with the CsA therapeutic protocols. The actual 1-year survival for 64 recipients of CD renal allografts treated during 1982 and 1983 (prior to CsA availability) was 65%. In contrast, the actual allograft survival is 85% (Table 3) for the 60 CsA-treated CD renal allograft recipients who have been followed for at least 12 months following transplantation. With a follow-up of 9–36 months, the cumulative allograft survival for the entire series of 87 patients is 84% (73/87). Nine allografts were lost to rejection, one was lost to donor bacteroides infection, and four others have been lost at the time of patient death. The etiology for the four patient deaths was as follows: viral pneumonia (6 months), a preforated peptic ulcer (12 months), amyloid hepatic failure (18 months), and a myocardial infarction (27 months).

Despite the excellent long-term prognosis for CsA-treated patients, acute rejection episodes were diagnosed in 45 of 68 CD recipients and 12 of 19 LRD recipients. These usually occurred during the first month following transplantation, after which documented episodes of rejection were infrequent. All rejection episodes were initially treated with additional doses of Solu-medrol®. However, 14 CD allograft recipients and six LRD recipients (35%) subsequently required antilymphocyte antibody treatment for steroid-resistant rejection. Seventeen of these patients had biopsy-confirmed rejection. CsA toxicity was excluded in each of these patients. Fourteen of this group received OKT3; the remainder received ATG. Although the rejection episode for which ALS was added was reversed in each of these patients, 12 of them developed later rejection episodes. In nine patients the subsequent episode of rejection was irreversible despite high-dosage steroids and/or further ATG therapy. Four of this refractory group were recipients of OKT3 who were subsequently treated with a 7–10—day course of ATG. No patient received two courses of OKT3 therapy. Nevertheless, the kidneys of 11 of these 20 patients were salvaged by antilymphocyte therapy, thus reducing in half the allograft loss to steroid-resistant rejection. Six of these patients are currently on triple drug therapy initiated after ALS treatment.

In the initial seven CsA-treated patients given OKT3 for acute rejection, the CsA dose was intentionally maintained at the pre-OKT3 level in order to exclude the possibility that subsequent improvement in allograft function might have resulted from manipulation of CsA levels. Six of these patients had rejection confirmed by biopsy. No CsA toxicity was evident. Although all patients responded to OKT3 treatment, the mean creatinine at completion of OKT3 therapy was 2.5 mg/dL. In contrast, in our previous experience with OKT3 therapy in azathioprine-treated patients we had routinely achieved a creatinine of less than 1.5 mg/dL. This observation has led us to conclude that occult CsA nephrotoxicity may irreversibly injure the allograft during periods of serious rejection. Therefore, we currently withdraw CsA during ALS treatment for severe rejection (Fig. 1).

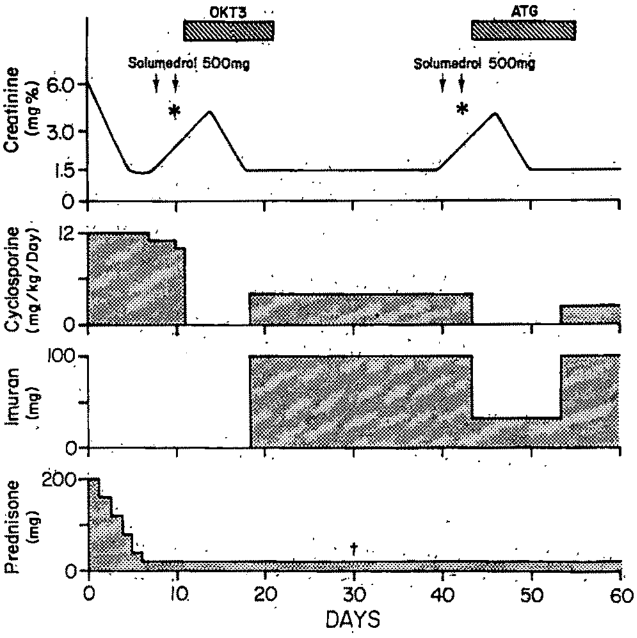

FIG. 1. Current therapeutic plan for patients with renal allograft with primary function followed by acute rejection. *Renal allograft biopsy; †patients with stable renal function and no episode of rejection would reduce their prednisone dose to 15 mg/day at 4–6 weeks following transplantation.

The incidence of early renal dysfunction requiring dialysis in CD allograft recipients in this series was 14.7% (10/68). All of these allografts recovered satisfactory function by 14 days following transplantation. In five patients CsA was discontinued between 3 to 12 days following transplantation (Table 2). ATG was administered daily during this period (8–14 doses). In the other five patients CsA was continued at a reduced dose (6 mg/kg/day), with two also receiving ATG during the first 2 weeks following transplantation. Although several of these patients were either highly sensitized or the recipients of a second allograft, no evidence of hyperacute or accelerated rejection was implicated in the initial episode of dysfunction. No recipients of LRD allografts

Cumulative allograft survival (9–36 m)	16/19 (84.2%)	57/68 (83.8%)

required hemodialysis because of primary allograft dysfunction.

Withdrawal of CsA was attempted in 40 recipients with stable renal function for at least 6 months following transplantation. Twenty-five of these patients (allograft recipients during 1984) had undergone CsA withdrawal prior to the randomized study. Since 1985, 15 patients have randomized to CsA withdrawal. Thirteen of the total group of 40 patients (32.5%) developed acute rejection beginning between 2 weeks and 6 months following CsA withdrawal. Treatment with intravenous methylprednisolone (500 mg) in all patients plus resumption of CsA (11/13) successfully reversed these late rejection episodes. Nevertheless, one patient died of complications related to a perforated peptic ulcer that developed in association with the increased steroid dosages. Since 1985, 14 other recipients were randomized to triple drug therapy as described in the Methods section. One of these patients required OKT3 treatment of acute rejection 3 months following the addition of azathioprine. None of the other triple drug patients has experienced an episode of rejection.

Discussion

Disagreement persists among transplant groups as to what role antilymphocyte antibody therapy should play in the immunosuppressive protocols of CsA-treated allograft recipients.[6] Recommendations range from proposals that ALS be given to every patient[7,8] to the caution that the two agents may produce overimmunosuppression if used together.[9] Our observations in 87 consecutive adult renal allograft recipients have led us to a selective approach with which the obvious benefits of ALS therapy are achieved, but which exposes only about 30% of patients to possible complications of an admittedly more intensive regimen. Thus, on the basis of this experience, we recommend the following ALS protocols (detailed in Fig. 1 and Table 3) for the CsA-treated patient: (1) ATG or ALG should be given and CsA discontinued in patients whose primary allograft dysfunction persists beyond 3 days; (2) OKT3 therapy should be reserved for primary episodes of acute rejection that are unresponsive to at least two boluses of IV methylprednisolone; (3) ATG may be employed for subsequent episodes of rejection that may occur following OKT3 withdrawal; and (4) the CsA dosage should be greatly reduced or even discontinued during periods of ALS therapy. These protocols of immunosuppression more precisely define the indications for ALS administration following CsA treatment and the appropriate use of currently available monoclonal and polyclonal preparations. Not all renal allograft recipients with primary allograft dysfunction or acute allograft rejection require ALS treatment. Approximately 70% of the renal allograft recipients in this series had uncomplicated postoperative courses and were successfully managed with CsA-steroid immunosuppression alone. This level of success is similar to the survival rates reported previously in multicenter trials.[1–3] With the selective addition of ALS therapy to the immunosuppressive protocols of the remaining subsets of patients (70% of patients with primary allograft dysfunction and 33% of patients with steroid-resistant rejection), we have achieved further improvement in allograft survival.

We have used ATG for prophylactic immunosuppression if necessary during early periods of allograft dys-

TABLE 3. *Current Protocol for Renal Allograft Recipients with Primary Dysfunction*

Day	Dialysis	CsA Dose (mg/kg/day)	Prednisone	ATG	Imuran (mg)

4	+	0	40	15 mg/kg/day	25–50
5–14	+	0	20	+	25–50
	–	4–6	20	–	75–100

function and reserved the use of OKT3 for episodes of steroid-resistant rejection, since many patients develop anti-idiotypic antibodies following initial treatment with OKT3.[10] The recommendation to withhold ATG or ALG for 72 hours following transplantation is based on our observation that 30% of patients who experienced primary dysfunction regained satisfactory function without ATG. Our approach has been to reduce the CsA dose for the first 3 days of dysfunction. If dialysis is still necessary at this time, the CsA is discontinued and ATG is begun (Table 3). Continuing CsA at reduced dosages for 72 hours has had no apparent adverse effect on the eventual resumption of allograft function, providing that CsA plasma levels were maintained in therapeutic range. Only five of the ten patients with primary dysfunction in this series had their CsA discontinued, and all of these allografts resumed function by 12 days following transplantation.

Because of the increased risk of nephrotoxicity and untoward hemodynamic effects following IV administration of CsA,[11] we do not use the parenteral preparation for renal allograft recipients. All patients, including diabetics, children, and even recipients who have undergone simultaneous bilateral nephrectomy, have been able to tolerate the oral preparation within 12 hours of operation.

In CsA-treated patients whose allografts function well immediately following transplantation, we have observed that the serum creatinine generally plateaus between 1.5 and 2.5 mg/dL at 7–10 days. In most patients persistent tapering of the CsA dose to maintain plasma levels of no greater than 150 ng/mL is required to achieve this level of function. In some patients significant nephrotoxicity is still encountered despite plasma levels in the 50–150 ng/mL range, and further reduction in CsA dosages is mandated, particularly if there are other signs of CsA toxicity such as hypertension and hyperkalemia (coincident with satisfactory urine output).

Subsequent deterioration in renal function usually indicates rejection. However, if the CsA level is greater than 150 ng/mL, the dosage is reduced further and, as noted in our rejection protocol (Fig. 1), a single dose of methylprednisolone has generally been administered. Continuing deterioration in renal function despite these measures necessitates a second bolus of IV methylprednisolone and usually a renal allograft biopsy. We have used the determination of acute rejection by biopsy and the failure to respond to bolus doses of methylprednisolone as the indication for administration of OKT3.

Thus far, all of the CsA-treated patients who have received OKT3 for a primary episode of rejection have experienced successful reversal. Although OKT3 therapy is as effective in CsA-treated patients as in those receiving azathioprine, CsA toxicity appears to exacerbate the dysfunction associated with a rejection episode. This became apparent in our first seven OKT3-treated patients in whom the CsA dosage was deliberately maintained at the prerejection level. Despite improvement in allograft function following OKT3 treatment, the serum creatinine fell only to a mean of 2.5 mg/dL, suggesting unremitting CsA toxicity. Our current approach is to discontinue CsA during OKT3 treatment (Fig. 1) as we rely on the OKT3 and a modest dose of prednisone to achieve sufficient immunosuppression. This policy is designed to avoid the long-term renal damage that we now suspect develops when rejection occurs in patients who simultaneously suffer from CsA nephrotoxicity. Thistlethwaite and colleagues have also considered that CsA nephrotoxicity may occur in some of their OKT3-treated patients, and they too have adopted a protocol involving CsA omission during OKT3 therapy.[12]

The addition of azathioprine at 7 days following the onset of OKT3 therapy is intended to reduce recurrent episodes of rejection in the CsA recipients who have already manifested steroid-resistant rejection. Subsequent rejection episodes in OKT3-treated recipients are initially treated with increased steroids. If continued evidence of biopsy-confirmed rejection is observed, ATG therapy is instituted. ATG rather than OKT3 has been selected in this circumstance because host anti-idiotypic antibodies to the OKT3 molecule, which often develop within 10 days of the initial OKT3 administration, neutralize the effective use of the monoclonal antibody.[10] However, if ATG has been administered for the primary episode of acute rejection, OKT3 may be given for the treatment of a subsequent rejection episode.

Similar to the experience of Morris and Tilney,[13,14] approximately 30% of our recipients were noted to have an episode of rejection following attempted withdrawal of CsA in the late post-transplant period, even though renal function had been stable for at least 6 months. Furthermore, we have noted that rejection can occur several months following CsA withdrawal, when one might have considered the patient to be beyond jeopardy. Treatment has routinely consisted of methylprednisolone and the necessity for ALS treatment has been rare. However, most of these patients have resumed CsA treatment indefinitely. We are currently conducting a randomized trial to determine whether it is more beneficial to remain on triple drug therapy *versus* attempting to withdraw CsA. Although the triple drug patients in this series have initially experienced less rejection following randomization, we are continuing the study because the long-term outcome of CsA therapy is unknown and the financial burden of CsA for many of our patients remains significant.

In our experience, the risk of infection following the concomitant administration of ATG to CsA-treated patients and the sequential administration of ATG and OKT3 to only a selected group of CsA patients has been minimal. As suggested by the 96% patient survival rate at 1 year, the 87 patients in this series experienced no increased risk of viral or opportunistic infection when compared to renal allograft recipients receiving azathioprine-prednisone-ALS immunosuppression.[15] We attribute this low incidence of infection to the markedly reduced daily dose of prednisone and the reduced dose of CsA that has been administered prophylactically and during ALS treatment. We have previously reported that ALS therapy can be used safely and effectively provided the dosage of other immunosuppressive medications is reduced during the period of ALS treatment.[16]

Alleviation of Cyclosporine Nephrotoxicity with Verapamil and ATP-$MgCl_2$

Mitochondrial Respiratory and Calcium Studies

Although recent studies have shown that combined treatment with verapamil and ATP-$MgCl_2$ (ATP) prevents cyclosporine (CyA)-induced nephrotoxicity, the mechanism of these effects remains unknown. To study this, rat kidneys were perfused at 100 mmHg for 100 minutes with Krebs buffer containing 7.5 g/dL of albumin and substrates. After an equilibration period of 30 minutes, 500 ng/mL CyA was added. In some experiments 1 μg/mL verapamil was added 10 minutes prior to CyA and in others 2 mM ATP was added to CyA. At the end of the perfusion, cortical mitochondria (mito) were isolated and mito Ca^{2+} and Mg^{2+} (μmoles/g protein) and respiratory control ratios (RCR) were measured. In addition, total tissue Ca^{2+} and Mg^{2+} levels were measured. The results indicate that CyA treatment leads to an accumulation of mito Ca^{2+} and a decrease in ADP/O ratio. Simultaneous administration of ATP with CyA led to an increased mito Ca^{2+} accumulation and depressed RCR, which were corrected by verapamil pretreatment. The combination of verapamil pretreatment and ATP cotreatment with CyA increased tissue ATP levels from 0.8 ± 0.4 (control) to 1.4 ± 0.1 μmol/g. This pharmacologic regimen may prevent CyA-induced nephrotoxicity by preventing mito Ca^{2+} accumulation and by preserving mitochondrial respiratory function. This allows a more efficient generation of ATP and consequently preservation of renal function.

CYCLOSPORINE (CYA) IS A potent inhibitor of lymphokine generation by T-helper cells that allows the survival of allografts without significant myelotoxicity. The main side effect, which limits the usefulness of CyA, has been the drug-induced nephrotoxicity that occurs frequently and is often difficult to distinguish from allograft rejection. The main impetus by researchers in this field has been twofold: (1) to develop a reliable animal model by which to analyze the pathophysiology of CyA nephrotoxicity under controlled and reproducible conditions, and (2) to use the model to investigate the effectiveness of combination pharmacologic drug regimens on the alleviation of renal dysfunction associated with cyclosporine.

We have recently reported[1,2] on a model of CyA nephrotoxicity using an isolated, perfused rat kidney preparation. Addition of CyA to the perfusing solution resulted in oliguria, a reduction in glomerular filtration rate and renal perfusate flow, and impairment of tubular reabsorption of protein, salt, and water compared to the CyA-vehicle-only control group. These early studies also demonstrated that pretreatment with verapamil, a calcium channel antagonist, and cotreatment with ATP-$MgCl_2$ could significantly reduce the nephrotoxic potential of CyA.

The aim of this study was to examine the morphology and mitochondrial function of these CyA-treated kidneys in an attempt to further characterize this acute, *in vitro* model of CyA nephrotoxicity and to study possible mechanisms for the beneficial effects of verapamil and ATP-$MgCl_2$. The results presented will show that an *acute* model of CyA nephrotoxicity can be derived using the isolated perfused rat kidney, which has functional, histologic, and mitochondrial properties similar to that seen clinically. The studies will also suggest that the combination of verapamil pretreatment and ATP-$MgCl_2$ cotreatment with CyA is successful in reducing the nephrotoxic potential of this immunosuppressive agent by preventing mitochondrial calcium accumulation, and by providing a more efficient generation and translocation of ATP.

Presented in part at the Seventy-second Annual Clinical Congress of the American College of Surgeons, New Orleans, Louisiana, October 20, 1986.

Methods

Isolated Perfused Rat Kidney Preparation

Male Holtzman rats (300 g) were used as kidney donors for the isolated perfused kidney preparation. They were fasted overnight but allowed free access to water. The rats were anesthetized with sodium pentobarbital (50 mg/kg, IP) prior to experimentation.

The procedure for kidney isolation was the same as that described in detail previously.[1-7] The abdominal cavity was exposed and the right ureter cannulated with heparinized PE-10 tubing. After systemic heparinization (500 U/kg body weight IV), the right renal artery was cannulated with an 18-g needle *via* the superior mesenteric artery. Perfusion is immediately begun from a gravity resrevoir so as not to interrupt flow to the kidney and to wash the renal vessels of blood. The kidney was then freed from the animal and perfused in a closed circuit perfusion system at 37 C. A mean renal arterial pressure of 90 mmHg was maintained with a nonpulsatile rotary pump and perfusate flow was continuously monitored by a Brooks flowmeter in series with the arterial cannula.

The perfusate consisted of a Krebs-Henseleit bicarbonate buffer solution containing 7.5 g/dL bovine serum albumin, Fraction V (Miles Laboratory, Elkhart, IN), 0.1 mg/mL glucose, 0.5 mg/mL creatinine, and a mixture of amino acids.[8]

Experimental Protocol

After an initial 10-minute equilibration followed by two 10-minute control clearance periods, either 500 ng/mL CyA or the CyA vehicle cremophor EL (BASF, Parsippany, NJ) was added to the perfusate. In some experiments 2 mM ATP-$MgCl_2$ (*i.e.*, 2 μmol/mL) was added simultaneously with CyA, whereas in others 1.0 μg/mL of verapamil was added 10 minutes prior to CyA. In the third group of experiments, the combination of 1.0 μg/mL verapamil pretreatment and 2 mM ATP-$MgCl_2$ cotreatment with CyA was studied. Kidneys were perfused for a total of 100 minutes and perfusate and urine samples were collected at 10-minute clearance intervals.

Mitochondrial Studies

At the end of experimentation, mitochondria were isolated as described by Wilson et al.[9] Briefly, the cortex was separated from the inner white medulla and capsule and immersed immediately in a chilled solution containing 210 mM mannitol, 70 mM sucrose, 0.1 mM EGTA, 0.5% bovine serum albumin, and buffered to 7.4 pH with 2 mM K-HEPES. The tissue was homogenized in the above buffer, centrifuged at 4 C twice, and the supernatant discarded. The mitochondrial pellet was resuspended in the 70-mM sucrose solution at 100 mg protein/mL. Protein content was determined by the Bio Rad protein assay.[10]

Recovery rate of mitochondria in *in vivo* and *in vitro* kidney preparation were similar and in the different experimental groups were also comparable (approximately 10–11% total mitochondria protein per mg of original kidney weight). Contamination of the mitochondrial preparation by endoplasmic reticulum during the isolation procedure was assessed by measurement of glucose 6-phosphatase, an endoplasmic reticulum marker.[9] There were minimal amounts of endoplasmic reticulum in the *in vivo* compared to *in vitro* renal mitochondria isolates, with the ratio of total cellular to mitochondrial pellet glucose 6-phosphatase activity being 31.3 *versus* 36.0 ($p > 0.05$), respectively.

Mitochondrial O_2 consumption was measured with a YSI O_2 monitor (Yellow Springs Instruments, Yellow Springs, OH) equipped with a Clark-type electrode and a temperature-regulated water bath. The reaction mixture contained 120 mM KCl, 2 mM phosphate, 4 uM rotenone, and 1 mM EGTA buffered with 5 mM Tris-HCl, pH 7.1. After equilibration of the mixture at 25 C, mitochondria (2–4 mg of protein) were added and the rate of oxygen consumption measured after addition of 5 mM K-succinate. State 3 respiration was initiated by addition of a phosphate acceptor (300 μmoles of ADP) and state 4 respiration was measured after all the ADP had been exhausted to ATP. The respiratory control ratio (RCR) is calculated as the ratio of O_2 consumption in the presence (state 3) and absence (state 4) of ADP and is a measure of the integrity of the mitochondrial preparation. The efficiency of phosphorylation is calculated from the oxygen trace and is equal to the ratio of the known amount of ADP added to the amount of oxygen consumed during the burst of the state 3 respiration. This approaches 2 with succinate as the substrate in mitochondria that exhibit high respiratory control. The maximal rate of O_2 consumption was measured after the addition of an uncoupler of oxidative phosphorylation, 0.2 μmoles FCCP (carbonyl cyanide p-trifluoro methoxypenyl hydrasone, Sigma Chemical Corp., St. Louis, MO).

Mitochondrial and tissue Ca^{2+} and Mg^{2+} were determined by atomic absorption (Perkin Elmer, Norwalk, CT). The isolated mitochondria (5 mg protein) were digested overnight in 200 μL nitric acid and then diluted in 5 mL deionized water prior to measurement while the tissue calcium and magnesium was determined from the initial cortical homogenate.

Rat kidneys were isolated and perfused *in vitro* with a modified Krebs HCO$_3$ buffer containing CyA, verapamil, and ATP-MgCl$_2$. After 100 minutes of perfusion, kidney cortex was separated from capsule and white medulla, homogenized (tissue homogenate), centrifuged, and the supernatant discarded. The pellet (mitochondria) was washed twice and resuspended in 70 mM sucrose. Ca^{2+} and Mg^{2+} were determined by atomic absorption. For details see Methods. Values are expressed as means ± SE, N = number of kidneys; CyA = cyclosporine; ATP = ATP-MgCl$_2$; V = verapamil.

* $p < 0.05$ compared with *in vitro* control.

† $p < 0.05$ compared with CyA.

Morphologic Studies

At the end of experimentation in some kidneys, a fixative consisting of 0.067M cacodylic acid, pH 7.4, 0.8% paraformaldehyde, 1.25% glutaraldehyde, and 0.01% CaCl$_2$, was allowed to perfuse the kidneys by gravity. A total of 300–400 mL of fixative was used in each kidney. Cortical slices of kidney were minced and placed in 0.2 M cacodylate buffer, pH 7.4 containing 8% dextrose for 1 hour. The tissue was then postfixed in 2% osmium tetroxide, dehydrated and epon embedded, sectioned with a diamond knife, and stained with uranylacetate and lead citrate. The sections were viewed in a Phillips 201 electron microscope. A total of three sections from a minimum of two different blocks from each of three rats per group was examined.

Statistical Analyses

Statistical analyses were performed by Student's t-test and ANOVA where applicable. Values of p less than 0.05 were considered statistically significant. Values are expressed as means ± standard error of the mean.

Results

Mitochondrial Studies

Table 1 shows that the CyA-treated kidneys had a small but significant mitochondria calcium accumulation compared to the control kidneys. This mitochondrial calcium loading was exacerbated by ATP-MgCl$_2$ treatment but prevented in both the CyA and the CyA + ATP-MgCl$_2$ group by verapamil pretreatment. Tissue calcium was unaffected by CyA treatment, but this rose with the addition of ATP-MgCl$_2$. This increased tissue calcium with ATP-MgCl$_2$ could be prevented by verapamil pretreatment. Mitochondrial and tissue magnesium levels were unchanged with CyA treatment. However, this increased in the kidneys treated with ATP-MgCl$_2$ and was not reversed by verapamil treatment. Further studies have shown that this increase is probably due to the MgCl$_2$ carrier since this finding could be reproduced with MgCl$_2$ treatment alone but not with ATP alone (unpublished observations).

Table 2 shows that cortical mitochondria from kidneys treated with CyA did not show any significant difference in state 3, state 4, or uncoupled oxidative phosphorylation compared to the control group. There was, however, a small but significant decrease in ADP/O ratios in the mitochondria isolated from CyA-treated kidneys. The ATP-MgCl$_2$ cotreated group and the verapamil pretreated group showed a significant loss of respiratory phosphorylative activity (state 3) and RCR compared to the control and CyA-treated groups. In addition, the verapamil pretreated group had a lower uncoupled oxidative phosphorylative activity. The combined treatment with verapamil, ATP-MgCl$_2$, and CyA restored mitochondrial respiratory activity to normal.

Renal Ultrastructure

There were no consistent histologic abnormalities seen in the glomerulus, arterioles, or distal tubular cells of the CyA-perfused kidneys. There were, however, TABLE 2. *O_2 Consumption in Mitochondria Isolated from Rat Kidneys Treated with Cyclosporine, ATP-$MgCl_2$, and Verapamil*

Cortical mitochondria were isolated and placed in a closed reaction vessel fitted with a Clark O_2 electrode and containing an incubating medium of 120 mM KCl, 2 mM phosphate, 4 μM rotenone, 1 mM EGTA, and 5 mM K-succinate. State 3 respiration (μmoles O_2/gm min) was the O_2 consumption measured when 300 μmoles ADP was added and State 4 respiration (μmoles O_2/gm/min) was the basal O_2 consumption when all ADP had been converted to ATP. The respiratory control ratio (RCR = State 3/State 4) is an indicator of how tightly coupled the mitochondria are and assesses the integrity of the mitochondria preparation. The uncoupled respiratory rate (μmol O_2/gm/min) is the maximal O_2 consumption in the presence of an uncoupler of oxidative phosphorylation. ADP/O is the ratio of the known amount of ADP added to the amount of oxygen consumed during the burst of the State 3 respirations and expresses the efficiency of phosphorylation. CyA = cyclosporine; V = verapamil; ATP = ATP-$MgCl_2$; N = number of kidneys.

* $p < 0.05$ compared with *in vitro* control.

† $p < 0.05$ compared with CyA.

some fairly consistent changes seen overall in the proximal tubule cells, although these were heterogeneous among different nephrons in the same kidney.

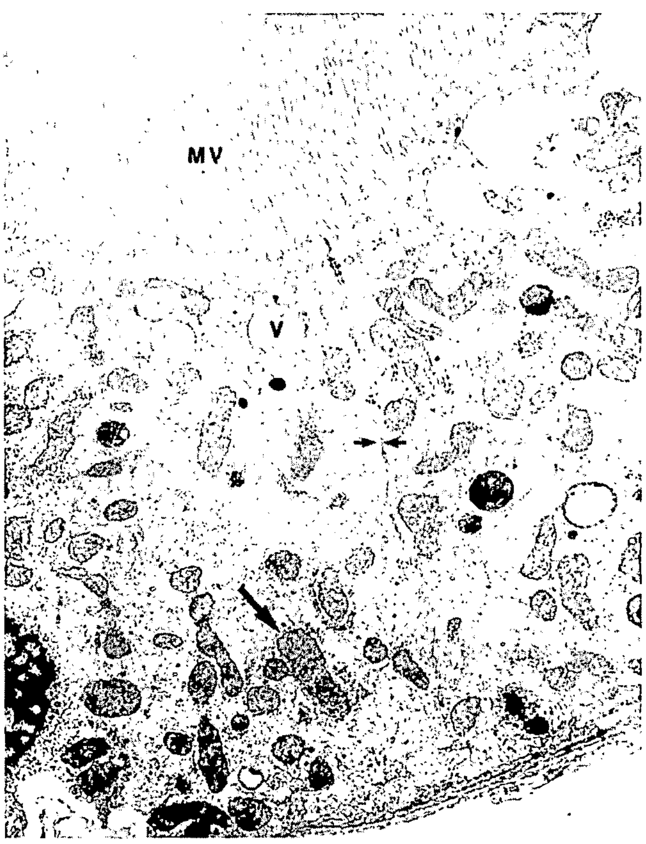

FIG. 1. Electron micrograph of proximal tubule segment of isolated rat kidney perfused for 100 minutes with 500 ng/mL cyclosporine. Note the appearance of vacuoles (V) and giant mitochondria (large arrow). MV = microvilli on apical portion of renal cell, small arrows showing cell junction. (Uranyl acetate-lead citrate, original magnification ×7000.)

The ultrastructure of a representative proximal tubule cell from a kidney treated with cyclosporine is shown in Figure 1. Although the presence of proximal tubule vacuoles (V) is also seen in the control group, the vacuoles appeared to be consistently increased in the CyA perfused kidneys and persisted despite treatment with ATP-$MgCl_2$ and verapamil. Occasional giant mitochondria (large arows) were also seen in the CyA-treated kidney.

Discussion

In our earlier studies,[1,2] 500 ng/mL of CyA in the perfusate led to a 90% reduction in GFR and a 67% fall in urine output with a lower but not statistically significant drop in renal perfusate flow. In addition, tubular reabsorption of protein, and to a lesser extent salt and water, was reduced acutely by CyA administration. In this study, mitochondrial function studies of kidneys after 100 minutes of CyA perfusion already showed a small but significant increase in mitochondrial calcium accumulation and statistically significant reduction in ADP/O, a measure of the efficiency of phosphorylation ratios. The increase in mitochondrial calcium occurred without a concomitant rise in tissue homogenate calcium levels. This suggests that the alterations are probably due to redistribution of intracellular calcium pools rather than a net influx of calcium from the extracellular compartment. A similar finding has been shown by Weinberg and coworkers in models of mercuric chloride and gentamicin nephrotoxicity.[11,12] Tissue and mitochondrial calcium accumulation did not occur until prolonged exposure to the nephrotoxins and just prior to development of cell necrosis. Studies with uranyl nitrate[13] have also suggested that an increase in mitochrondrial calcium may occur during the early phases of renal injury.

Evidence for cyclosporine-induced mitochondrial membrane damage is scant and conflicting. Humes and coworkers have reported a dose-dependent CyA inhibition of mitochondrial respiration supported by succinate in the S_3 segment of proximal tubule; however, no membrane permeability changes were noted.[14] Kirwan and collaborators showed that CyA had no effect on respiratory or oxidative phosphorylation in isolated rat renal cortical mitochondria or in mitochondria incubated from rats on chronic CyA administration.[15] Hay and coinvestigators have shown that CyA is associated with structural alteration in renal mitochondria at the molecular level, but this was predominantly in the medulla mitochondria rather than cortical mitochondria. They hypothesize that CyA interferes with mitochondrial biogenesis and replenishment rather than by direct inhibition of respiratory enzymes.[16] In our study, the mitochondria of CyA-treated kidneys were tightly coupled and effective in their normal function of oxidative phosphorylation, although the efficiency of phosphorylation (ADP/O ratios) is slightly lower. The finding of mitochondrial calcium accumulation and a decrease in ADP/O ratios after only 100 minutes of CyA perfusion may indicate an early subtle dysfunction that might manifest itself with longer periods of perfusion and CyA administration; however, further studies are needed in order to clarify these issues.

Histology of the CyA perfused kidneys showed increase vacuolization and occasional giant mitochondria in the proximal tubular cells compared to the control CyA vehicle perfused kidneys. These vacuoles varied in size and contained occasional dense bodies or myeloid bodies. The ultrastructure of the glomerulus and distal tubular cells, however, showed no abnormalities compared to the perfused control kidneys. Proximal tubule vacuolization has been reported by others[17,18] and is said to be consistent with clear lysosomes. The morphologic alterations induced by CyA seen in this study are consistent with those seen in whole animal models and with those in man,[19] although the latter is much more pronounced than in the experimental animal. The variability of the degree of morphologic findings has been viewed by some investigators as a result of cyclical toxicity,[18,19] but the lack of correlation between morphologic and functional parameters in other experimental models remains unclear. Nonetheless, it is important to bear in mind that CyA nephrotoxicity in man or animals is morphologically and functionally different from other forms of drug toxicity and that different pathogenic mechanisms probably underly the development of acute and chronic CyA toxicity.

Using the combination of verapamil pretreatment and ATP-$MgCl_2$ cotreatment with CyA almost completely reduced the nephrotoxic potential of this immunosuppressive agent.[1,2] GFR was restored to control values, renal perfusate flow and urine output were raised to supranormal levels, and tubular reabsorptive capacity was maintained at near control levels. The mechanism of the beneficial effect of this combination is not completely defined by the present study, but several interesting observations emerge. First, as previously reported,[1,2] the beneficial effects of ATP-$MgCl_2$ and the calcium channel blocker, verapamil, may be concentrated on different functional parameters with ATP-$MgCl_2$, improving tubular functions and tissue ATP levels while verapamil improved GFR, RPF, and urinary output primarily. Thus, the benefits of the combination therapy could be simply due to the sum of the effects of each drug. Secondly, the combination therapy resulted in ATP levels that were much higher than even the *in vivo* controls.[1,2] This supranormal ATP level might account for the marked improvement in function seen with verapamil and ATP-$MgCl_2$ administration with the increased intracellular ATP available for organelle utilization. Whether the high tissue ATP level might reflect a decreased but more efficient use of ATP or whether there is an actual increase in ATP production remains unknown.

Analysis of mitochondrial function of the various experimental subgroups indicates that while CyA administration resulted in no mitochondrial respiratory function abnormalities and only a slight accumulation of mitochondrial calcium, the addition of ATP-$MgCl_2$ resulted in an excessive accumulation of mitochondrial and tissue calcium leading to impaired respiratory mitochondrial function. Despite this impaired mitochondrial function, tissue ATP levels were still comparable, if not higher, than the untreated controls; this level of tissue ATP may be artificially lowered because of the impaired mitochondrial system. The results of this study indicate that the pretreatment with verapamil and cotreatment with the ATP-$MgCl_2$ corrected the mitochondrial dysfunction seen with ATP-$MgCl_2$ treatment alone and resulted in the supranormal tissue ATP levels seen with the combination therapy. High levels of calcium are known to produce a loss of mitochondrial function[20] and can lower the ATP synthetic activity.[21] Mitochondrial calcium transport takes precedence over oxidative phosphorylation.[22] The further loading of mitochondria with calcium leads to calcium phosphate precipitation and permeability changes in the membrane, which further inhibits oxidative phosphorylation. In addition, the permeability changes alter the electrochemical gradients responsible for ATP production. These calcium-induced mitochondrial permeability alterations can be mitigated by inhibiting the calcium influx. Zoccarato and colleagues have shown that Mg^{2+} and the adenine nucleotides can inhibit the uptake of externally added Ca^{2+} and phosphate.[23] Furthermore, intracellular calcium influx associated with ATP-$MgCl_2$ treatment has been demonstrated in the isolated hepatocyte model[24] and the resultant excess calcium accumulation by the mitochondria was postulated to impair ATP translocation from the mitochondria to the cytoplasm, thus lowering ATP stores.

The therapeutic implications of our *in vitro* studies become more important when one considers the most recent studies reporting that verapamil may potentiate CyA immunosuppressive properties. McMillen and coworkers have shown that verapamil would not only inhibit murine lymphocyte proliferation to lectin and alloantigen stimulation *in vitro* but, when given with CyA, can potentiate the inhibition of human lymphocyte proliferation.[25] Their studies taken together with the findings of this study suggest that the pretreatment with verapamil and the cotreatment of ATP-$MgCl_2$ with CyA would not only reduce the nephrotoxicity of CyA but, in addition, if verapamil enhances CyA immunosuppression, then a lower dose (and hence, less nephrotoxic potential) of CyA would be needed. Clinically this has important implications in providing transplant recipients with a less myelosuppressive and nephrotoxic agent.

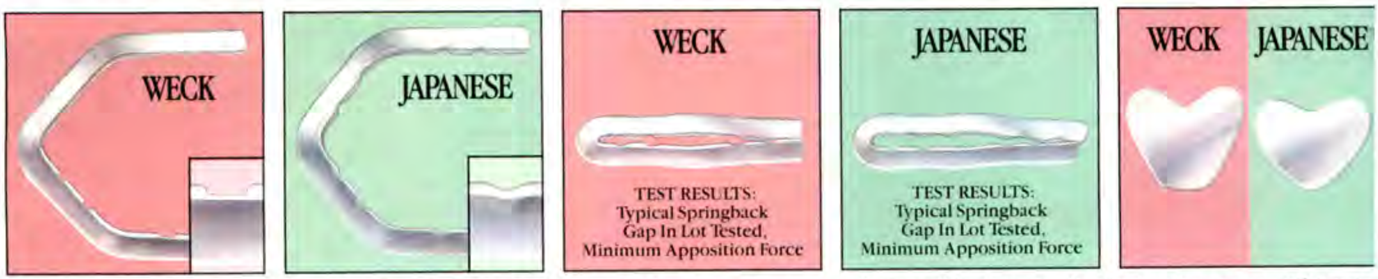
We make the Hemoclip® clip like it is because of the way nature made blood vessels.

Hemoclip® ligating clips are made for blood vessels.

That sounds obvious, but it's not to everyone.

It's not easy to make ligating clips that are finely balanced between strength and malleability–two desirable ligating clip properties.

But in a quarter-century of manufacture, Weck has learned to do the job on this key implant device as no one else has.



The Hemoclip® ligating clip is coined with distinct rectangular transverse grooves, designed for longitudinal gripping power. Clip wire is processed metallurgially for malleability in closure. The Japanese imitation clips have shallow-drawn wire, and smaller, rounded transverse grooves. Deeper Hemoclip® wire shape aids retention in Weck appliers. (Typical closure illustrated from independent study.)

But now there's a problem you should be aware of. Some U.S.-based companies have begun distributing–not manufacturing–Japanese imitations of the Hemoclip® ligating clip. These clips are not the product of Weck manufacturing expertise and the technical performance of these clips is simply not the same as that of Hemoclip® ligating clips, an exclusive Weck product.

They may look the same, but they're not.

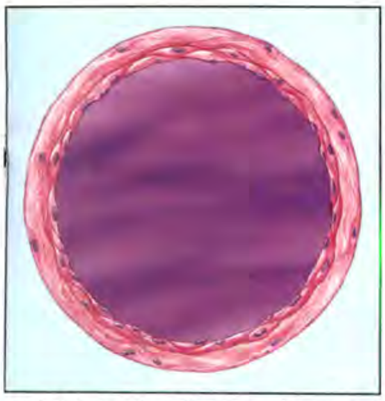
The recently-introduced Japanese clips look the same as Hemoclip® ligating clips to the naked eye. But a recently completed independent lab study of sample quantities of clips confirms Weck's own observation of substantial differences in closure properties between the Japanese clips and Weck clips.

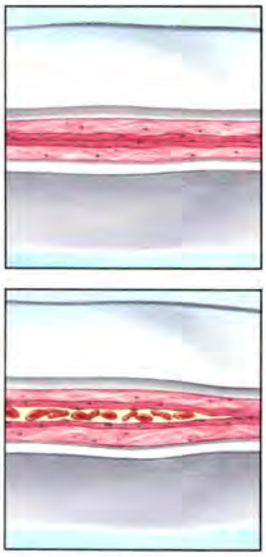
Vessel walls may be as thin as one-twelfth of vessel diameter.

Veins, in contrast to arteries, have very thin walls. When you consider that the vein tributaries ligated in surgery are sometimes one millimeter in diameter or smaller, with combined vessel walls as small as seven-thousandths of an inch (178 microns) according to animal studies on comparable vessels, you can appreciate the functional importance of differences in closure gap.

Arterial tributaries can be tiny, too, and although their walls are generally thicker than vein walls, arteria pressure is higher than venous pressure.

It seems prudent to employ ligating clips which offer the response and clip-closure performance Weck usage has established in your surgery





ABOVE. A vein tributary of 1mm can have a combined wall thickness of just seven-thousandths of an inch (178 microns), according to animal studies. RIGHT. A ligating clip that demonstrates greater springback than the clip you have regularly used for such vessels may be more likely to leave a closure gap larger than the vessel-wall thickness of a tiny vessel.

Weck's titanium clip vs. their titanium clip. A 23-27% difference.

Examine the chart for a visual representation of the difference in closure springback an independent research firm discovered between a set of Weck titanium medium-size clips and a set of Japanese titanium medium-size clips obtained directly from U.S. distributors of those clips. Both sets of clips were closed in Weck appliers through use of force-control devices.

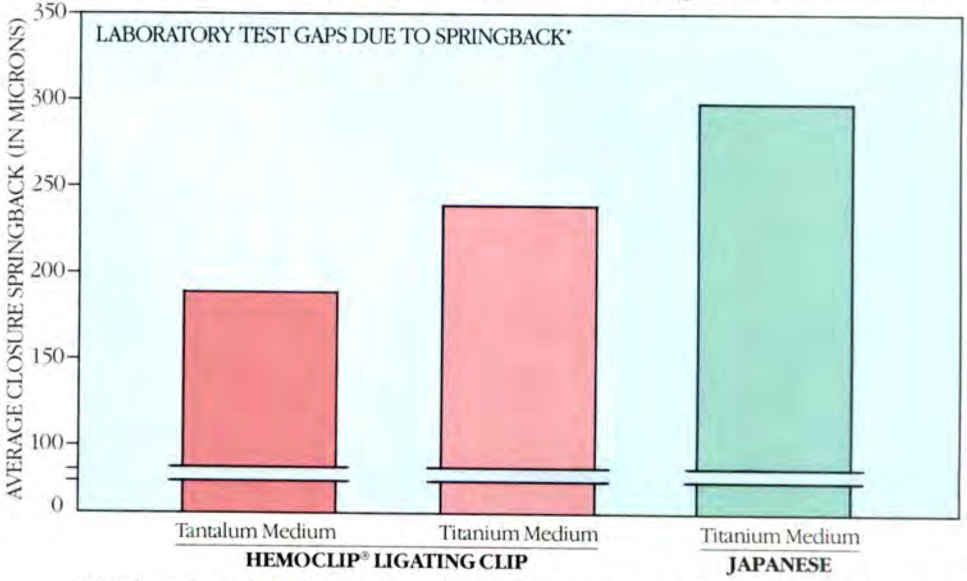
Closure of two sample sets of 25 Japanese titanium medium clips at forces adequate to achieve initial complete ouching along clip legs resulted in closures of about 12 thousandths of an inch (305 microns) for the Japanese clips, 23-27% larger than the Weck titanium clip closure gap.

Weck's tantalum clips vs. their titanium clips. A 56% springback difference.

The comparison of Japanese titanium with Weck tantalum clips is even more important.

The Japanese companies make only titanium clips, and so they have sold hard on the benefits of titanium.

Tantalum is a softer material known for excellent clip closure. And the study revealed 56% and 61% larger mean closure gaps after springback for two sets of Japanese titanium clips, a ringing endorsement of the closure advantages of the Weck tantalum clips tested.



An independent lab study on two sample sets of 25 Japanese imitation clips vs. Weck clips found that the Japanese medium-size clips, closed to initial complete touching of clip legs, evidenced mean closure gaps, due to springback, 23-27% larger than Weck medium-size titanium clips, and 56-61% larger than Hemoclip® tantalum clips from Weck. Other sizes produced similar results. (Closure gap in microns-one micron = one thousandth of one millimeter).

**Stronger closure forces would likely be employed during actual surgery cases.*

The comparison was similar for Weck stainless vs. Japanese titanium, with the stainless scoring substantially smaller gaps after springback.

Odds are, if you are using Weck clips you are accustomed to tantalum or stainless steel clip closure, because the vast majority of Weck accounts use these two metals.

And a new Weck-funded NMR major-university study indicates that magnetic deflection of tantalum clips is negligible, just as it is for titanium clips. So if your local competitive salesman distributing Japanese clips tries to convince you that titanium clips are exclusively acceptable for NMR magnetic deflection in preference to tantalum, we suggest you cite the new Weck-sponsored university study.

Look for the Weck name on the cartridge.

To visually and quickly confirm that you really are using Weck clips, look at the end of the clip cartridge. If you are using Weck clips, you should see there the Weck name molded into the plastic The Weck name is your assurance of genuine Hemoclip® clip processing experience and knowledge.

Improved Results from a Standardized Approach in Treating Patients with Necrotizing Fasciitis

LAURA A. SUDARSKY, M.D., JOHN C. LASCHINGER, M.D., GENE F. COPPA, M.D., and FRANK C. SPENCER, M.D.

Necrotizing fasciitis has been associated with significant morbidity and mortality. Thirty-three patients were studied over a 3-year period. Predisposing factors included intravenous drug abuse (30%), diabetes (21%), and obesity (18%). Severe pain (94%) and abnormal temperature (88%) were present, whereas laboratory data and x-ray were nonspecific. Gram-positive organisms were most frequently recovered (B-hemolytic streptococcus 45%). Treatment consisted of antibiotics, surgical debridement, re-exploration 24 hours before surgery, nutritional support, and early soft tissue coverage as needed. Mean duration from admission to operation was 43 hours. The average number of operative debridements was three and the average length of hospitalization was 47 days. Patients operated on less than 12 hours from admission or greater than 48 hours had shorter hospital stays (36 and 38 days). The critical time period was 12–48 hours after admission; all deaths (2) and amputations (3) were in this group and the average hospital stay was 62 days ($p < 0.05$). The number of operations did not correlate to hospital stay. Despite antibiotics and aggressive debridement, significant morbidity exists if operation is delayed more than 12 hours. Methods of early detection such as local bedside diagnostic incision and fascial inspection may be needed in high risk patients to further reduce the morbidity and mortality.

NECROTIZING FASCIITIS (NF) is a well-defined, persistent, and pervasive disease in which the fascia is the primary site of infection. The disease involves extensive necrosis of the superficial and deep fascia with concomitant thrombosis of the cutaneous microcirculation (Fig. 1). Necrotizing fasciitis has been described in medical texts since 1871[1] and in the surgical literature since 1924.[2] Since these reports the mortality rate for patients with NF has ranged from 8.7%[3] to as high as 73%[4] and, in most cases, has equalled or exceeded the 20% mortality originally reported by Meleney[2] over 60 years ago.

From the Department of Surgery, New York University Medical Center, New York, New York

Recently a significant increase in the incidence of NF initiated a review of our experience and that of others. Predisposing clinical factors, etiologic incident, microbiological results, surgical treatment, and clinical outcome were analyzed. A significant number of patients have immunodeficiency complicating a relatively minor etiologic event. Early diagnosis and a regimen of vigorous resuscitation, nutritional support, broad spectrum antibiotics, and aggressive debridement with mandatory re-exploration are crucial in patient management. The results of this study correlate the timing of operative treatment with patient morbidity and mortality.

Materials and Methods

The medical records of 33 patients with NF treated during the period from September 1983 to April 1986 at New York University Hospital, Bellevue Hospital, and Manhattan Veterans Administration Hospital were reviewed. The data studied included age, sex, duration of hospitalization, associated disease states, etiologic factors, laboratory findings, location of primary infection, bacteriology, and treatment methods. Of the 33 patients studied, 27 had confirmation of the NF diagnosis by pathologic examination and six patients had a clinical diagnosis of NF primarily based on operative findings.

Surgical treatment was instituted as soon as the diagnosis of NF was considered. Therapeutic guidelines included institution of vigorous fluid resuscitation, arterial and venous monitoring, broad spectrum antibiotics, and aggressive surgical debridement of the involved fascia. Mandatory reexploration was performed within 24 hours. Repeat explorations and debridements were performed daily as needed until all the necrotic tissue was

erradicated. Medically unstable patients or patients in whom re-exploration revealed progression of infection in an extremity required amputation. Nutritional support was instituted with enteral or parenteral alimentation, supplying at least 3000 calories per day.

All results are expressed as the mean (±) standard deviation. Statistical analysis was performed using the F test with variance ratios.

TABLE 1. *Predisposing and Etiologic Factors in NF (33 Patients)*

Risk Factors	No. of Patients	Etiology	No. of Patients
IVDA	10 (30%)	IVDA	9 (27%)
Diabetes	7 (21%)	Skin infection	9 (27%)
Obesity	6 (18%)	Minor trauma	5 (15%)
PVD	5 (15%)	Perirectal infection	5 (15%)
Malnutrition	5 (15%)	Incarcerated hernia	2 (6%)
IVDA + diabetes	3 (9%)	Bites	2 (6%)
Paraplegia	1 (3%)	Postoperative	1 (3%)
Postoperative	1 (3%)		
None	3 (9%)		

Results

Risk Factors

There were 22 male and 11 female patients ranging in age from 25 to 78 years (mean ± SD = 46.2 ± 12.8 years). Ten of the 33 patients were intravenous drug abusers (IVDA) and seven were diabetic. Three patients were both diabetic and IVDA. Six patients were morbidly obese, five had clinical or laboratory evidence of malnutrition (serum albumin < 3.0 gm/dL), and five had peripheral vascular disease (PVD). Although three patients had no known predisposing factors, ten patients had more than one risk factor (30%) (Table 1).

Etiology

The most common events leading to NF in the 33 patients studied were minor skin infections (27%), intravenous drug injection (27%), minor trauma (15%), and perirectal abscesses (15%). Necrotizing fasciitis also resulted from complications of incarcerated herniae, animal and insect bites, and after surgery as a complication of an exploratory laparotomy for diffuse carcinomatosis (Table 1).

Signs and Symptoms

Thirty-one of the 33 patients (94%) presented to the hospital complaining of severe pain. One patient without pain was paraplegic with a perirectal infection source and the other was obtunded with organic brain syndrome. At the time of operative intervention, 24 patients (73%) treated with intravenous antibiotics for at least 1 day had progression of the infection. Twenty-five patients (76%) had developed cellulitis and skin changes (*i.e.*, blebs, ulceration, or frank skin necrosis). Twenty-seven patients (82%) had a temperature greater than 101 F, two patients had a temperature less than 97 F, and only four patients were normothermic. In six patients crepitus was present on physical examination (Table 2).

Site of Infection

Twenty-two of 33 patients (67%) had extremity lesions, 17 (52%) upper and five (15%) lower. In eight patients (24%) perineal infections extended to the buttocks and upper thighs. Necrotizing infections of the trunk were less common, occurring in three patients (9%).

Laboratory Findings

Abnormalities in red and white blood cell count, serum calcium levels, and acid-base balance were observed (Table 2). Anemia (hematocrit < 35%) (64%), hypocalcemia (Ca < 8.5 mg/dL) (33%), acidosis (arterial blood gas pH < 7.36 or serum bicarbonate < 20 mmol/L) (27%), and leukocytosis (>10.0 cells/mm^3) (88%) were the abnormalities most frequently found. One patient suffering from acquired immune deficiency syndrome (AIDS) was leukopenic (<3.0 cells/mm^3). Soft tissue radiography demonstrated gas in eight patients (24%) (Table 2).

Bacteriology

The average number of bacterial types isolated from each infection site was 1.95. Beta-hemolytic *Streptococcus* was the organism most frequently cultured (Table 3). *Escherichia coli,* alpha-hemolytic *Streptococcus,* and *Staphylococcus aureus* were also common. In patients with mixed infections a wide variety of gram-negative rods were present in operative cultures, while in monomicrobial infections *E. coli* was recovered. *Staphylococcus epidermis,* anaerobic diptheroids, microaerophilic Streptococcus, and Peptostreptococcus were also occasionally cultured. Two patients had no organisms recovered.

Morbidity and Mortality

Seven patients (21%) underwent surgery within 12 hours of admission (Group A) and ten (30%) patients after 48 hours (Group B) (Table 4). The mean hospital stay for these patients was 36 days (Group A) and 38 days (Group B), respectively. There were no deaths or amputations in these two groups. Sixteen patients (49%) were operated on between 12 and 48 hours (Group C), with a mean hospital stay of 62 days. The increase in hospital morbidity of Group C patients was statistically significant when compared with patients in Groups A and B. There were two deaths and three amputations in Group C patients. The number of operative procedures did not correlate with the patient group or hospital morbidity. The mean number of operative procedures for all patients was 3.24 ± 1.0. Two of the 33 patients died as a direct result of NF and a third patient died during the hospitalization from unrelated factors, resulting in a mortality rate of 6.1%.

Discussion

Necrotizing fasciitis is no longer an uncommon disease rarely reported in medical or surgical literature. Awareness of this potentially fatal infection and an increase in the number of patients with predisposing factors have contributed to the overall increase in incidence. In our series, 33 patients with NF were identified in 31 months. Patients with NF and other necrotizing soft tissue infections not involving the fascia are managed on a daily basis at our institution.

TABLE 2. *Clinical and Laboratory Date in NF (33 Patients)*

Clinical Signs and Symptoms	No. of Patients	Laboratory	No. of Patients
Severe pain	31 (94%)	Leukocytosis	29 (88%)
Temperature abnormalities		Anemia	21 (64%)
>101 F	27 (82%)	Hypocalcemia	11 (33%)
<97 F	2 (6%)	Acidosis	9 (27%)
Skin changes	25 (76%)	Gas (x-ray)	8 (24%)
Cellulitis—progressive	24 (73%)		
Crepitus	6 (18%)		

Earlier interest in this disease centered on developing anatomic or bacteriological classifications. Attempts were made to correlate the site of infection and the presence or absence of skin involvement with clinical factors. The microbiology of infection has also been studied extensively. No clinical differences or improvement in patient survival were evident in studies of individual bacteria. In general, however, polymicrobial infections have longer clinical incubation periods than monomicrobial infections, making the former more difficult to detect at an early stage.

The mean mortality rate reported in previous studies of NF between 1924 and 1986 is 32.2 ± 18.8% and ranges from 8.7% to 73.0%.[2–4,6–14] The wide range and high mean mortality rate reported in these studies reflect differences in definitions and diagnostic criteria for NF, prevalence of risk factors and etiology among the patient populations studied, and variations in the effectiveness of the treatment methods.

The mortality rates have been reported to be especially high in the presence of old age, peripheral vascular disease, and diabetes. The common factor in our patients is an underlying immune defect due to one or

TABLE 3. *Microbiology in Patients with NF*

Bacteria	No. of Patients
Gram-positive	
B-hemolytic Streptococcus	15 (45.4%)

TABLE 4. *Analysis of the Hospital Morbidity of NF*

Group	No. of Patients	No. of Debridements	Average Stay (Days)
A (<12 hrs)	7	3.0 ± 1.1	36
B (>48 hrs)	10	3.3 ± 1.0	38
C (12–48 hrs)	16	3.2 ± 1.2	62
Total (43 hrs)	33	3.24 ± 1.1	47.1

more diseases (91%); only three patients who were otherwise healthy developed NF. The most common predisposing conditions included intravenous (IV) drug abuse, diabetes, or both (61%) (Table 1). A significant percentage of patients (48%) had peripheral vascular disease, obesity, or malnutrition; 30% patients had more than one risk factor. Rea et al.[7] noted a 67% mortality in patients with NF who were older than 50 years. In our series one patient over 50 years of age died for a mortality of 7.1% in this age group. Many of our patients (30%) were IV drug abusers, the group reported to have a lower mortality from NF than diabetics. Melluzzo et al.[16] reported no deaths in three cases of NF related to IV drug abuse and Schecter et al.[15] reported only one death among 21 NF patients who were IV drug abusers.[15] Mortality rates of up to 80% have been reported for NF in diabetics.[4] None of the patients suffering from diabetes or IV drug abuse died in this study.

Etiologic incidents in our patients were IV drug injection, skin infections, minor trauma, or perirectal abscess (Table 1). In an earlier report by Rea et al.[7] on a series of 44 patients with NF, minor trauma was the initiating event in 80% of the cases and the reported mortality was 30%. In contrast, in the current series 54% of the patients developed NF directly from IV drug abuse or minor skin infections, and 30% of the patients developed NF from minor trauma or perirectal infections. The overall mortality rate was 6.1%. Disparities in etiology and mortality may reflect differences in patient populations studied. However, early detection and effective therapy have been associated with lower mortality.[5]

The most common presenting complaint was severe pain in the affected region, often of a severity disproportionate to the local physical findings (Table 2). This symptom was present in all patients except for two with alteration in pain response due to neurologic dysfunction. The pain was frequently associated with signs of systemic toxicity, including hypo- or hyperthermia, abnormal white blood cell count, and acidosis. Classically, NF has been associated with skin changes in less than 50% of patients. However, factors such as etiology, delay in presentation, and the type of bacteria account for variations in this aspect of clinical presentation. In our series local physical findings most often included extension to the skin with changes such as blebs, ulcers, o necrosis superimposed on pre-existing cellulitis. A striking finding was the progression of cellulitis during hospitalization despite the administration of appropriate broad spectrum antibiotics. This skin change was evidence of continued underlying tissue necrosis. Crepitus was identified in only 18% of patients, usually as a late clinical sign.

Previous reports have suggested that patients with NF of the extremities have an improved survival compared to those with involvement of other areas.[4,12,15] In this study there were 22 extremity infections with one death (4.5% mortality rate), eight perineal infections with one death (12.4% mortality rate), and three trunk infections with no deaths.

At least one gram-positive organism was cultured in 79% of patients. These included beta-hemolytic Streptococcus, *Staphylococcus aureus* and *epidermidis,* and alpha-hemolytic Streptococcus (Table 3). Gram-negative rods were recovered in 73% of patients. Two patients had pure gram-negative organism infections and eight had pure gram-positive infections. Fourteen patients had mixed gram-positive (Staphylococcus or Streptococcus) and gram-negative organisms, and two patients had sterile cultures. In six patients, anaerobic or microaerophilic organisms were found in combination with gram-positive and gram-negative organisms. NF is usually a polymicrobial disease caused by diverse organisms, usually two or more. These findings confirm the observation that NF is a clinical pathologic process affecting an organ system, the fascia, which is independent of the specific bacteria present.[8] The finding of Streptococcus, gram-negative aerobes, and anaerobes supports the use of a combination of high-dose penicillin, an aminoglycoside, and clindamycin or metronidazole as the empiric agents of choice in patients with NF.

A standardized treatment was evaluated in this series of patients. All patients were treated by aggressive resuscitation, surgical debridement with mandatory re-exploration at 24 hours, and as clinically required, IV antibiotics, nutritional support, and early soft tissue coverage. All patients in this series had a diagnosis of NF that was confirmed by pathologic studies or documented clinically by the presence of liquefaction necrosis of the fasica, which allowed the surgeon to pass a blunt instrument or hand freely along the normally adherent tissue planes. The pathologic process seems based on vascular ischemia to the end vessels of the fascia, perhaps due to effects of exotoxin release. The fascia responds as a diseased organ system, resulting in initial local impairment and then systemic septic effects.

Our data support a policy of early fascial exploration for all patients in high risk groups presenting with severe pain, particularly if accompanied by cellulitis, local skin changes, or crepitus. Early fascial exploration is also indicated for all patients in whom cellulitis progresses and severe symptomatic toxicity develops despite administration of appropriate antibiotics.

Variability in the rate of development of NF was originally described by Wilson in 1942.[3] He noted that the infection may affect an entire extremity within 24 hours or slowly progress over several weeks. In other patients the disease is dormant and then spreads rapidly without any readily apparent reason. Our study identified three clinical groups of patients that may represent these differences. The patients with rapidly progressive disease who were debrided less than 12 hours after admission (Group A) had the same hospital morbidity as the patients with infection that spread slowly and required operation after 48 hours (Group B). However, patients with rapidly progressive infection in whom debridement was delayed for 12–48 hours (Group B) remained hospitalized significantly longer (Table 4). The most serious sequelae of NF (death and amputation) were observed in patients operated on more than 12 hours after admission. This confirms the study of Kaiser and coworkers,[5] which indicated that the length of delay between recognition of a surgical infection and initiation of surgical therapy had a significant positive correlation with mortality.

The factors that cause NF to be aggressive or even lethal within 24 hours in some patients and remain relatively unaggressive in others remain unidentified. The virulent phase of this disease must be diagnosed quickly and accurately. Exploration and fascial examination of suspicious areas can easily be performed under local anesthesia at the bedside by incision and inspection of the fascia noting the color, odor, presence of necrosis, and status of fascial planes. Liquefaction necrosis, grey nonviable fascia, or separation of the fascia from the subcutaneous tissue or muscle indicate the need for operative debridement. The results of this study suggest that there is an increased incidence of the disease. The common clinical presentation involves an IVDA or diabetic with a minor skin infection of an extremity. The significant findings are severe pain, fever, and progressive cellulitis, accompanied by anemia and leukocytosis. The diagnosis is based on frequent physical examination and confirmed by inspection of the fascia either locally or in surgery. Definite treatment includes a unified plan consisting of vigorous preoperative resuscitation, broad spectrum antibiotics (including penicillin), aggressive surgical debridement with mandatory re-exploration at 24 hours and thereafter as needed, parenteral or enteral nutritional support, and early soft tissue coverage. With the above approach the overall hospital morbidity was 47 days and the mortality rate was 6.1%.

PTFE Grafts for Hemodialysis Access

Techniques for Insertion and Management of Complications

SESHADRI RAJU, M.D.

In a series of 602 procedures, over 90% of primary forearm insertions of PTFE grafts between the radial artery and a cubital vein were possible. Thrombosis of the graft, which was invariably due to venous outflow obstruction, was the most common complication encountered. Revision of the venous anastomosis was not necessary in about one-third of the thrombosed grafts if a size 3 coronary dilator could be passed and the augmentation test was satisfactory. For revisions, creation of a new venous anastomosis using a jump graft was preferred over patch angioplasty or venous endarterectomy. Crossing the elbow for this purpose did not adversely affect graft patency. The incidence of aneurysm formation and infection was 16% and 35%, respectively. Infections involving the graft were managed by drainage, antibiotics, and bypass of the infected portion. Immediate bypass and delayed bypass were equally effective. About one-half of the infected grafts were salvaged by these techniques. The most common organism was *Staphylococcus aureus*. With a combination of the techniques outlined above, the service life of individual PTFE grafts can be extended. Two-year access patency in this series was 77%.

WITH THE INCREASING NUMBER of patients sustained on chronic hemodialysis, access related surgery forms a significant proportion of vascular surgical practice today. A cursory review of current procedures reveals a considerable variety in techniques of insertion and in the management of complications. For example, some centers prefer the upper arm straight graft[1,2] while some others advocate the forearm loop.[3,4] Considerable differences exist in the choice of artery or vein and the location for access insertion. In this report, we present our experience with over 600 dialysis access grafts, emphasizing insertion technique and management of complications.

From the Department of Surgery, University of Mississipp
Medical Center, Jackson, Mississipp

Materials and Methods

A total of 602 PTFE hemodialysis access grafts wer inserted in 532 patients at the University of Mississipp Medical Center during the period 1976–1986. Othe types of access fistulae, such as Cimino AV fistula Scribner shunt, etc., were excluded from this review. substantial number of patients were lost to follow-u because of transfer to other chronic dialysis facilities an other reasons (Table 1). Adequate follow-up data wer available on 312 grafts.

Insertion Technique

A straight graft in the forearm of the nondominan hand was preferred. Local anesthesia (1% Xylocaine infiltration) was used, except in the occasional instanc in which a general anesthetic was required for poor pai tolerance, uncooperativeness, extreme apprehension, o other reasons. Patients subjected to local anesthetic wer not kept NPO as a general rule, thus ensuring uninterrupted continuation of scheduled medications (*e.g.*, antihypertensives) and allowing flexible scheduling without extended fasting. Patients were premedicated wit oral Valium® given on call. A second generation cephalosporine was administered intramuscularly at the sam time.

The radial artery was exposed near the wrist with 1-inch longitudinal incision. The antecubital vein exposed through a transverse incision was the preferre outflow. When this vein was unavailable due to inadequate size or thombosis from previous venipuncture, th cephalic or basilic vein was chosen. Tunneling an placement of the graft between the two incisions wa

carried out before heparin (5000 U) was given. The technique of tunneling was considered important. The tunneling instrument should be somewhat smaller than the 6-mm size access graft. This ensures tamponade of the tunnel by the distended graft, which helps to secure hemostasis and prevent tunnel hematoma and subsequent infection. The long "disposable" metal trocar that is often supplied with chest tubes was particularly suitable for this purpose. A hole drilled through the end allows easy fixation of the graft to this tunneling device. The metal trocar is easily bent into any shape required for tunneling. The graft should be placed as subcutaneously as possible (Fig. 1). Counter pressure applied against the tip of the tunneling device with a sponge helps to achieve this placement. Deeper placement of the graft results in difficult access puncture, frequently leading to multiple holes, tears, and perigraft hematoma resulting in compartmental syndromes, or infection. The tunnel should be deeper near the incisions (Fig. 1A, offset) to provide for thick flaps at those points to ensure prompt primary healing. Beveled anastomoses are made to the artery and vein with continuous 6-0 Prolene using loop magnification. Heparin may be left unreversed if hemostasis is satisfactory after completion of the anastomoses.

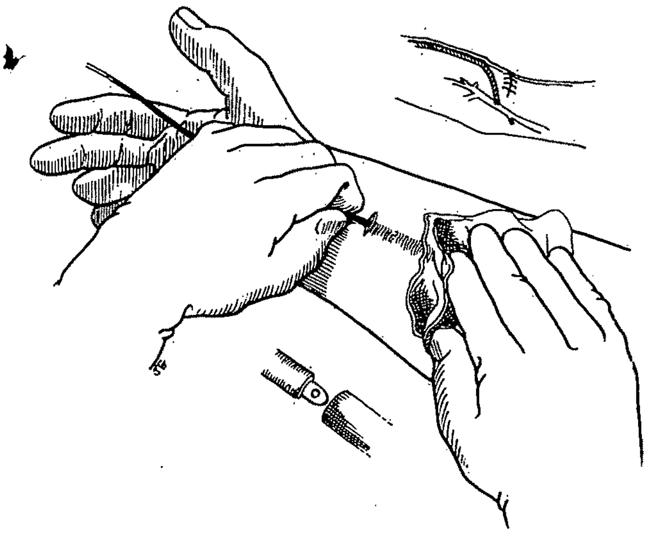

FIG. 1A. Tunneling techniques. Counter pressure against the instrument assures a superficially located tunnel. The tunneling instrument should be somewhat smaller in size than the graft diameter to ensure tamponade of the tunnel by the distended graft (offset below).

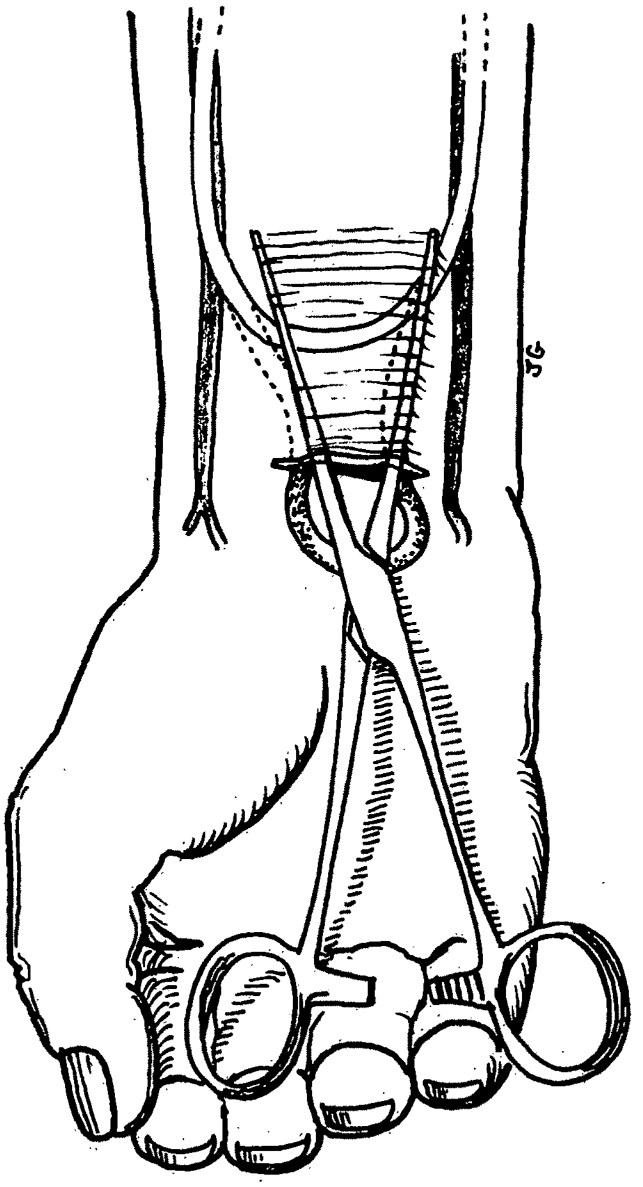

FIG. 1B. In looped grafts, counter incision for tunneling should not be located over the loop to avoid erosion by the graft. The maneuver depicted allows dislocation of the loop away from the incision.

After the procedure, the pulsatility of the graft should be monitored with and without clamp occlusion of the outflow end of the graft. A palpable increase in pulsatility with this maneuver confirms satisfactory outflow. In our experience, this maneuver has been more reliable than palpating "thrill" for this purpose. Since the most common cause of early graft thrombosis is inadequate outflow, this step is particularly important. Orally administered antibiotic with antistaphylococcal activity, usually cephalosporine or other, is continued for 3 to 5 days after surgery. The patient is instructed to avoid

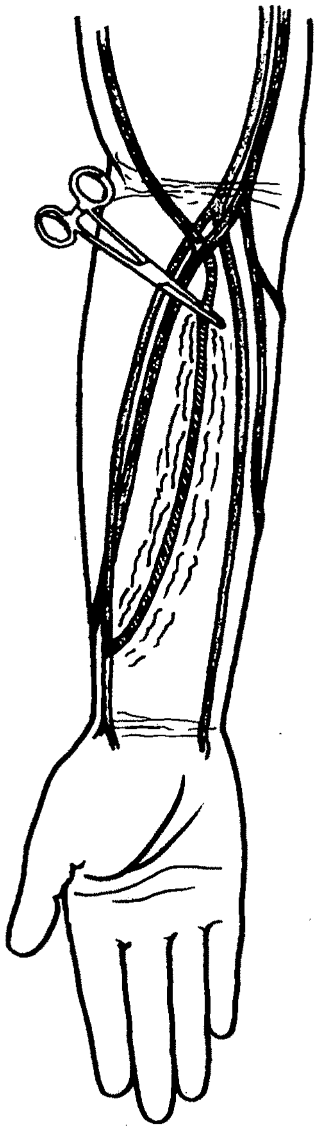

FIG. 2. Augmentation test to ensure adequate venous outflow to the graft. A palpable increase in pulsatility on occlusion of the outflow end confirms satisfactory outflow.

sleeping with the elbow bent acutely and to keep the arm elevated on a pillow for a few days after surgery.

Management of Complications

Thrombosis of the graft. A thrombosed access graft should be examined for palpable pulsations near the arterial end. These are invariably present, suggesting a problem at the venous end. Absence of pulsations at the arterial end of the graft may indicate poor inflow or propagation of thrombus into the arterial tree. Thrombosed grafts should be approached through the old antecubital incision used for construction of the venous anastomosis. A newer incision, creating a bridge of skin between two incisions with tenuous blood supply, is considered unnecessary. Circumferential control of the graft is likewise unnecessary and may lead to injuring the deep surface of the graft while attempting to pass an instrument around it. An incision is made over the "cobra head" in the prosthesis and the venous side thrombectomized with a Fogarty catheter. Heparin (5000 U) is immediately instilled into the open vein *via* a catheter. A Fogarty catheter (number 3 or 4) should be used next to declot the graft from the arterial end. Retrieval of the bullet-shaped clot from the arterial end with establishment of satisfactory inflow denotes a successful effort. A separate incision over the arterial end of the graft may occasionally be necessary to establish complete and satisfactory thrombectomy.

In approximately one-third of cases, the revision of the venous end is unnecessary as the venous anastomosis easily admits a 3-mm or larger coronary dilator. A positive augmentation test for pulsatility as previously described denotes satisfactory outflow (Fig. 2). Absence of satisfactory augmentation indicates the need for revision of the venous end. Revision may be carried out by a jump graft with a new venous anastomosis to an adjoining vein (basilic or cephalic) or to the same vein in a more cephalad location. The jump graft can cross the elbow crease if necessary to achieve this purpose. Venous endarterectomy and patch venoplasty are less preferred alternative procedures for revising the venous anastomosis. Venous endarterectomy is carried out by scraping the hyperplastic new intima at the venous orifice with a #5 blade that is carefully swirled circumferentially through the anastomosis (Fig. 3). Forceful dilation of venous stenoses with coronary dilators is unsatisfactory and often leads to injury and rupture of the venous segment.

Revision of the arterial end. Stenosis of the arterial anastomosis can be enlarged satisfactorily by incising the stoma with a Pott's micro scissors, introduced through an incision in the access graft placed directly over the anastomosis (Fig. 4). The enlarged stoma should be secured by a few sutures of fine Prolene to prevent extravasation and false aneurysm formation. However, this is usually not a problem because the graft is generally adherent to the artery for some distance beyond the anastomosis. Arterial control for this procedure is preferably obtained by a tourniquet (see below), thus avoiding tedious circumferential dissection around the arterial anastomosis for vascular control.

False aneurysm. Tourniquet control with systemic heparinization provides satisfactory vascular control and minimizes the extent of dissection around the false aneurysm. With tourniquet control, the aneurysm is boldly incised and the clot evacuated. The destroyed access graft is trimmed until a healthy graft is encountered. The missing segment is replaced by introducing a new piece of PTFE graft within the bed of the false aneurysm and anastomosis to the ends of the old graft for continuity. More extensive destruction of the PTFE graft by extensive aneurysm formation from repeated needle punctures is more appropriately treated by defunctionalizing the entire segment and bypassing the damaged length with a fresh graft routed through a separate adjoining tunnel and anastomosed to the undamaged ends of the old graft. At least 3–5 cm of the old graft should be preserved at each end for dialysis puncture until the fresh graft matures. Stenotic lesions in the access graft from intimal build-up or partial destruction may be similarly treated by segmental bypass.

Infection. Extensive infection of the graft with cellulitis and involvement of the suture lines will usually require complete excision of the graft and drainage for satisfactory control of the infection and sepsis. More limited infections may be successfully managed by incision and drainage with adequate antibiotic coverage. Superficial infections and, occasionally, a deep infection of the graft may heal with this approach. More frequently, the infected segment of the graft must be excised and bypassed for salvage of the access device. The bypass may be done immediately prior to the incision and drainage, or as a staged procedure a few days later when the inflammatory reaction has subsided following incision and drainage (Fig. 5). Occasionally we have succeeded in salvaging a prosthesis involved with a very localized chronic infection, presenting as a chronic sinus, without a bypass. The sinus and the infected tissue are completely excised; the graft itself is scraped clean of tissue and covered by adjoining healthy tissue by primary closure. Systemic antibiotics are necessary for successful salvage.

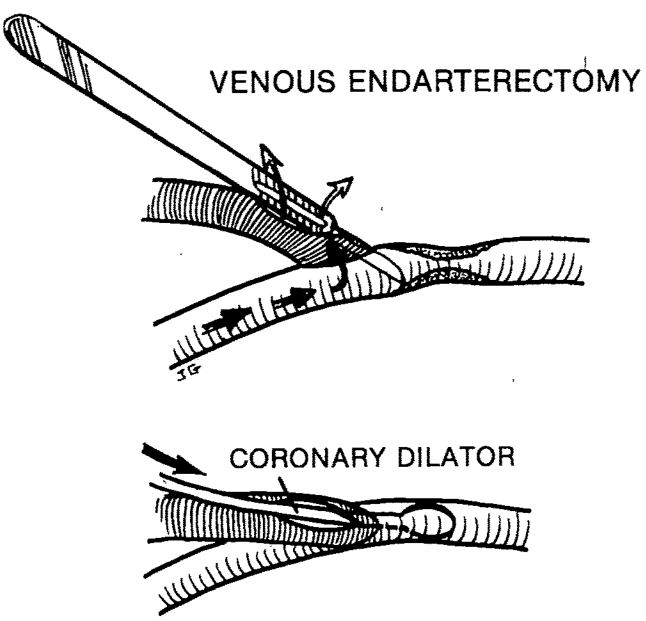

FIG. 3. Technique of venous endarterectomy. The coronary "dilator" should be used for sizing and minimal dilatation only. Ambitious dilatation usually results in false passage. Note "backbleeding" from distal vein.

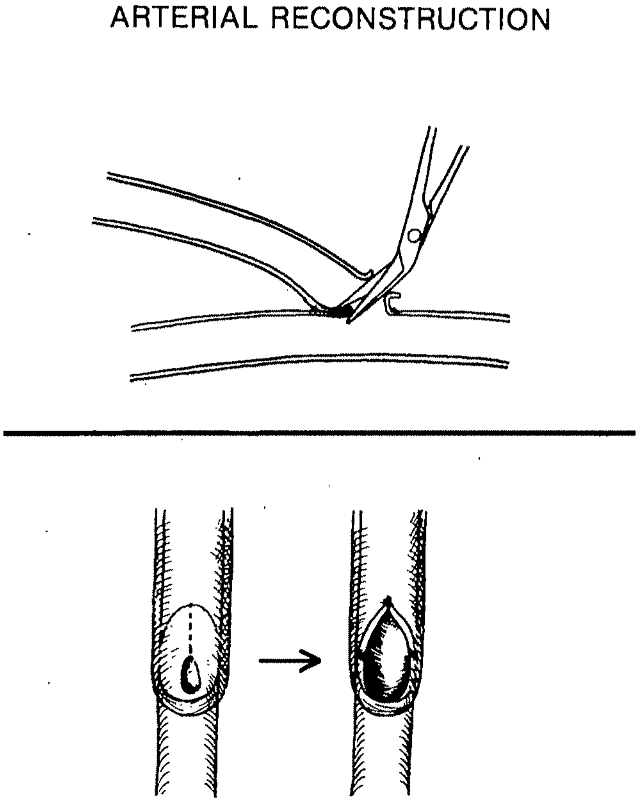

FIG. 4. Technique of arterial anastomotic revision. Because the graft is adherent to the artery for some distance, the common septum may be divided without fear of extravasation. A few sutures placed from inside ensure integrity of the stoma.

Results

Among the 602 forearm grafts inserted, only 28 loop grafts used the brachial artery. In all others a straight graft originating from the radial artery was used. Of the 28 loop grafts, the brachial artery was electively used in 15. In 13 others the radial artery was initially examined and found to be unsuitable to carry inflow into the access. Only then was the brachial artery chosen for access inflow. Among the 312 grafts with adquate follow-up, the straight graft was converted into a loop with inflow

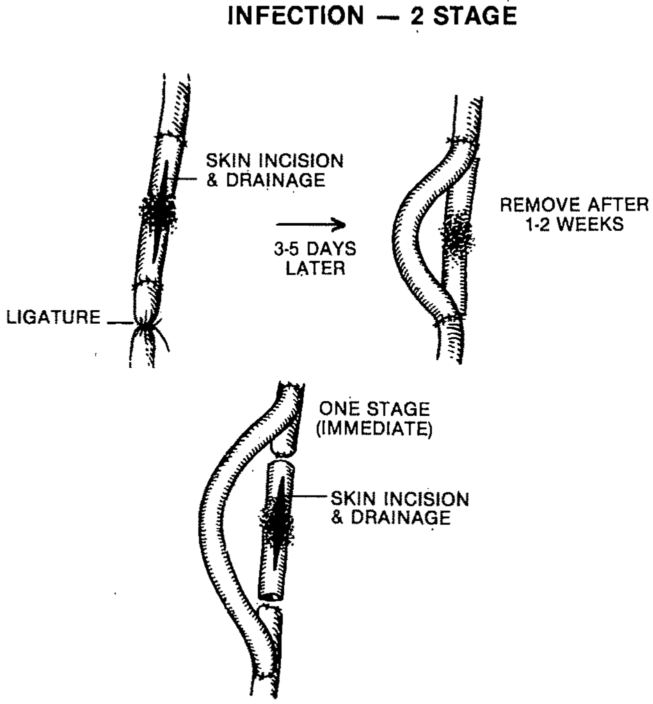

FIG. 5. Infections can be treated in two stages (top) with incision and drainage followed by a secondary bypass, or in one stage with a primary bypass (bottom).

from the brachial artery in a total of 17 grafts. Conversion was dictated by infection (5 grafts), inadequate radial artery inflow (8 grafts), or other technical reasons (2 grafts). Among the 312 grafts followed for a year or more, no further complications presented in 117. Complications were encountered in 195 grafts (64%). The mean interval between insertion and onset of first complication was 330 days for these 195 grafts. Of these 195 grafts, 124 suffered a recurrent complication, with a mean time interval of 182 days. A third complication was encountered in 62 grafts with a mean time interval of 178 days (*i.e.*, complication-free interval was stable for grafts suffering from recurrent complications).

The variety and incidence of complications are listed in Table 2. There were 372 primary and recurrent complication events in these 312 PTFE grafts. Thrombosis was the most frequently encountered complication, occurring in two thirds of the access grafts. Approximately one third of the complications were infection-related. Fifty false aneurysms were encountered in this series, usually due to repeated needle puncture at the same graft site. There were six instances of steal and three of gangrene in this series. Two of the three patients with gangrene were diabetic and carrying loop grafts from the brachial artery. There were no instances of access-induced cardiac failure in this group.

Access Thrombosis. There were 203 initial episodes of graft thrombosis and 282 total episodes including recurrent thrombosis. Twenty-four per cent of initial episodes (49 in 602 insertions for 8% incidence) were early, occurring within 2 weeks of graft insertion, while 76% occurred later. Over one-third (37%) of all thrombotic episodes were classified as simple (*i.e.*, no technical basis such as stenosis or poor inflow could account for the thrombosis). In the remaining two-thirds, a structural basis required surgical revision of the graft. Two-thirds of the revisions were needed at the venous end (Table 3). Arterial revision was required in 15% and replacement of a segment of stenosed or destroyed graft was necessary in 15%. In approximately one-third of the episodes requiring graft and/or arterial anastomotic revision, a concomitant venous revision was also necessary (Table 4). Jump graft with the new venous anastomosis was the preferred method of revision. Venous endarterectomy (Fig. 3) was resorted to in 13% of venous revisions. Patch venoplasty was used in 8%, often in association with venous endarterectomy (Table 4). Crossing the elbow crease for segmental revision did not adversely affect graft patency or recurrent thrombosis.

Graft infection. There were 110 episodes of infection in these 312 grafts. Staphylococcus was the most common infection (54%). Other organisms were encountered in 10%. In a surprisingly large number (36%) with clinical infection, there was no growth on bacteriological culture. This is possibly related to antibiotic coverage prior to culture or the presence of a responsible anaerobic organism, as anaerobic culture was not routinely done in these instances. Ninety grafts required surgical intervention for control of infection. Six of these 90 were nonfunctional old grafts and were simply excised. The infection was serious enough to warrant excision and abandonment of 24 functioning grafts. Simple incision, drainage, and systemic antibiotics was the mode of treatment in nine grafts. Six of these were subsequently salvaged with elimination of infection. The three grafts that did not respond to this treatment regimen were abandoned. Localized infection was excised and the graft covered over by fresh tissue in seven grafts. This maneuver eliminated infection in three, while the remaining four required subsequent excision of the graft and abandonment.

A local bypass around the area of infection was performed in 44 grafts. Thirty-nine (90%) had successful salvage of the graft with this maneuver. In 28 instances, the bypass was classified as primary (*i.e.,* the bypass was performed at the same sitting as the incision and drainage). In 16 others, the bypass was performed a few days after initial incision and drainage of the abscess with ligation of the graft to stall flow through the infected area. There was no difference in the salvage rate between primary and secondary bypass methods (Table 5).

The modified patency rate of the 312 grafts studied was 93% at 1 year and 77% at 2 years. The term "modified patency" denotes inclusion in survival statistics of those grafts salvaged by appropriate surgical intervention for management of the aforementioned complications.

Discussion

Certain principles of technique in dialysis access surgery using PTFE grafts merit emphasis. When possible, the graft should be placed in an accessible location (forearm) of the nondominant limb. The graft should be placed as superficially as feasible beneath the skin so that access puncture is easy, thus helping to minimize injury to the graft from multiple punctures, tangential punctures, etc. In our experience, the radial artery is preferred for the takeoff of the PTFE graft. Because of the natural size limitations of inflow, cardiac failure is virtually absent when this vessel is used. Since thrombotic and infectious complications are quite common in this group of patients, the choice of radial artery for initial insertion allows the option of moving up the arm to other arterial locations if the primary graft should be abandoned from complications. With infectious complications involving the suture line, the potential threat to limb or life is also much less when the radial artery is used rather than brachial or more proximal arterial points of takeoff. Most of the published reports[3,5] have used upper arm or loop grafts for PTFE dialysis grafts. The incidence of thrombotic and infectious complications reported in these more proximally located grafts, with a larger inflow artery, is in many respects quite similar to our experience with straight grafts reported herein.

TABLE 4. *Dialysis Access: Thrombectomy/Revision (282 Procedures)*

	Per Cent
Simple thrombectomy (103)	37
Thrombectomy with revision (179) *(approximately 2/3 require revision)*	63
Segmental replacement (156/179)	87
Venous endarterectomy (23/179) (8% with patch venoplasty)	13

The most common complication in our and other series[6,7] continues to be thrombosis of the graft. In about one-third of these complications, the thrombosis is cryptogenic (*i.e.,* no structural basis for thombosis could be found). In the other two-thirds, however, a stenosis was usually found at the venous end. For this reason, the venous anastomosis must be constructed meticulously with assurance of an excellent runoff at the time of primary insertion. This could help to reduce the incidence of early thrombosis of the grafts even though late thrombosis from intimal hyperplasia appears insensitive to good insertion technique. In our experience, the augmentation maneuver described in Figure 2 has been more useful to gauge adequate outflow than is monitoring for a thrill at the venous end. It is important to make the venous anastomosis to one of the named veins in the antecubital region. Unnamed subcutaneous veins, however large, have been disappointing in providing lasting runoff. The reason for this may be kinking of subcutane-

TABLE 5. *Salvage* Procedures for Access Infection*

* Thirty grafts were abandoned for extensive infection and required excision.

ous veins with elbow flexion, which does not appear to be a problem with the named veins situated beneath the fascia. Systemic heparinization is routinely used to prevent intraoperative vascular thrombosis.

Despite ensuring adequate runoff, some PTFE grafts repeatedly thrombose in the early period after insertion. The precise cause for this is not clear. Flexion of the elbow, creating kinking of the graft at the venous outflow, dehydration and low perfusion state, prolonged compression of the relatively immature graft for hemostasis at the needle puncture site, or clotting of the dialysis lines and apparatus are possible explanations. Appropriate measures, including an arm pad to keep the upper limb extended, hydration, maintenance of adequate perfusion pressure, and careful technique during dialysis, should be exercised. Despite all these precautions, every dialysis center has seen the occasional patient in whom the PTFE graft must be abandoned because of recurrent unremittent thrombosis in favor of some other dialysis technique.

Few PTFE dialysis grafts escape thrombosis at some point during their dialysis life. The problem can be localized to the venous end when arterial pulsations are present at the arterial end of the graft. When these are absent, an inflow problem, along or combined with an outflow stenosis, should be expected. In any event, thrombectomy of the graft should be approached through the old skin incision used for the venous anastomosis. A separate skin incision some distance away creates a skin bridge with compromised blood supply and moves away from the point of anastomosis at which the stenotic problem usually resides. If satisfactory declotting is achieved and the venous anastomosis admits a 3-mm or larger coronary dilator, anastomotic revision is usually unnecessary.

While venous endarterectomy and vein patch angioplasty can be used to correct discrete stenosis at the venous takeoff, we have come to rely increasingly on a jump graft to bypass the stenosed area altogether. The jump graft can be anastomosed to the same or other adjoining vein in a virgin area. This is usually accomplished through the same skin incision, especially when the anastomosis can switch from the cephalic to the basilic vein and vice versa. A large antecubital vein also provides a suitable outflow for primary insertion and subsequent revisions. If necessary, there should be no hesitation to cross the elbow joint in search of a suitable outflow vein, as joint crossing does not seem to affect patency.[8] Others have noted inferior patency[3] with patch venoplasty compared to the jump graft with new venous anastomosis. On the relatively infrequent occasions of stenosis of the graft at the arterial anastomosis, revisional procedures are simple and easily effected. Most primary insertions and revisions are accomplished under local anesthesia as an outpatient procedure.

In our experience and that of others,[3,9] the incidence of infection in dialysis grafts appears distressingly high. Infection leads to graft abandonment in a significant number and apparently recurs in at least some patients. It is not clear whether inattention to proper technique or inherent immune deficiency is responsible for this individual predilection. Even infection of the prosthesis can be managed with successful salvage of the graft if the infective process is relatively localized and extensive tunnel infection is absent. In some renal dialysis patients, even extensive tunnel infection may present with little outward signs of inflammation or tenderness. Despite close physical examination, such grafts may appear completely normal. Because of this experience, we tend to explore aggressively and to ligate grafts when evidence for bacterial seeding is present. Even when a tunnel infection was not encountered, ligation of the graft has resulted in cessation of the bacteremia in a few instances, suggesting suture line seeding.

While ligation usually results in immediate improvement in the status of the patient, the focus of infection must usually be excised eventually. In an occasional patient, septicemia has persisted despite ligation of the graft and was relieved only when the graft was completely excised and removed. The surprisingly large number of access devices salvaged from localized infection by bypass was gratifying. Results appear to have been equally good whether the bypass was primary or secondary. The choice between these two techniques resides primarily on the status of the graft site during drainage. If significant cellulitis of surrounding tissue is present, a secondary bypass followed by initial incision and drainage is appropriate. Primary bypass is useful for a very localized inflammatory process or for chronic and indolent sinuses.

Pseudoaneurysms are a frequent complication of PTFE grafts. Many of these occur in long-standing grafts subjected to repeated puncture and injury. An element of venous obstruction from stenosis is present in many, potentiating the false aneurysm from high pressure in the graft.[10] Despite careful instruction to the contrary, some patients tend to stick the PTFE graft through the same needle tract, exacerbating this complication. Revision of the false aneurysm and replacement with a segment of fresh graft is relatively easy. It has been our experience that the technique is made considerably easier by using a tourniquet for vascular control, rather than circumferential dissection for clamp application. In fact, in most other revisional surgical procedures involving the PTFE graft, either tourniquet, digital, or Fogarty vascular control is used as necessary to avoid circumferential dissection. Circumferential dissection has a potential for injury to the deep aspect of the graft and vessels and should be avoided when possible.

When the lifetime of a PTFE graft is finally expended from repeated and recurrent complications, a site in the forearm on the same or opposite side for secondary insertion should be easily achieved. Even among patients who have been on dialysis for 10 years or more, loss of site for access insertion has seldom occurred in our experience.

Ornithine-alpha-ketoglutarate Improves Skeletal Muscle Protein Synthesis as Assessed by Ribosome Analysis and Nitrogen Use After Surgery

JAN WERNERMAN, M.D., FOLKE HAMMARQVIST, M.D., ALEXANDRA VON DER DECKEN, PH.D., and ERIK VINNARS, M.D.

Total parenteral nutrition (TPN) was given for 3 days after elective abdominal surgery. The control group (N = 9) received TPN only and one group of patients (N = 6) received TPN supplemented with ornithine-alpha-ketoglutarate (0.35 g/kg bw/day). Protein synthesis in skeletal muscle was assessed from the total ribosome concentration and the percentage of polyribosomes. In the control group the total concentration of ribosomes decreased after surgery by 23% ($p < 0.05$) and the percentage of polyribosomes decreased by 21% ($p < 0.01$), whereas in the ornithine-alpha-ketoglutarate group both variables remained unaffected. The cumulative urinary urea excretion was significantly larger in the control group than in the ornithine-alpha-ketoglutarate group ($p < 0.05$). The calculated nitrogen balance was negative in the control group on each day of the study ($p < 0.05$), but that of the ornithine-alpha-ketoglutarate group was not statistically different from zero. The results show that postoperative maintenance of muscle protein synthesis and a more effective nitrogen use was achieved by supplementing TPN with ornithine-alpha-ketoglutarate, 0.35 g/kg bw/day.

From the Department of Anesthesiology and Intensive Care, Huddinge University Hospital, Department of Anesthesiology and Intensive Care, St. Göran's Hospital, and Wenner-Gren Institute for Experimental Biology, University of Stockholm, Sweden

IN NONMALNOURISHED ADULT patients, the immediate post-traumatic period is characterized by whole body protein catabolism and a negative nitrogen balance.[1] Nutritional support, including total parenteral nutrition (TPN), counteracts the nitrogen losses and improves the negative nitrogen balance without attaining equilibrium.[2,3] The postoperative nitrogen supply is influenced by increasing the total amount of nitrogen provided[4] or by increasing the proportion of branched chain amino acids given,[5,6] without reversing the negative nitrogen balance to positive values.

After trauma, protein metabolism is influenced differently in individual tissues; skeletal muscle is of special interest because it constitutes the largest protein reservoir in the human body.[7] Protein synthesis in skeletal muscle decreases after surgery,[3,8] whereas the rate of protein breakdown remains unaffected after surgery of a moderate magnitude.[8,9] Nutritional support does not seem to be sufficient to reverse these changes.[3,8]

Supplementation of TPN with ornithine-alpha-ketoglutarate has been shown to maintain nitrogen balance after abdominal surgery.[10] The characteristic postoperative increase in the intracellular concentrations of some essential amino acids in skeletal muscle is also counteracted by ornithine-alpha-ketoglutarate.[11] In this investigation following elective abdominal surgery, a control group of patients received TPN only. Another group, given TPN supplemented with ornithine-alpha-ketoglutarate, showed a lower cumulative urinary urea excretion and a maintenance of skeletal muscle protein synthesis as assessed by the concentration and size distribution of ribosomes compared with the control group.

Materials and Methods

Patients

Fifteen metabolically healthy patients admitted to the hospital for elective cholecystectomy participated in the study. Their voluntary consent was obtained after the study's purpose, procedure, and risks were explained. The study protocol was approved by the Ethics Committee of the Karolinska Institute, Stockholm, Sweden. The characteristics of the patients, along with the operating time and the postoperative blood loss, are given in

Reprint requests and correspondence: Jan Wernerman, M.D., Department of Anesthesiology and Intensive Care, Huddinge University Hospital, S-141 85 Huddinge, Stockholm, Sweden.

Submitted for publication: February 23, 1987.

Table 1. Premedication was given in the form of morphine-scopolamine and anesthesia was administered using pentothal, diazepam, fentanyl, pencuronium, and N_2O/O_2. As prophylaxis against postoperative thrombotic complications, 500 mL of dextran 70, 60 mg/mL (Macrodex, Pharmacia Infusion, Uppsala, Sweden), was given. Intercostal blocks using bupivacaine, 5 mg/mL (Marcain, Astra, Södertälje, Sweden), were administered to relieve postoperative pain and ketobemidone was given on request. No patients requiring replacement of blood products were included in the study.

Nutritional Support

The patients were given intravenous fluids, 35 mL/kg bw/day. During the surgical procedure, 25 mg/mL of glucose (Rehydrex, Pharmacia Infusion) was infused. TPN included 0.2 g N/kg bw/day given as a balanced amino acid solution (Vamin-Glukos, KabiVitrum, Stockholm, Sweden) and 135 kJ/kg bw/day was supplied as equal parts of fat (Intralipid, KabiVitrum) and carbohydrate (Glukos, 100 mg/mL, Pharmacia Infusion). The nutrition was supplemented with electrolytes, trace elements (Addex-Kalcium Spår, Pharmacia Infusion), and vitamins (Vitalipid Adult and Soluvit, KabiVitrum). On the day of operation, half the nutritional regimen was administered.

The patients were randomized into two groups. The control group (N = 9) followed the TPN regimen previously described and the ornithine-alpha-ketoglutarate group (N = 6) was given the TPN regimen supplemented with ornithine-alpha-ketoglutarate, 0.35 g/kg bw/day (Ornicetil, Laboratoires Jaques Logeais, Paris, France). This amount of ornithine-alpha-ketoglutarate contains 0.01 g/kg bw/day of nitrogen, which was included in the calculation of the nitrogen balance but was disregarded as a nitrogen source with regard to the comparability of the two groups. The caloric content of 0.35 g of ornithine-alpha-ketoglutarate is approximately 5 kJ, which was regarded as neglectable as an energy source in the calculations.

Ribosome Analysis

The method for analyzing the ribosomes from skeletal muscle has been described in detail previously.[12] Muscle biopsy specimens of 50 mg wet weight were taken by the percutaneous needle technique after local anesthesia of the skin.[13] The specimens were frozen in liquid nitrogen within 2 minutes and then stored at −80 C for less than 2 weeks before analysis. The biopsy specimens were homogenized in a medium containing an RNase inhibitor. After centrifugation at 1500 × g for 10 minutes, the pellet was saved for the determination of DNA. The supernatant was ultracentrifuged at 102,000 × g for 2 hours in a 40.2 rotor (Beckman Instruments, Palo Alto, CA). The ribosome pellet obtained was suspended in medium. A portion of the suspension was layered onto a linear density gradient between 0.4 and 1.5 M sucrose. After centrifugation in a SM 50.1 rotor (Beckman Instruments) for 60 minutes at 149,000 × g, the gradient was pumped through a continuous flow cuvette and the absorbency was monitored at 260 nm. The area under the absorbency curve was determined. The total ribosome concentration was determined from the absorbency at 260 nm. The concentration was expressed as optical density (OD) units per milligram of tissue DNA. The DNA content was analyzed by a fluorometric method[14] using salmon DNA as a standard.

TABLE 1. *Characteristics of Patients and Surgical Procedure (Mean ± SEM)*

	Control Group	Ornithine-alpha-ketoglutarate Group
Sex (female/male)	5/4	4/2
Age (years)	58 ± 4	58 ± 6
Height (cm)	171 ± 4	168 ± 4
Weight (kg)	70 ± 4	69 ± 6
Operating time (min)	86 ± 15	102 ± 12
Peroperative blood loss (mL)	210 ± 30	180 ± 40

Urea Excretion and Nitrogen Balance

Urine was collected in 24-hour portions and assayed for urea.[15] The serum concentration of urea was determined daily and it varied less than 2 mmol/L; hence, the total urea pool of the patients was considered constant since there was no change in their body weight during the study. The nitrogen balance was calculated using the approximation suggested by MacKenzie,[16] estimating the nonurea urinary nitrogen losses to be 1.8 g/24 hours and the nonurinary nitrogen losses to be 1.7 g/24 hours.

Statistics

All values are given as mean ± SEM. Student's t-test for paired samples was used to compare different observations, and a two-way analysis of variance was used to compare the two different groups.[17]

Results

Skeletal muscle biopsies were performed immediately before the operation and on the morning of the third day after surgery. The ribosome fraction was isolated from the biopsy specimen and the concentration and size distribution of the ribosomes was determined. The percentage of polyribosomes was determined from the ribo-

Day 3	−3.1 ± 0.9	−1.0 ± 1.3

some profile, where the area under the curve is proportional to the amount of ribosome particles of different mass. The percentage of polyribosomes out in the total number of ribosomes decreased by 21% on the third day after surgery compared with the initial values in the control group ($p < 0.05$). No such decrease was demonstrated in the ornithine-alpha-ketoglutarate group (Table 2). The alteration was significantly different between the two groups on the third postoperative day ($p < 0.05$).

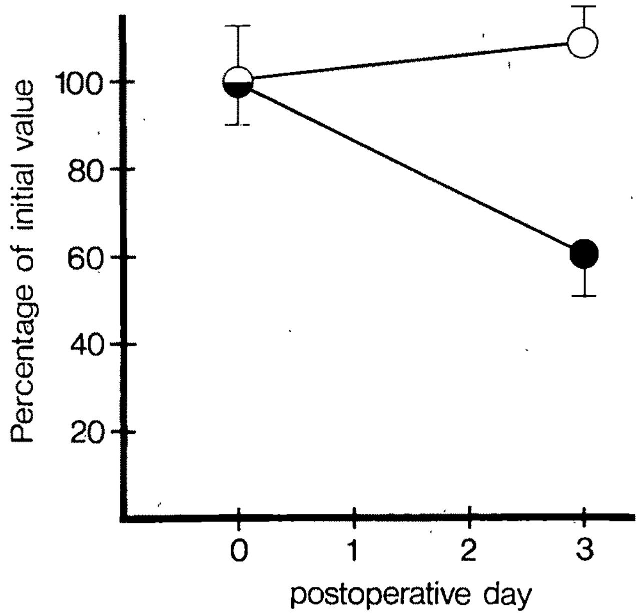

FIG. 1. The polyribosome concentration in skeletal muscle before surgery and on the third postoperative day in patients undergoing elective abdominal surgery. Patients received TPN (N = 9, filled circles) or TPN supplemented with ornithine-alpha-ketoglutarate (N = 6, open circles). The values are expressed as percentage of the original values noted before surgery. In the control group, the polyribosome concentration decreased significantly ($p < 0.001$). There was no postoperative decrease in the ornithine-alpha-ketoglutarate group. On the third postoperative day there was a significant difference between the two groups ($p < 0.01$). Values are given as mean ± SEM.

A comparison of the pre- and postoperative conditions in the control group showed a decrease in the total concentration of ribosomes per milligram of DNA by 23% on the third day after the operation ($p < 0.01$; Table 2). In the ornithine-alpha-ketoglutarate group no difference between the values was noted before and after surgery. On the third day following surgery the changes were significantly different between the two groups ($p < 0.05$). The concentration of polyribosomes per milligram of DNA was calculated from the total concentration of ribosomes and the percentage of polyribosomes. In the control group there was a 38% decrease in the polyribosome concentration between the original value and that of the third postoperative day ($p < 0.001$; Table 2). In contrast, the ornithine-alpha-ketoglutarate group showed no change in the polyribosome concentration 3 days after surgery (Fig. 1). On the third day after surgery the difference between the two groups was highly significant ($p < 0.01$).

Urinary urea was analyzed in 24-hour portions (Table 3). There was a significant larger cumulative excretion during the initial 3 days after surgery in the control group compared with the ornithine-alpha-ketoglutarate group ($p < 0.05$). Nitrogen balance was calculated from the urinary excretion of urea as presented in the Materials and Methods section. In the control group the nitrogen balance was negative on each day of the study ($p < 0.05$; Table 3). In the ornithine-alpha-ketoglutarate group the nitrogen balance was not statistically different from zero on any of the first 3 days after surgery. The cumulative nitrogen balance was calculated for the initial 3 postoperative days (Fig. 2). The difference between the two groups became statistically significant on day 3 after surgery ($p < 0.05$).

Discussion

Protein metabolism was evaluated by ribosome analysis. The total concentration of ribosomes is interpreted as a measure of the capacity for protein synthesis.[18,19] A high content of polyribosomes corresponds to a high rate of protein synthesis.[20] Hence, the percentage share of polyribosomes is a measure of the activity of protein synthesis. Especially when several consecutive samples are available, changes in protein synthesis activity can be studied over a prolonged period.[12,18,21] The reproducibility of total ribosome concentration per milligram of DNA and the percentage of polyribosomes is approximately 6% in both cases when the current technique is used.[22]

Protein synthesis in skeletal muscle was assessed from the total concentration and size distribution of ribosomes. Applied to human muscle tissue, this technique shows a decrease in both variables after elective abdominal surgery, regardless of whether TPN is given in the immediate postoperative period.[3] An isonitrogenous amino acid solution enriched with branched-chain amino acids cannot prevent this decrease.[6] Supplementation of a standard TPN program with ornithine-alpha-ketoglutarate prevented the fall in both the total ribosome concentration and the percentage of polyribosomes. These findings are in accordance with the normalization of the intracellular concentrations of free branched chain and aromatic amino acids seen after surgery.[11] The preserving effect of ornithine-alpha-ketoglutarate on whole-body nitrogen economy, as indicated by the improvement in nitrogen balance, confirmed previous results.[10]

The mechanism for the nitrogen sparing effect of ornithine-alpha-ketoglutarate is not clear. Supplementation of TPN with ornithine has no beneficial effect on nitrogen economy after surgery (E. Vinnars, unpublished results). One hypothesis is that alpha-ketoglutarate, being the corresponding ketoacid to glutamic acid, can counteract the increase seen after trauma in nitrogen efflux from the periphery to the splanchnic area. Ornithine-alpha-ketoglutarate, 0.022 g/kg bw/h, given for 150 minutes to healthy male volunteers after an overnight fast, does not affect the efflux of amino acids from peripheral tissue.[23] The effect on amino acid flux in patients in protein catabolic states remains an open question. To improve nitrogen use and to benefit from the nitrogen sparing effect, ornithine-alpha-ketoglutarate possibly should be given with a nitrogen supply.

The balanced amino acid solutions that are commercially available do not include glutamine, and the content of glutamic acid is limited by its tendency to evoke nausea when given in high concentrations. The alpha-ketoglutarate included as ornithine-alpha-ketoglutarate presumably provides enough carbon skeletons to compensate for a shortage of glutamine/glutamic acid in the commercially available amino acid solutions. In animal experiments, post-traumatically administered glutamine prevents the profound decrease in the intracellular free glutamine concentration in skeletal muscle seen otherwise,[24] and the overall nitrogen economy is improved. Ornithine-alpha-ketoglutarate given to patients undergoing colonic resection does not prevent the decrease in the intracellular concentrations of free glutamine.[11] In animals both the influx of branched chain amino acids and the total intracellular free amino acid nitrogen are correlated to the efflux of amino acid nitrogen from peripheral tissue after surgery. To determine if a shortage of glutamine is the critical point in post-traumatic protein catabolism, it seems reasonable to give glutamine to human subjects also. The pharmaceutical difficulty involved in preparing a stable glutamine solution remains a crucial problem. The dipeptides currently available for research purposes may be another future source in this context.

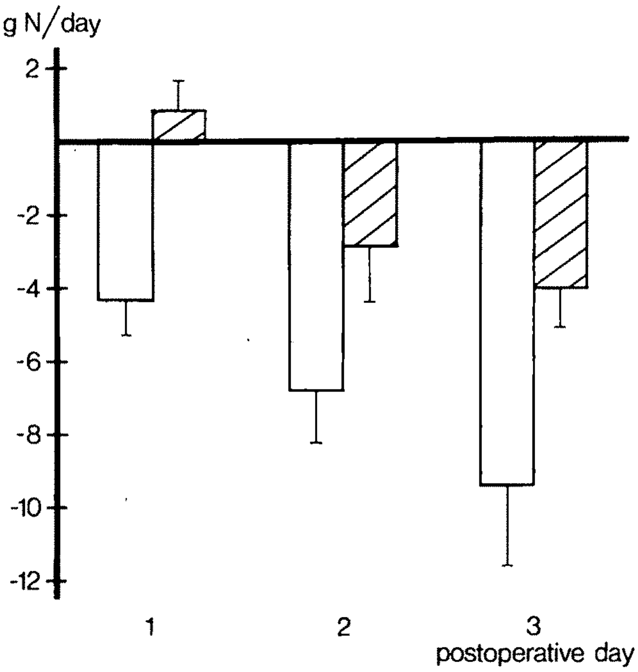

FIG. 2. The cumulative calculated nitrogen balance on days 1–3 immediately after elective abdominal surgery. Patients received TPN (N = 9, open bars) or TPN supplemented with ornithine-alpha-ketoglutarate (N = 6, hatched bars). There was a significant difference between the two groups on each day ($p < 0.05$). Values are given as mean ± SEM.

In conclusion, after elective abdominal surgery, TPN supplemented with ornithine-alpha-ketoglutarate prevented the decrease in skeletal muscle protein synthesis normally observed with TPN only and diminished urinary urea excretion. The findings suggest the use of ornithine-alpha-ketoglutarate as a supplement to nutritional support after major surgery and in septic patients. The mechanisms underlying the nitrogen sparing effect of ornithine-alpha-ketoglutarate are not clear and require further investigation.

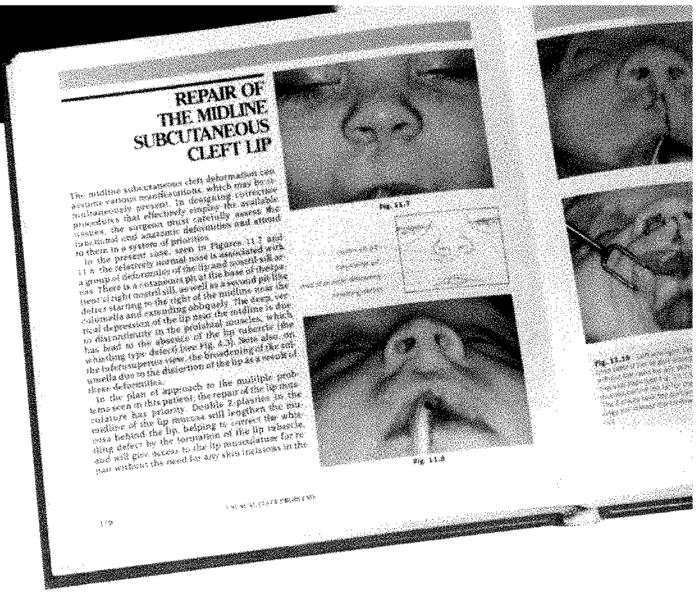
A vivid, FULL COLOR ATLAS...



Techniques in CLEFT LIP, NOSE AND PALATE RECONSTRUCTION

...show you the art of reconstructive plastic surgery for children born with cleft deformities

By Donald I. Kapetansky, M.D.

Foreword by D. Ralph Millard, Jr., M.D.

250 Beautiful, full-color illustrations...

. . . show you some of the most effective and efficient procedures in use today to correct cleft deformities in children. Sequential photographs of operations show each step of repair. Clear, close-up photographs show cleft deformities from various angles to help you fully understand the patient's condition. Detailed line drawings, full-color schematic diagrams, and explanatory text accompany the photographs and clarify important aspects of the deformities and the surgical techniques employed to correct them.

Complete coverage of surgical procedures

This book is divided into four parts, each focusing on a particular type of congenital deformity. Parts I and II focus, respectively, on primary and deferred corrective procedures for unilateral and bilateral cleft lip and nose reconstruction. These sections are primarily concerned with improving the child's appearance. Part III deals with cleft palate reconstruction and pharyngeal-flap procedures. This section details surgical techniques aimed at restoring the function of the palate in speech production—without producing iatrogenic facial deformities. Two types of transverse pharyngeal-flap surgery are described in this section. Part IV deals with some unusual cleft problems and three case studies in long-term cleft reconstruction.

Considers the total perioperative picture

With 25 years of practice and more than 2500 cleft operations to his credit, the author brings a wide range of experience and an authoritative viewpoint to this work. From a concentration on techniques that require fewer staged procedures, to methods of suturing the skin, to the use of long-acting local anesthetics even with general anesthesia—you'll find a multitude of suggestions for pre- and postoperative care and interoperative planning that aim to ease the strain on children enduring multiple surgical procedures.

Surgery of the Gallbladder and Bile Ducts. Lawrence W. Way, Carlos A. Pellegrini. 700 pp. Philadelphia: W. B. Saunders Co. 1987. $85.00.

THIS IS A COMPREHENSIVE BOOK that consists of 43 chapters spanning 676 pages and a 24 page index. It covers almost every aspect of biliary tract disease as well as pertinent physiology and pathophysiology. Fifty authors contribute their expertise and insight. With few exceptions, the chapters are remarkably uniform in their approaches. In addition to the traditional subjects, there are chapters dealing with parasites and infestations, fistula, pediatric problems, and even trauma. One can only quibble with certain minor omissions. Someone not completely familiar with the field may have difficulty in trying to decide what is the best approach to treating a particular biliary tract problem, for the style of the book is directed at a fairly knowledgeable audience. The latter will appreciate its depth. The chapters are particularly well referenced.

Not all of the chapters approach certain aspects from the point of view that there is controversy; those that do are masterful. The neophyte may have a problem knowing that controversy exists and that a particular author's view represents an extreme bias, but the information presented serves as a solid foundation for exploring the original literature. Those sections dealing with the technical aspects of surgery contain the usual amount of dogma. Near perfection would have been achieved had the authors given the historical and physiologic or rational bases or more comprehensive explanations for certain operative approaches or details. Even these omissions, however, do not detract from enjoying the crisp, informative style of the chapters. This is a book for surgeons and gastroenterologists alike, but not for someone looking for the nuances of the technical aspects of biliary tract surgery. Would I buy it? Yes, it's a new standard reference.

DAVID FROMM, M.D.
Syracuse, New York

Atlas of Advanced Surgery. Martin S. Litwin. 198 pp. New York: Yorke Medical Books. 1986. $95.00.

FULFILLING THE EDITOR'S PLAN, 42 authors contributed 37 chapters on surgery of the enteric and splanchnic venous systems to this attractive book so that ". . . the reader has ready access to contemporary descriptions of these operations in a clearly illustrated way that does not necessitate a literature search." Sampling a quarter of the articles shows the array: Ellis, *Esophagogastrectomy;* Urschel, *[Esophageal] Diversion and Exclusion . . .*; Thal, *Fundic Valvuloplasty . . .*; Hill, *Hiatal Herniorraphy. . .*; Longmire, *Intrahepatic Cholangiojejunostomy. . .*; Calne, *Hepatic Resection;* Jones, *Transduodenal Sphincteroplasty;* Litwin, *Pancreaticoduodenectomy;* Kock, . . . *Continent Ileostomy;* Localio, *Abdominosacral Resection*. . . . The typography is clear. Original and adapted renditions by a single artist lend desirable consistency.

In redaction the publishers have done less well. Typographic errors begin in the preface. 'This' is frequent as a pronoun without an antecedent. Superfluous 'It. . . that' clauses begin sentences. Orotund and self-evident statements are permitted. Some units of measure are nonstandard or obsolete: gm for gram; 0.5 needle; # 40 French in one part, no. 40 French in others. 'Pancreatico-' is confused with 'pancreato-.' Some trade names are capitalized, others not.

The question a potential buyer might ask is, "What is 'advanced' surgery?" Although some topics included in *Zollinger and Zollinger* are also to be found in this book, complex vascular and endocrine surgery are not. This is a fine reference in alimentary tract surgery for chief residents and stages beyond.

RONALD A. MALT, M.D.
Boston, Massachusetts

Surgery of Coronary Artery Disease. D. J. Wheatley. 676 pp. St. Louis: The C. V. Mosby Co. 1986. $79.95.

SINCE CORONARY ARTERY bypass surgery became an acceptable clinical procedure, a vast amount of literature has been written addressing the subject. Numerous attempts to assimilate, organize, and condense this large amount of material into a comprehensive teaching and reference text have met with a wide array of results. Few have been as successful in attaining this monumental task as has D. J. Wheatley in *Surgery of Coronary Artery Disease.*

This text represents a comprehensive manuscript "intended primarily for the trainee and practising cardiac surgeon." Beginning with a detailed historic review of the subject, it outlines completely the entire scope of patient management, including up-to-date diagnostic modalities, indications for medical therapy, and newer invasive medical techniques (percutaneous transluminal coronary angioplasty and intracoronary thrombolysis). The entire scope of surgical treatment, including preoperative assessment, operative technique, and postoperative care is thoroughly reviewed, and the management of associated complications and concomitant illnesses discussed.

The contributing authors represent a roster of many of the world's outstanding cardiovascular physicians in their particular field. The list of references following each chapter is extensive, well-organized and complete.

Some of the illustrations obtained from coronary angiography are not clear, and a number of those in the text could have been eliminated without detracting from its overall content. The information rendered by various contributing authors at times overlaps in subject matter. Lacking is a chapter dealing with the treatment of end-stage coronary ischemia and myocardial failure, including the use of mechanical support devices and cardiac transplantation. However, these deficiencies are minor when compared with the overall superiority of the text.

I second the opinion of Dr. Denton A. Cooley, who states in the Foreword of the text: "This elegant book is a careful, studious approach to the surgical treatment of coronary artery disease . . . and will be a reference of inestimable value both to cardiologists and cardiovascular surgeons as they meet the needs of patients with coronary artery disease."

KENT W. JONES, M.D.
Salt Lake City, Utah

A Colour Atlas of Gastrointestinal Endoscopy. K. F. R. Schiller, Roy Cockel, Richard H. Hunt, with the collaboration of B. Sterry Ashby, Giles W. Stevenson. 240 pp. Philadelphia: W. B. Saunders Co. 1987. $110.00.

GASTROINTESTINAL ENDOSCOPY is a visual procedure. Although the final diagnosis should be based on histopathology, pattern recognition of lesions and the detection of abnormality (to prompt taking biopsies) are of primary importance. It is therefore surprising that few atlases of normal and abnormal appearances have been published, despite the wealth of experience throughout the world over the last 20 years and the billions of photographs that have been taken.

The scarcity of atlases reflects the size of the task in assembling a comprehensive selection of good quality pictures, encompassing all areas of the gastrointestinal tract and its diseases.

This atlas certainly succeeds in its aim, to provide a manual for less experienced endoscopists and a reference source for the experienced. The photographs are generally of high quality. There are some exceptions where the rarity of the lesions, or the excitement of the occasion, may have affected the outcome. Thus, some illustrations of rarer types of polyps and of emergency procedures in bleeding patients are less than ideal. Experts will review these pictures carefully to see if they disagree with any interpretation. The pancreatogram illustration of "minimal change pancreatitis" might be interpreted as more severe disease by some. We question the description of the common periampullary diverticulum as "congenital" and do not like the described method for placing a feeding tube, which appears to involve passing the endoscope with the forceps protruding from the tip. There are some minor errors in the references. The line drawings, although of good quality, add little to the clarity, since they are not annotated.

This atlas should be available in all areas where endoscopy training programs are pursued, and many individual gastroenterologists will wish to have a personal copy.

PETER B. COTTON, M.D.
Durham, North Carolina

Letters to the Editor

November 21, 1986

Dear Editor:

Drs. Rotstein, Pruett, and Simmons[1] demonstrated that fibrin deposition by peritonitis significantly impairs phagocytosis of bacteria by neutrophils enmeshed in fibrin, and that contaminated fibrin predispose to residual abscess formation even if an adequate number of normal leucocytes were present.

Considering that fibrin deposition blocks the action of parenterally administered antibiotics because of its lack of vascularity, and that it is at the same time the main cause of early and late intestinal obstructions (due to the anarchical arrangement of bowel loops), there is every reason to admit that the removal, in some way or another, of this fibrino-purulent coat would constitute an essentially therapeutic approach in the treatment of acute septic peritonitis.

Hudspeth[2] resorted to the so-called "radical surgical debridement," employing a scrupulous cleansing procedure of the entire peritoneal surface "by forceps and gentle dissection," but the author himself qualifies this procedure as tedious and time-consuming (average operating time 3 hours). This type of operation was viewed with skepticism and did not gain acceptance.

Polk and Frey[3] did a randomized, prospective comparison study between radical peritoneal debridement (RPD), of Hudspeth type, and standard surgical management of peritonitis, concluding that RPD shows no benefit in survival nor reduction of frequency of reoperation between the two treatment groups, and that data further suggest that elderly patients tolerate radical peritoneal debridement poorly, as indicated by uniform death of patients over 60 years of age in the RPD group.

At the discussions about this study at the 100th Annual Session of the American Surgical Association (Atlanta, April 23–25, 1980), the speakers[3] qualified RPD as: a disastrous approach; risk of spreading the infectious process and increase of paralytic ileus; difficult job to remove all the exudate, particularly in some of the recessed pockets and spaces of the peritoneal cavity, such as the subphrenic areas and the lesser peritoneal sac.

Starting in the early 1960s, I employed in a series of patients with peritonitis an enzymatic debridement, utilizing freshly (ad hoc) prepared solutions of crystallized trypsin or chymotrypsin in isotonic saline: by gently wiping with a pad soaked in this solution, it is possible to remove quite easily, quickly and atraumatically the fibrino-purulent pseudo-membranes without bleeding or visceral trauma, especially to the intestines. To prevent a prolonged enzymatic action upon the peritoneum, the respective field is intermittently irrigated with isotonic saline (at body temperature). At the end of the procedure, before closing the abdomen, one irrigates again systematically and abundantly the abdominal cavity. Proceeding in this manner, I achieved in some cases startling results with respect to survival, and in others a remarkable lack of major complications (recurrent abscess formation, intestinal obstructions).

Due to reasons beyond my control, I was unable to conduct any experimental studies pertaining to systemic or local side effects, to the optimal enzymatic concentrations, or to the utilization of other proteolytic enzymes/(new substances?), but I do believe that this approach could be (for the interested in this problem) an object of investigation.

VICTOR E. MUNTEAN, M.D.
Stuttgart, West Germany

April 9, 1987

Dear Editor:

Thank you for the opportunity to reply to Dr. Muntean's letter. The three major defense mechanisms comprising the body's response to bacterial soiling of the peritoneal cavity are: (1) mechanical clearance of bacteria *via* the diaphragmatic lymphatics, (2) influx of phagocytic cells (initially macrophages and then neutrophils), and (3) sequestration of bacteria by fibrin deposition.[1] The consequences of bacterial sequestration by fibrin appear to be somewhat paradoxical. In the initial phases of peritonitis, fibrin plays an important role in preventing the systemic spread of bacteria, thereby reducing the mortality associated with a large bacterial inoculum into the peritoneal cavity.[2,3] However, studies from several laboratories, including our own, have demonstrated that the infected fibrin sequestrum can act as a nidus for residual infection and subsequent abscess formation.[2–4] Thus, the scientific rationale for debridement of fibrin (either mechanical or enzymatic) as a means of preventing abscess formation is well based.

Both heparin and low molecular weight dextran have been shown to be capable of preventing abscess formation and improving survival in animal models of intra-abdominal infection (usually intestinal devascularization).[5–7] In the single reported study in which intra-abdominal abscesses were initiated by enmeshing bacteria with a fibrin clot, heparin and heparin fractions without anticoagulating properties failed to prevent abscess formation.[8] The use of fibrinolytic agents as suggested by Dr. Muntean has been tested by Rodeheaver et al.[9] in a wound infection model. These authors demonstrated that several fibrinolytic agents were able to obviate subcutaneous infection initiated by an infected plasma clot. Further rationale for the use of fibrinolytic agents is gained from examining peritoneal adhesions as an analogy for abscess formation. Their pathogenesis derives from sterile fibrin exudates, which act as matrices for collagen deposition and subsequent adhesion formation.[10] Experimentally, adhesions have been prevented with the fibrinolytic agents streptokinase and urokinase, which act by converting plasminogen to plasmin.

Prevention of abscess formation following surgery for diffuse peritonitis would contribute significantly to the reduction of morbidity and mortality in this disease. The ideal fibrinolytic agent must act locally in the peritoneal cavity, should cause minimal local tissue trauma, and should effect gradual dissolution of the infected nidus so that the beneficial sequestering action of fibrin will not be lost. Studies examining different fibrinolytic agents in this role are presently being performed by one of the authors (O. R.). The rationale for these studies are echoed in Dr. Muntean's letter.

March 18, 1987

Dear Editor:

In their article, "Jejunal Interposition for Benign Esophageal Disease," C. Wright, M.D., and A. Cuschieri, M.D., in Ann Surg 1987; 205:54–60, describe their procedures in 30 patients, 21 of which were for intractable reflux stricture. The surgery for these 21 procedures deals with the end result of a pathologic process, not with the basic cause. It was also accompanied by 25 significant complications. The basic cause of reflux may still remain. If the stricture can be dilated, antrectomy and Roux-n-Y gastroduodenostomy results in cessation of reflux and no further stenosis.[1–4] Is it possible that the incidence of carcinoma of the gastric pouch would be less than the 4.5-fold increase reported after 20 years, with diversion of bile with the Roux-en-Y?[2] McCallum et al.,[5] have shown that gastric emptying of an isotope-labeled semisolid meal was delayed in 41% of patients with gastroesophageal reflux. This could result in distraction of the gastric wall and the valvuloplasty with return of reflux.

It is interesting to note that Nissen may have recognized the causative factor of reflux in small hiatal hernias and in reflux without hiatal hernia, where he found the angle of His was obtunded. Here he did both an anterior gastropexy and a fundoplication.[6] The loss of the angle of His may be early evidence of poor gastric emptying and distraction of the gastric wall.

Kim and Malagelada[7] have described a pacemaker present in the distal greater curvature of the stomach that regulates gastric emptying. Bradygastria, tachygastria, and arrhythmia may upset the normal 3 cycles/minute of the pacemaker, resulting in poor gastric emptying and antral dysfunction. Medical management with metaclopramide may be helpful. Rather than surgery, could there be a place for an implanted pacemaker responsive to gastric wall distraction?

April 8, 1987

Dear Editor:

In reply to Dr. Lawrence Braslow's letter, oesophageal replacement with a jejunal loop, or for that matter colon, is recommended for disease that necessitates *excision* of the involved gullet. It is not recommended as the treatment for reflux disease. The high postoperative morbidity due largely to respiratory complications described in this series reflects the very high incidence of chronic obstructive airways disease and cigarette smoking in Scotland and is comparable to that encountered after major abdominal surgery in this country. The safety of the procedure is reflected by the one postoperative death (3.5%) that occurred in a patient in whom the oesophageal resection and jejunal replacement were performed as an emergency after severe rupture, complicating attempts at dilatation of an intractable stricture.

A. CUSCHIERI
Dundee, Scotland

April 23, 1987

Dear Editor:

Starr and Cornicelli[1] have reported a method to improve accuracy of central venous catheter placement in 84 patients presenting for cardiac surgery. Although of interest, their technique cannot be considered as a method of choice for two reasons.

First, the high incidence of serious, acute complications associated with the subclavian route for insertion of central venous catheters is well documented.[2] Indeed, the occurrence of subclavian artery punctures (3 patients), pneumothoraces (2 patients), and persistent skin bleeding (2 patients) in Starr's patients who were about to undergo cardiac surgery (presumably with positive-pressure ventilation and heparin administration) is a testament to the frequency of serious complications that are encountered with this approach. In practice, cannulation of the right internal jugular vein is preferable, and safer, prior to anticoagulation.[3]

Second, it seems anomalous to produce a minor complication (premature atrial contractions) to verify successful positioning of a central venous catheter. When accurate location of the catheter tip is mandatory, the standard methods to confirm position remain chest roentgenography, transduced pressure wave form, and P wave configuration on ECG with the saline-filled catheter functioning as a unipolar ECG lead.[4]

Richard H. Riley, M.B., B.S.
Neville J. Davis, F.F.A.R.A.C.S, F.F.A.R.C.S.

May 20, 1987

Dear Editor:

Our recent paper describes the use of a floppy tip J-wire to deliberately induce PACs during CVP catheter placement, in order to ensure correct catheter tip location.

The letter from Dr. Riley and Dr. Davis contains two criticisms. The first relates to our use of the subclavian route, as opposed to the internal jugular or other route, for the successive introduction of the 18G needle, floppy tip guidewire, and catheter. The perennial subclavian/internal jugular controversy is moot to the point of the paper, since the guidewire technique can equally well be used with either of these methods. I concede that the weight of literature is in favor of the internal jugular route, but my personal feeling is that, in such an operator-dependent area, each doctor must use the method that gives him or her best results in terms of correct placement ratios, complications, and time spent on the procedure. However, the paper purposely did not pretend to enter this controversial area.

The second criticism relates to the anomaly of using deliberate induction of PACs to detect the presence of the J-wire tip in the right atrium. Perhaps the most challenging concept in our paper was the proposition that such PACs are in fact benign, and rather than being considered a complication, should be considered a signpost to the right atrium.

Lastly, our method was intended to supplement and not to replace the standard methods mentioned in the letter. Indeed it was our dissatisfaction with the existing methods (for technical or logistical reasons) that led us to look for a simpler and more reliable index of CVP catheter placement. My personal view is that, in hospitals blessed with an efficient and accurate x-ray department, an immediate chest x-ray is the procedure of choice for confirming correct CVP tip location. Thus the "procedure of choice" concept referred to above must depend on each hospital's strengths and weaknesses. Our paper merely introduced another methodology for the consideration of our colleagues.

David S. Starr, M.D.
Toledo, Ohio

April 20, 1987

Dear Editor:

Dunnington et al. report that jaundice in patients with alcoholic cirrhosis is rarely the result of cholelithiasis.[1] Almost 25 years ago, before the advent of ultrasound and radionuclide scans, similar conclusions were made in another study of alcoholic liver disease.[2] The axiom of that report seemingly remains valid: ". . . the performance of an exploratory operation in order to exclude common duct disease is not justified in the majority of cases."

The symptomatology and clinical findings in patients with alcoholic liver disease frequently simulates gallstone disease and it would have been informative if Dunnington and associates had included those laboratory and radiologic studies that prompted surgical intervention in the 22 patients. Because of the rarity of choledocholithiasis in cirrhotic subjects, ERCP is rarely necessary in my opinion.

It might interest Dr. Dunnington to learn that my study of alcoholic liver disease was prompted by a (world) renown surgeon who, during my presentation of such cases as the gastorenterology fellow, would frequently admonish me for failing to refer these patients to surgery since "we were overlooking gallstones and common duct obstruction." I am, of course, eternally grateful for his goading me into reporting my findings.

Lee R. Sataline, M.D.
Cheshire, Connecticut

May 26, 1987

Dear Editor:

We appreciate Dr. Sataline bringing to our attention his fine article published in the *American Journal of Medicine* 25 years ago. This report approached the cirrhotic patient from a somewhat different perspective than ours, namely, the differential diagnosis of a biochemical abnormality, an elevated alkaline phosphatase value. Our report, however, discussed the problem of diagnosis and management of patients with documented cholelithiasis and symptoms consistent with acute cholecystitis or choledocholithiasis.

With regard to the indications prompting surgical intervention, we refer to Table 1 in our report, which states that most patients were explored for symptoms of biliary colic and/or acute cholecystitis. Ours was a retrospective review and, from what we have learned from this experience as well as from Dr. Sataline's review, we would hope that exploration could be avoided in a high percentage of these patients by using the algorithims we outlined. Although ERCP is rarely necessary, it is a useful adjunct in the patient with cholelithiasis and a dilated common duct by ultrasound. No other diagnostic study can so effectively rule out a common duct stone in this setting. It seems to us to be a more reasonable option than those available to Dr. Sataline when he reported his series of patients, *i.e.*, the use of liver biopsy or nutritional support in the hopes that symptoms of alcoholic hepatitis might resolve.

Gary Dunnington, M.D.
C. W. Putnam, M.D.
Tucson, Arizona

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

CLASSIFIED AD SECTION

Classified advertising is available in **ANNALS OF SURGERY** for those recruiting personnel or interested in obtaining positions. Display space also is available for those desiring greater visibility or more space for their message.

Classified ad copy, like other advertising copy, will be reviewed for approval prior to publication.

Classified Rates: $9.00 per line or fraction of line. The average line will be 40 characters.

Box Numbers: Replies may be directed via Box # to J.B. Lippincott Company, at an extra charge per insertion of $6.50 to cover handling costs in forwarding such replies to the advertiser.

How to Order: Send typewritten text copy for the ad with remittance in full to:

Chief, Surgical Service — Veterans Administration Medical Center, Albuquerque, NM and University of New Mexico School of Medicine are seeking an individual to lead active clinical, teaching and research programs for undergraduates and residents in General, Thoracic, Plastic, Urologic and Orthopaedic Surgery. Individual will have major clinical and academic responsibilities and must have experience and accomplishments to qualify for senior academic appointment in the Department of Surgery, University of New Mexico, School of Medicine. Inquiries should be accompanied by resume and addressed to **Donald E. Fry, M.D., Chairman, Dept. of Surgery, c/o Chief of Staff, VA Medical Center, 2100 Ridgecrest Drive S.E., Albuquerque, New Mexico 87108.** VA Medical Center, Albuquerque is an equal opportunity employer.

BC/BE general surgeon to join expanding department in multispecialty group practice serving FFS and prepaid patients in Central Massachusetts. Practice in university—affiliated hospitals with opportunities for clinical research. Send CV to **Medical Director, Fallon Clinic, 630 Plantation Street, Worcester, Massachusetts 01605.**

COSMETIC SURGERY FELLOWSHIP, DEPARTMENT OF COSMETIC SURGERY, GRADUATE HOSPITAL, Philadelphia, PA. Available July 1988. Twelve month program. Yearly case load of over 3,000 facial, breast, and body cosmetic procedures. Candidates must have had an otolaryngology/head and neck, plastic and reconstructive surgery, general surgery, or gynecologic residency to qualify. Upon completion you will be eligible to take the board examination in cosmetic surgery. Call or write: **Julius Newman, M.D., Chairman, 1455 City Line Avenue, Philadelphia, Pennsylvania, 19151, 215-896-6677.**

Director Department of Surgery—Challenging career opportunity is available at Saint Luke's Hospital of Cleveland, Ohio, a 450-bed hospital affiliated with CWRU. Candidates must be board certified in a surgical specialty/sub-specialty with evidence of productive scholarship and with recognized skills in clinical care and surgical teaching at the student, resident and faculty level. Management and organizational capabilities are necessary to administer a large diverse department with particular ability to supervise/direct residency programs in general surgery and several surgical subspecialties. Interested applicants should forward C.V. and 3 references to Daniel C. Worthington, M.D., Chairman, Director of Surgery Search Committee. **Saint Luke's Hospital, 11311 Shaker Blvd., Cleveland, Ohio 44104.** An Equal Opportunity Employer, M/F/H/V.

FELLOWSHIP/CRITICAL CARE MEDICINE—One year fellowship in Critical Care Medicine, beginning July 1, 1988, are available at the Maryland Institute for Emergency Medical Services Systems. The Institute specializes in the care of adult trauma victims, and is the center of a state-wide trauma network. Approximately 45 beds (of a total of 96) are devoted to intensive care. Admission numbers are about 2800/year. Opportunities for elective experience in Pediatric ICU, trauma anaesthesia, open heart recovery, and hyperbaric medicine are available. Respond to: **John S. Britten, M.D., Department of Critical Care Medicine c/o MIEMSS 22 S. Greene Street, Baltimore, Maryland, 21201.**

GENERAL SURGEON: BC/BE to join another and well-established HMO practice in south suburban Boston. Competitive salary and benefits. Send curriculum vitae to: **Director of Physician Recruitment, Medical East Community Health Plan, 325 Wood Road, Braintree, MA 02184, (617) 849-3061.** We are an equal opportunity/affirmative action employer.

GENERAL SURGEONS—Newly established prepaid group practice desires to begin offering general surgery services. Looking for general surgeons interested in establishing and building a department. Physicians must be from high quality residency programs. Positions available immediately. C.V.s to: **Larry A. Oates, M.D., Regional Medical Director, Carolina Permanente Medical Group, P.A., 2900 Highwoods Blvd., Raleigh, N.C. 27604 (919) 878-9870.**

GENERAL SURGEON, University trained. NEEDED Immediately Upstate New York. Guaranteed Income. Send resume to **Box No. ANN11E to J.B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

GENERAL SURGEON: To join busy private practice in Capital District/Upstate New York. Excellent benefits and salary leading to partnership. **Box ANN11D, J.B. Lippincott Co., East Washington Square, Philadelphia, PA 19105.**

Hahnemann University Hospital, Division of Transplantation, has an opening for a Transplant Fellow, available 7/1/88. Responsibilities include organ recovery, clinical transplantation with patient management, and teaching of general surgical residents. Research is encouraged, and a second year of research is recommended. Send CV to **Stuart M. Greenstein, M.D., Acting Director, Division of Transplantation, Hahnemann University, MS 413, Broad and Vine Street, Philadelphia, PA 19102.**

Large physician owned multi-specialty medical group seeks General Surgeon to join department of four. We offer an excellent salary/incentive bonus and benefit package as well as opportunity for partnership. Easy access to beach, mountains or desert. Please send C.V. to **Patti J. Hines, Friendly Hills Medical Group, 951 S. Beach Blvd., La Habra, CA 90631.**

Long-established 47 physician multispecialty clinic in the Puget Sound area seeking BE/BC General, Vascular and Non-Cardiac Thoracic Surgeon. Guaranteed salary leading to stockholdership. Excellent fringe benefits. Send CV and letter to: **Box ANN11C, J. B. Lippincott Co., East Washington Square, Philadelphia, PA 19105.**

PRIVATE SCRUB—Certified Surgical Technologist seeks position in private or group practice. Ten years experience; vascular, transplants, cardiac. Trained first assistant. NY/New England area. Contact: **Larry Sussman, CST, 40 Mediterranean Dr. #46, Weymouth, Ma. 02188.**

SOUTHEASTERN NEW MEXICO: We are seeking a board certified/board eligible general surgeon interested in a lucrative career move with a first year guaranteed salary of $90,000. This up-to-date private practice has a service area population of approximately 30,000. For additional information, please send current CV to **Linda Smith, Occupational Health Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri, 64111; or call 800-821-5147 or 816-561-2105.**

THORACIC/GENERAL SURGEON—Thoracic/General Surgeon with experience in pulmonary surgery and thoracic trauma to join 34 physician multi-specialty clinic. Potential vascular work. Two established Pulmonologists on staff. Must be Board Certified or eligible. 100 miles southeast of St. Louis. Population 28,000 plus 25,000 Southern Illinois University students. Drawing area near 100,000. Flexible compensation package with generous fringe benefits including health and disability insurance, vacation, CME leave, and profit sharing retirement plan. Fee-for-service plus prepaid. Contact: **Bill Harris, Administrator; Carbondale Clinic, S.C.; 2601 West Main Street, Carbondale, IL 62901 or call (618) 549-5361.**

Surgeon for Oncology Clinic and Hospital. BC/BE General Surgeon, Salary negotiable. Send CV to: **P.O. Box 35161, Dallas, Texas 75235.**

The community of **ARTESIA, NEW MEXICO** is seeking a Board Certified or Eligible GENERAL SURGEON to establish a private practice. Fully-equipped office with established referral patterns available for purchase. Community-based financial assistance may be available to the right individual. Artesia is a community of 14,000 located in Southeast New Mexico. A great place to raise a family—peaceful community with year-round recreation and excellent weather. Fully equipped, 38-bed new hospital. Please submit CV to: **Bill Norris, Southwest Community Health Services, P.O. Box 26666, Albuquerque, NM 87125-6666; or, call 1-800-545-4030, Ext. 8300.**

THORACIC SURGERY— Well established Group in suburban New York area is seeking a Board Certified/Board Eligible university trained associate to provide quality General/Thoracic/PV Surgery (no open heart). Excellent salary and benefits leading to partnership. Malpractice paid. Send C.V. to **Box ANN11B, J.B. Lippincott Co., East Washington Square, Philadelphia, PA 19105.**

VASCULAR SURGEON—The Department of Surgery, Medical College of Pennsylvania is recruiting a board certified/eligible vascular surgeon for a full-time academic position. Responsibilities include patient care, research, medical student and resident instruction. Benefits and insurance included. **Apply to Division of Vascular Surgery, Medical College of Pennsylvania, Philadelphia, PA 19129.**

VASCULAR SURGEON: Full time academic position. Excellent opportunity with large clinical volume and funds for research. Candidate should be eligible for appointment as Assistant Professor of Surgery, SUNY Stony Brook. Attractive area on North Shore of Long Island. Must be board certified or eligible for vascular certificate. Excellent salary/benefits. Send curriculum vitae to: **Leslie Wise, M.D., Chairman-Department of Surgery. Long Island Jewish Medical Center, 270-05 76th Avenue, New Hyde Park, NY 11042.** An Equal Opportunity Employer.

Victoria Ann-Lewis moves so gracefully on stage the audience doesn't even know she has polio.

VICTORIA ANN-LEWIS/ARTIST IN RESIDENCE AT THE MARK TAPER FORUM IN LOS ANGELES.

Believe in them. Break the barriers.

PRESIDENT'S COMMITTEE ON EMPLOYMENT OF THE HANDICAPPED,
WASHINGTON D.C. 20210

PRODUCED BY THE SCHOOL OF VISUAL ARTS PRESS LTD

RESEARCH FELLOWSHIP

The Surgery Branch, National Heart, Lung, and Blood Institute is accepting applications for a two year Fellowship for Training in Clinical and Laboratory Research for the years 1989-1991. Candidates should have a minimum of two years of general surgery postgraduate training. Prior experience in a laboratory is desirable. Major emphasis during the nine months of clinical experience is placed on complex and challenging problems of valvular, hypertrophic cardiomyopathic and ischemic heart disease patients. Fifteen protected months are devoted to training and experience in clinical and laboratory research. Basic studies in physiology, biochemistry, metabolism and bioengineering are encouraged. Salary is $30,000 first year, $32,000 second year. Apply by letter to:

Richard E. Clark, M.D.
Chief, Surgery Branch, NHLBI
National Institutes of Health
Building 10, Room 2N244
9000 Rockville Pike
Bethesda, MD 20892

Made of # Fr. biocompatable silicone for minimum trauma without sacrificing efficiency of performanc

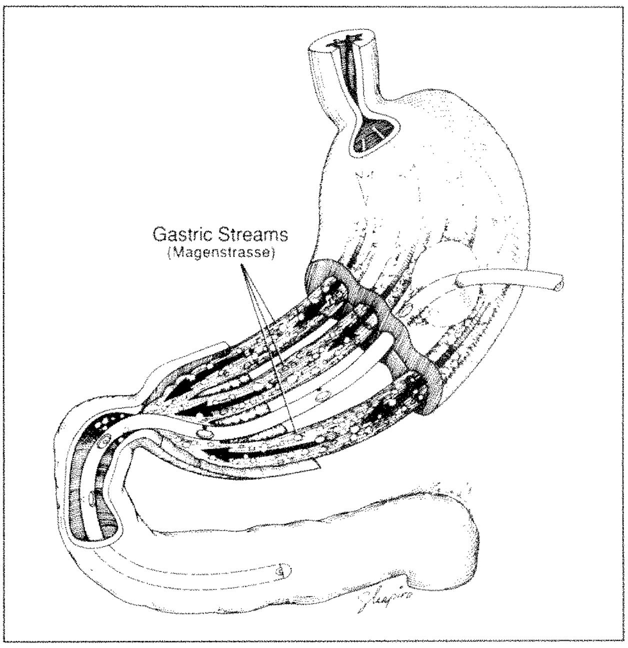
* Send for reprints documenting results from independent clinical centers.

INCOMPARABLE MOSS® TUBES ....

(but compare with other feeding-decompression tubes anyway.)

1. Decompression Site

Gastric suction alone cannot work! The stomach's longitudinal folds mimic parallel segments of intestine. Aspiration orifices may empty a single "Magenstrasse" (figure A). Most swallowed air avoids suction, and is propelled through the pylorus via adjacent channels. A clinical study of other N-G and G-tubes measured 32-42% inefficiency. *A toll booth in the center of a wide highway cannot collect from traffic in the outer lanes.*
Removal of air is most effective at constricted (single-file) sites. Measured efficiency increases 12-fold by adding aspiration within the adjacent esophagus and/or duodenum. And flowing duodenal digestive juices "self-cleanse" the tube of occluding mucus.

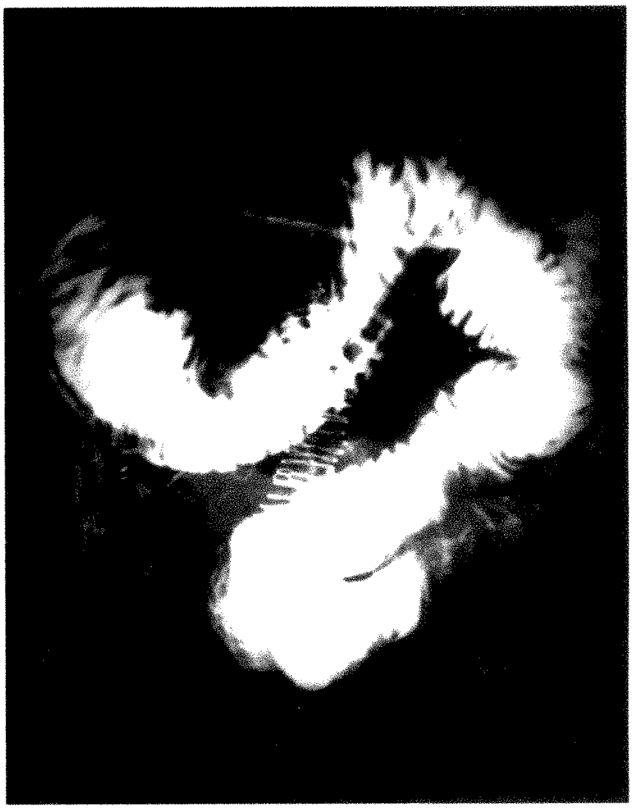


A. The functioning stomach subdivides into discrete"Magenstrasse". Any tube can only evacuate the single gastric stream within which it lies.

2. Feeding site

Gastric feeding risks distention and aspiration. **Jejunal** delivery bypasses 1-3 feet of proximal intestine, acting as a barrier to retrograde decompression. Aspiration of feedings is less likely, but remains a risk. Minimal initial infusion (starvation) is manditory initially.

The **Moss®G-Tube's duodenal** delivery site is the most effective. With proximal duodenal aspiration (patented), the initial distal feeding rate is unlimited. Clinical x-rays visualized removal of all excess feeding, with none reaching the stomach. (Fig. B) The full length of intestinal absorption is available immediately. Earliest "enteral hyperalimentation" is safely instituted within the recovery room. Positive nutritional balances are achieved, leading to enhanced sepsis resistance, accelerated wound healing and shorter L.O.S.



B. Study @ 5 minutes. Note effective removal of all excess barium flowing retrograde, none visualized to reach the stomach.

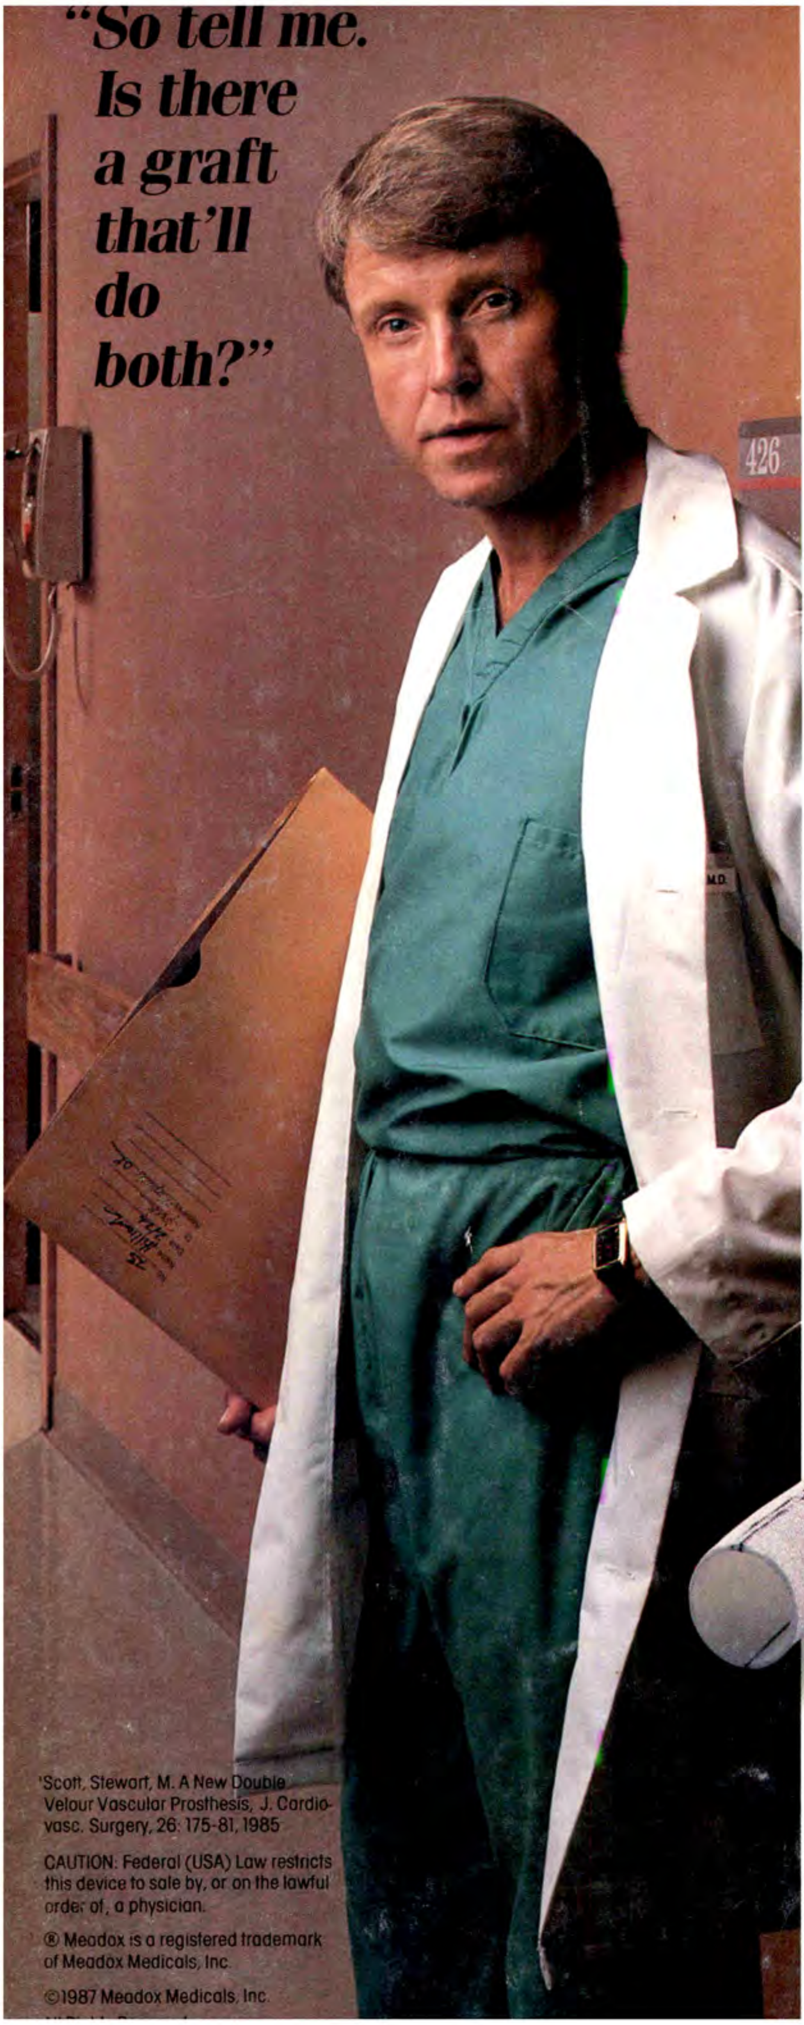
3. Aspiration Orifices

Uniformly sized orifices (**all others**) "suck in" mucosa to occlude the openings and stop decompression. Mucosal release then requires a null period (intermittant suction). Prograde air or retrograde feedings can be propelled accross and beyond the stomach, causing distention or aspiration.

By pairing each large orifice with a patented, smaller "suction buster"®opening (**Moss®G-tube**), continuous aspiration is maintained despite inadvertantly elevated suction.

4. Biomaterials

The **Moss®G-Tube** is **all silicone**, the accepted "gold standard" for optimum long term stability, tissue tolerance and biocompatibility.



"So tell me. Is there a graft that'll do both?"

"Absolutely. The Meadox® Woven Double Velour."

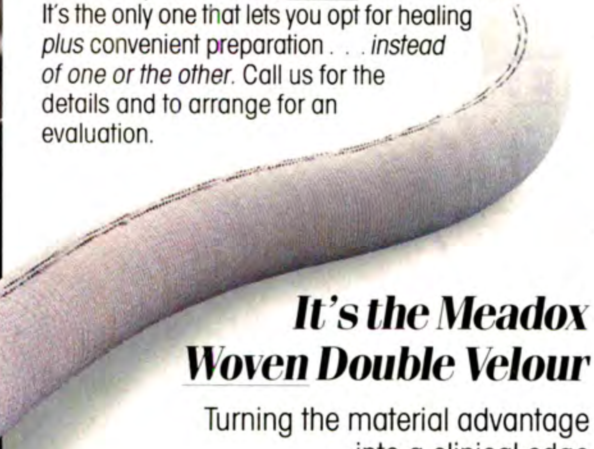
Reduces surgical time and preparation . . .

In the world of grafts, there are several advantages only a true hybrid, like the Meadox Woven Double Velour can offer. Easy and controllable *in situ* preparation—we call it *Quick-Prep*—is one. Then there's its low porosity combined with high strength. . . plus a weave so unique you won't think you're handling and suturing a woven graft at all. But that's only half the story.

And improves your patient's prognosis

This versatile graft is, in fact, a unique high strength woven offering true, low profile velour healing properties — such as thorough tissue ingrowth, a well anchored neointima, and excellent long-term patency.[1] All of this is available in a selection of 30 sizes . . . more than enough to make it your first all-around choice.

So try the Meadox Woven Double Velour. It's the only one that lets you opt for healing *plus* convenient preparation . . . *instead of one or the other.* Call us for the details and to arrange for an evaluation.



It's the Meadox Woven Double Velour

Turning the material advantage
into a clinical edge

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV

(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE

TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,[*] *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*[†] (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,[*] *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,[†] and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species[†]).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*[†]), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus*.[†]

[*] **NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

[†] Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS

CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS

Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS

GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION

TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6[*] grams	3 g every 12 hours IV

[*] Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose[*]	Every 12 hours
10-30	Usual Recommended Dose[*]	Every 24 hours
<10	Usual Recommended Dose[*]	Every 48 hours

[*] Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED

CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

The Angelchik®
Anti – Reflux
Prosthesis

Redesigned

The Angelchik Prosthesis was redesigned in 1982. Since this change, the reported complication rate has been reduced to less than 1% with the new circumferential stra configuration.

*For specified patients with documented severe or life threatening gastroesophageal reflux. Refer to Medicare Issues Manual, June 1987, or call Mentor Corporation for details.

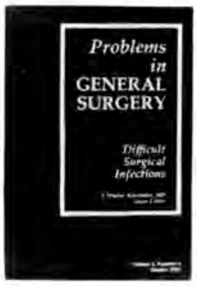
Journals and Series of Interest to SURGEONS

Indispensable tools for maintaining professional competency



Problems in General Surgery

Lloyd M. Nyhus, M.D., Editor.

This series of hardbound volumes features a symposium on a specific topic in general surgery in each issue. It serves as an outlet for the publication of original articles aimed at defining and suggesting solutions to difficult problems encountered in practice. Clinical problems are emphasized, with concentration on difficulties and complications. Leading authorities, chosen for their expert knowledge in their assigned topics, contribute articles on specific subjects, pooling the expertise of specialists for the benefit of generalists.

Published quarterly. Individual rate $59.00 per year (U.S.), $68.00 (elsewhere). Residents $39.00 (U.S. only).

Annals of Surgery

Official Publication of The American Surgical Association, The Southern Surgical Association, Philadelphia Academy of Surgery, and the New York Surgical Society

David C. Sabiston, Jr., M.D., Chairman of Editorial and Advisory Board.

Annals of Surgery—the world's oldest exclusively surgical journal—has provided the medical community with reports on significant contributions to the advancement of surgical science and practice for over 100 years. Its 20,000 subscribers find it a practical way to keep up to date with important developments in surgery.

Published monthly. Individual rate $53.00 per year (U.S.), $70.00 (elsewhere). Residents $35.00 (U.S.), $52.00 (Canada).

The American Surgeon

Official Publication of the Southeastern Surgical Congress, the Midwest Surgical Association, the Association of Clinical Anatomists, and the Society of American Gastrointestinal Endoscopic Surgeons (SAGES)

Arlie R. Mansberger, Jr., M.D., Editor-in-Chief.

An authoritative forum for the publication of original papers contributing to the advancement of surgery. Each issue contains information on the clinical application of new methods used in the management of patients; review articles with continuing education questions; condensed reviews of unusual case reports; "How I Do It" articles emphasizing the technical aspects of surgery.

Published monthly. Individual rate $49.00 per year (U.S.), $60.00 (elsewhere). Residents $32.00 (U.S. only).

Current Surgery

The Official Journal of the Association of Program Directors in Surgery

Lloyd M. Nyhus, M.D., Editor.

An internationally renowned editorial board prepares abstracts from every dependable source of surgical information throughout the world. Drawing on their own clinical experience and that of other recognized authorities, the members of the board provide commentary to further amplify and illuminate the material contained in each abstract. Also included are editorials, reports of new discoveries, residents' corner, and book reviews.

Published bimonthly. Individual rate $40.00 per year (U.S.), $46.00 (elsewhere). Residents $26.00 (U.S.), $32.00 (Canada).

Diseases of the Colon and Rectum

Official Journal of the American Society of Colon and Rectal Surgeons and the International Society of University Colon and Rectal Surgeons

Robert W. Beart, Jr., M.D., Editor-in-Chief.

This journal publishes reports on contemporary practice in the diagnosis and management of proctologic diseases and surgery. International in scope, it includes articles from physicians worldwide who share their important discoveries that offer new insights into basic research in metabolism, pathology, virology, radiology, and the clinical practice of medicine and surgery.

Published monthly. Individual rate $74.00 per year (U.S.), $89.00 (elsewhere). Residents $44.00 (U.S.), $59.00 (Canada).

Journal of Cardiovascular Surgery

Official Journal of the International Society for Cardiovascular Surgery

J. E. Connolly and S. S. Rose, Co-chief Editors.

The Journal is devoted to disease of the heart and the entire vascular system. It presents concise, informative coverage of the most significant work being done in diagnostic, experimental, and clinical surgery of the heart and blood vessels.

Published bimonthly. Individual rate $80.00 per year (North America only).

THROMBOSTAT IS OPERATING UNDER A NEW COVER

New sterile packaging for 5,000- and 10,000-unit vials

THROMBOSTAT® (Thrombin, USP), along with a matched volume of diluent, is now available in a new sterile package—minimizing the potential for contamination. This new packaging permits the entire contents of the inner tray to be directly introduced into the sterile operating field.

Offers mixing convenience

Sterile packages of THROMBOSTAT also feature a convenient new transfer device. So mixing is faster and easier than ever before. With THROMBOSTAT, surgical preparation has never been simpler.

THROMBOSTAT®
THROMBIN, USP

PD-34-JA-3853-P-1(1-87)

THROMBOSTAT® THROMBIN, USP
(Bovine Origin)

Before prescribing, please see full prescribing information. A Brief Summary follows:

Thrombostat must not be injected! Apply on the surface of bleeding tissue as a solution or powder.

INDICATIONS AND USAGE
Thrombostat (Thrombin, USP) is indicated as an aid in hemostasis wherever oozing blood from capillaries and small venules is accessible.

In various types of surgery, solutions of Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP for hemostasis.

CONTRAINDICATIONS
Thrombostat is contraindicated in persons known to be sensitive to any of its components and/or to material of bovine origin.

WARNING
Because of its action in the clotting mechanism, Thrombostat must not be injected or otherwise allowed to enter large blood vessels. Extensive intravascular clotting and even death may result. Thrombostat is an antigenic substance and has caused sensitivity and allergic reactions when injected into animals.

PRECAUTIONS
General:
Consult the absorbable gelatin sponge product labeling for complete information for use prior to utilizing the thrombin-saturated sponge procedure.

Pregnancy—
Teratogenic effects: Pregnancy Category C. Animal reproduction studies have not been conducted with Thrombin, Topical (Bovine). It is also not known whether Thrombin, Topical (Bovine) can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Thrombin, Topical (Bovine) should be given to a pregnant woman only if clearly indicated.

Pediatric Use:
Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
Allergic reactions may be encountered in persons known to be sensitive to bovine materials.

DOSAGE AND ADMINISTRATION
General: Solutions of Thrombostat may be prepared in sterile distilled water or isotonic saline. The intended use determines the strength of the solution to prepare. For general use in plastic surgery, dental extractions, skin grafting, neurosurgery, etc., solutions containing approximately 100 units per mL are frequently used. For this, 10 mL of diluent added to the 1000 unit package is suitable. Where bleeding is profuse, as from cut surfaces of liver and spleen, concentrations as high as 1000 to 2000 units per mL may be required. For this the 5000 unit vial dissolved in 5 mL or 2.5 mL, respectively, of the diluent supplied in the package is convenient. Intermediate strengths to suit the needs of the case may be prepared by selecting the proper strength package and dissolving the contents in an appropriate voulme of diluent. In many situations, it may be advantageous to use Thrombostat in dry form on oozing surfaces.

Caution: Solutions should be used immediately upon reconstitution. If necessary, refrigerate the solution and use within 3 hours of reconstitution.

The following techniques are suggested for the topical application of Thrombostat.
1. The recipient surface should be sponged (not wiped) free of blood before Thrombostat is applied.
2. A spray may be used or the surface may be flooded using a sterile syringe and small gauge needle. The most effective hemostasis results when the Thrombostat mixes freely with the blood as soon as it reaches the surface.
3. In instances where Thrombostat in dry form is needed, the vial is opened by removing the metal ring by flipping up the plastic cap and tearing counterclockwise. The rubber-diaphragm cap may be easily removed and the dried Thrombostat is then broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.
4. Sponging of treated surfaces should be avoided in order that the clot remain securely in place.

Thrombostat may be used in conjunction with Absorbable Gelatin Sponge, USP as follows:
1. Prepare Thrombostat solution of the desired strength.
2. Immerse sponge strips of the desired size in the Thrombostat solution. Knead the sponge strips vigorously with moistened gloved fingers to remove trapped air, thereby facilitating saturation of the sponge.
3. Apply saturated sponge to bleeding area. Hold in place for 10 to 15 seconds with a pledget of cotton or a small gauze sponge.

Sterile Packages
Thrombostat Sterile Packages are available in two strengths, 5000 units and 10,000 units. A Sterile Package contains one sterile vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile transfer device. The Sterile Package may be used as follows:
1. Remove the Tyvek® blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared using the transfer device.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

Thrombostat Kit
Thrombostat Kit contains one sterile 20,000 unit vial of Thrombostat, one sterile vial of Isotonic Saline Diluent, and one sterile pump sprayer cap. The kit may be used as follows:
1. Remove the Tyvek® blister lid by pulling up at the indicated corner. The sterile inner tray can be lifted out or introduced into the operating field.
2. The cover to the sterile inner tray is removed by pulling up on the finger tab, exposing the sterile contents.
3. Thrombostat solution of the desired strength is prepared and the pump sprayer cap inserted and seated on the Thrombostat solution vial. Note: Several strokes of the pump sprayer will be required before the Thrombostat solution is expelled.
4. Alternatively, when Thrombostat in dry form is needed, the vial is opened as described above and the dried Thrombostat broken up into a powder by means of a sterile glass rod or other suitable sterile instrument.

Caution—Federal law prohibits dispensing without prescription.

BURN FELLOWSHIP

The New York Hospital-Cornell Medical Center Burn Center is a modern burn treatment facility with 24 intensive care beds and annual admissions of 850 in-patients and 3,000 out-patients. During the year's experience, the Fellow will be responsible for the surgical critical care of all burned patients, for house officer education, and for participation in original and on-going clinical research protocols. The Burn Center is the recipient of an NIH Burn Research Center Grant and supports comprehensive laboratories with state-of-the-art instrumentation and active investigators in the fields of wound healing, immunology, metabolism, nutrition, and cardiopulmonary response to injury. An additional year in the laboratory may be elected by the Fellow. Candidates preferably should be Board eligible in General Surgery, but we will strongly consider academically oriented senior surgical residents from university programs incorporating the Fellowship as part of their training programs. Send inquiries to:

No therapy

Important new data[1] rule out no therapy

Today there is.

10 MG TABLETS

Nolvadex®

TAMOXIFEN CITRATE

Adjuvant Monotherapy

Now, the treatment of choice

A recent National Institutes of Health consensus report states that following surgery, "Tamoxifen [NOLVADEX] should now be regarded as standard therapy for postmenopausal patients with positive axillary lymph nodes and positive hormone receptor status."[1]

NOLVADEX increases disease-free time[2-5] by delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T_{1-3}, N_1, M_0). Moreover, NOLVADEX improves overall survival, with a 34% reduction in risk of mortality, as observed in the NOLVADEX Adjuvant Trial Organization (NATO) study.[4] This treatment is extremely well tolerated by patients[2-5]; in fact, one double-blind, placebo-controlled study demonstrated a NOLVADEX side effects profile similar to placebo.[2] And, since NOLVADEX has a mild side effects profile and is easy to administer, patients are afforded a better quality of life. NOLVADEX—today's promising breast cancer therapy for the postmenopausal woman—in the adjuvant setting and in metastatic disease.

Please see next page for brief summary of prescribing information.

ICI PHARMA
Division of ICI Americas Inc
WILMINGTON, DELAWARE 19897 USA

Nolvadex® 10 MG TABLETS
TAMOXIFEN CITRATE

BRIEF SUMMARY
INDICATIONS AND USAGE: NOLVADEX is effective in the treatment of metastatic breast cancer in postmenopausal women. Available evidence indicates that patients whose tumors are estrogen receptor positive are more likely to benefit from NOLVADEX therapy.

NOLVADEX is effective in delaying recurrence following total mastectomy and axillary dissection in postmenopausal women with breast cancer (T1-3, N1, M0). The estrogen and progesterone receptor values may help to predict whether NOLVADEX therapy is likely to be beneficial. In some NOLVADEX adjuvant studies, most of the benefit to date has been in the subgroup with 4 or more positive axillary nodes.

CONTRAINDICATIONS: None known.

WARNINGS: Pregnancy Category D: NOLVADEX may cause fetal harm when administered to a pregnant woman. Individuals should not become pregnant while taking NOLVADEX. Effects on reproductive functions are expected from the antiestrogenic properties of the drug. In reproductive studies in rats at dose levels equal to or below the human dose, nonteratogenic developmental skeletal changes were seen and were found to be reversible. In addition, in fertility studies in rats and in teratology studies in rabbits using doses at or below those used in humans, a lower incidence of embryo implantation and a higher incidence of fetal death or retarded in utero growth were observed, with slower learning behavior in some rat pups. The impairment of learning behavior did not achieve statistical significance in one study, and, in another study where significance was reported, this was by comparing dosed animals with controls of another study. Several pregnant marmosets were dosed during organogenesis or in the last half of pregnancy. No deformations were seen and although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. There are no adequate and well-controlled studies in pregnant women. There have been reports of spontaneous abortions, birth defects, fetal deaths, and vaginal bleeding. If this drug is used during pregnancy or the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus.

Ocular changes have been reported in a few patients who, as part of a clinical trial, were treated for periods greater than one year with NOLVADEX at doses at least four times the highest recommended daily dose of 40 mg. The ocular changes consist of retinopathy and, in some patients, there are also corneal changes and a decrease in visual acuity.

In addition, a few cases of ocular changes including visual disturbance, corneal changes, and/or retinopathy have been reported in patients treated with NOLVADEX at recommended doses. It is uncertain if these effects are due to NOLVADEX.

As with other additive hormonal therapy (estrogens and androgens), hypercalcemia has been reported in some breast cancer patients with bone metastases within a few weeks of starting treatment with NOLVADEX. If hypercalcemia does occur, appropriate measures should be taken and, if severe, NOLVADEX should be discontinued.

PRECAUTIONS: General: NOLVADEX should be used cautiously in patients with existing leukopenia or thrombocytopenia. Observations of leukopenia and thrombocytopenia occasionally have been made, but it is uncertain if these effects are due to NOLVADEX therapy. Transient decreases in platelet counts, usually to 50,000-100,000/cu mm, infrequently lower, have been occasionally reported in patients taking NOLVADEX for breast cancer. No hemorrhagic tendency has been recorded and the platelet counts returned to normal levels even though treatment with NOLVADEX continued.

Laboratory Tests: Periodic complete blood counts, including platelet counts, may be appropriate.

Carcinogenesis: While no conventional bioassay has been conducted, endocrine changes in immature and mature mice were investigated in a 13-month study. Granulosa cell ovarian tumors and interstitial cell testicular tumors were found in mice receiving NOLVADEX, but not in the controls.

Mutagenesis: No genotoxic potential has been found in a battery of in vivo and in vitro tests with pro- and eukaryotic test systems with drug metabolizing systems present.

Impairment of Fertility: Fertility in female rats was decreased following administration of 0.04 mg/kg for 2 weeks prior to mating through day 7 of pregnancy. There was a decreased number of implantations, and all fetuses were found dead.

Following administration to rats of 0.16 mg/kg from days 7-17 of pregnancy, there were increased numbers of fetal deaths. Administration of 0.125 mg/kg to rabbits during days 6-18 of pregnancy resulted in abortion or premature delivery. Fetal deaths occurred at higher doses. There were no teratogenic changes in either rat or rabbit segment II studies. Several pregnant marmosets were dosed with 10 mg/kg/day either during organogenesis or in the last half of pregnancy. No deformations were seen, and, although the dose was high enough to terminate pregnancy in some animals, those that did maintain pregnancy showed no evidence of teratogenic malformations. Rats given 0.16 mg/kg from day 17 of pregnancy to 1 day before weaning demonstrated increased numbers of dead pups at parturition. It was reported that some rat pups showed slower learning behavior, but this did not achieve statistical significance in one study, and in another study where significance was reported, this was by comparing dosed animals with controls of another study.

The recommended daily human dose of 20-40 mg corresponds to 0.4-0.8 mg/kg for an average 50 kg woman.

Pregnancy Category D: See WARNINGS.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from NOLVADEX, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

ADVERSE REACTIONS: The most frequent adverse reactions to NOLVADEX are hot flashes, nausea and vomiting. These may occur in up to one-fourth of patients, but are rarely severe enough to require discontinuation of treatment.

Less frequently reported adverse reactions are vaginal bleeding, vaginal discharge, menstrual irregularities and skin rash. Usually these have not been of sufficient severity to require dosage reduction or discontinuation of treatment.

Increased bone and tumor pain and, also, local disease flare have occurred, which are sometimes associated with a good tumor response. Patients with increased bone pain may require additional analgesics. Patients with soft tissue disease may have sudden increases in the size of preexisting lesions, sometimes associated with marked erythema within and surrounding the lesions and/or the development of new lesions. When they occur, the bone pain or disease flare are seen shortly after starting NOLVADEX and generally subside rapidly.

Other adverse reactions which are seen infrequently are hypercalcemia, peripheral edema, distaste for food, pruritus vulvae, depression, dizziness, light-headedness and headache. There have been infrequent reports of thromboembolic events occurring during NOLVADEX therapy. Since for cancer patients in general an increased incidence of thromboembolic events is known to occur, a causal relationship to NOLVADEX remains conjectural. An increased incidence has been reported when cytotoxins are combined with NOLVADEX.

If adverse reactions are severe, it is sometimes possible to control them by a simple reduction of dosage without loss of control of the disease.

OVERDOSAGE: Acute overdosage in humans has not been reported. Signs observed at the highest doses following studies to determine LD_{50} in animals were respiratory difficulties and convulsions. No specific treatment for overdosage is known; treatment must be symptomatic.

DOSAGE AND ADMINISTRATION: One or two 10 mg tablets twice a day (morning and evening). In the three single agent adjuvant NOLVADEX studies noted above (See Clinical Pharmacology), NOLVADEX was administered for two years. The optimal duration of adjuvant therapy is not known.

HOW SUPPLIED: Tablets containing tamoxifen as the citrate in an amount equivalent to 10 mg of tamoxifen (round, biconvex, uncoated, white tablet identified with NOLVADEX 600 debossed on one side and a cameo debossed on the other side) are supplied in bottles of 60 tablets and 250 tablets. Protect from heat and light.

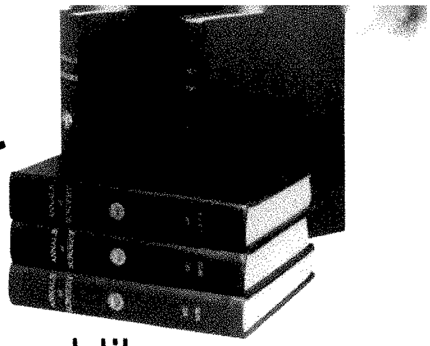
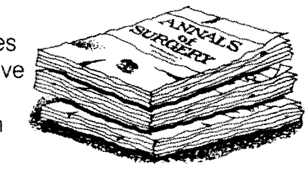
New for 1987



For your professional library **Bound volumes** of Annals of Surgery



Long after your personal copies of ANNALS OF SURGERY have been read, shared with your office staff, used up and worn out, you can have instant access to the unique and valuable information in back issues of this distinguished journal by ordering bound volumes.

Your bound volumes give you a permanent and comprehensive reference for changes and advances in your specialty—a source that will grow and increase in usefulness over the years. Each volume features:

- *all text pages of every issue, including the complete author and title indexes*
- *no advertising—only professional, clinically pertinent material (a space-saver on your bookshelves)*
- *handsome, durable bindings in maroon buckram, with the journal name, year, and volume number imprinted in gold on the spine*

No need to return your personal copies to us, or to go to the trouble and expense of having them bound locally. We over-run copies of each issue in order to have sufficient quantities on hand. But we must tell our printer how many we need, so please let us know right away.

You must be a current subscriber to take advantage of this bound volume offer.

Use the convenient coupon to order your 1987 volumes today. They will be on their way to you shortly after the publication of the final volume issue.

Yes! Please send me the 1987 bound volumes of ANNALS OF SURGERY (65-98635/65-98643) for $49.00 U.S. ($59.00 elsewhere).

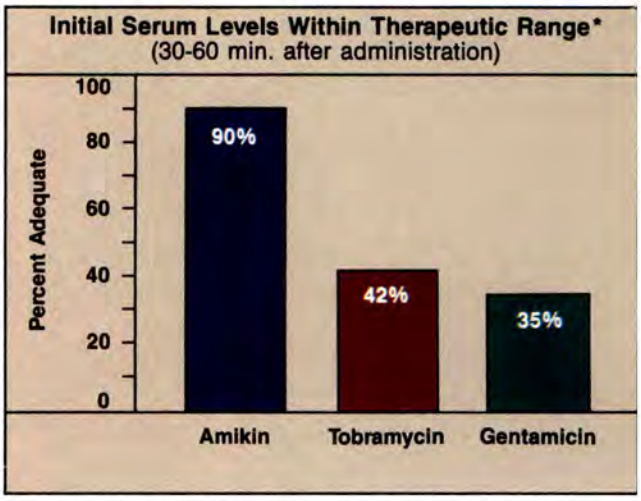
IN EMPIRIC THERAPY OF NOSOCOMIAL INFECTIONS

Peace of mind. Right from the start.

When infection develops in the hospitalized patient, there's no time to be wrong. Amikin® (amikacin sulfate) delivers the aggressive First-Dose therapy that can save lives.

First-Dose Predictability.

After the first dose, Amikin produces therapeutic blood levels that are more predictable than those of the other aminoglycosides.[1]

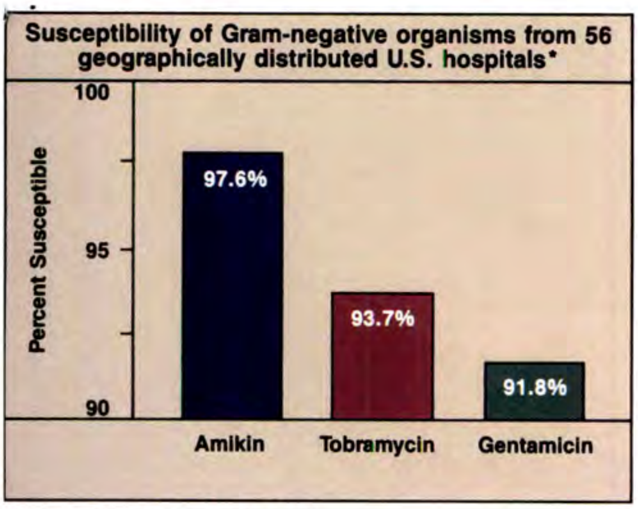


*Adapted from Holloway WJ: Management of sepsis in the elderly. *Am J Med* 80 (suppl 6B): 143-148, 1986.

BRISTOL®
NDC 0015-3020
Amikin®
AMIKACIN SULFATE
INJECTION For I.M. or I.V. Use
EQUIVALENT TO
500 mg AMIKACIN Per 2 ml
CAUTION: Federal law prohibits dispensing without prescription.
30
40

First-Dose Antimicrobial Activity.

Amikin has the broadest spectrum of any aminoglycoside.[2]



Total Amikin isolates = 247,503

In vitro data may not be directly correlated to clinical effectiveness. Data on file, Bristol Laboratories.

First-Dose Synergy.

In combination with antipseudomonal penicillins and latest generation cephalosporins, Amikin is overall the most synergistic of the aminoglycosides.[3,4]

First-Dose Economy.

The least expensive aminoglycoside is not necessarily the one with the lowest acquisition cost. It's the one *not* requiring replacement with a more effective agent.[5]

BRIEF SUMMARY OF PRESCRIBING INFORMATION (1) 10/83
For complete prescribing information, please consult product literature.

WARNINGS

Patients treated with aminoglycosides should be under close clinical observation because of the potential ototoxicity and nephrotoxicity associated with their use.

Ototoxicity, both auditory and vestibular, can occur in patients treated at higher doses or for periods longer than those recommended. The risk of amikacin-induced ototoxicity is greater in patients with renal damage. High frequency deafness usually occurs first and can be detected only by audiometric testing. Vertigo may occur and may be evidence of vestibular injury.

The ototoxicity potential of amikacin in infants is not known. Until more safety reports become available, amikacin should be used in infants only in those specific circumstances when susceptibility testing indicates that other aminoglycosides cannot be used or are otherwise contraindicated, and when the infant can be observed closely for evidence of toxicity.

Aminoglycosides are potentially nephrotoxic. Renal and eighth-nerve function should be closely monitored in patients with known or suspected renal impairment and also in those whose renal function is initially normal but who develop signs of renal dysfunction during therapy. Such impairment may be characterized by decreased creatinine clearance, the presence of cells or casts, oliguria, proteinuria, decreased urine specific gravity or evidence of increasing nitrogen retention (increasing BUN or creatinine).

Evidence of impairment in renal, vestibular or auditory function requires discontinuation of the drug or dosage adjustment.

Serum concentrations should be monitored when feasible, and prolonged peak concentrations above 35 mcg/ml should be avoided. Urine should be examined for increased excretion of protein, the presence of cells and casts, and decreased specific gravity.

Concurrent and/or sequential use of topically or systemically neurotoxic or nephrotoxic antibiotics, particularly kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin should be avoided.

AMIKIN should not be given concurrently with potent diuretics (ethacrynic acid, furosemide, meralluride sodium, sodium mercaptomerin or mannitol). Some diuretics themselves cause ototoxicity, and intravenously administered diuretics enhance aminoglycoside toxicity by altering antibiotic concentrations in serum and tissue.

CONTRAINDICATIONS

A history of hypersensitivity to amikacin is a contraindication for its use.

WARNINGS

See "Warning" box above.

PRECAUTIONS

AMIKIN is potentially nephrotoxic, ototoxic, and neurotoxic. The concurrent or serial use of other ototoxic or nephrotoxic agents should be avoided either systemically or topically because of the potential for additive effects. Such agents include antibacterial drugs such as kanamycin, gentamicin, tobramycin, neomycin, streptomycin, cephaloridine, paromomycin, viomycin, polymyxin B, colistin and vancomycin as well as certain diuretic agents such as ethacrynic acid or furosemide.

Ototoxicity — See "Warning" box.

Nephrotoxicity — Since AMIKIN is present in high concentrations in the renal excretory system, patients should be well hydrated to minimize chemical irritation of the renal tubules. Kidney function should be assessed by the usual methods prior to starting therapy and daily during the course of treatment.

If signs of renal irritation appear (casts, white or red cells or albumin), hydration should be increased. A reduction in dosage (see "Dosage and Administration") may be desirable if other evidence of renal dysfunction occurs such as decreased creatinine clearance, decreased urine specific gravity, increased BUN, creatinine or oliguria. If azotemia increases or if a progressive decrease in urinary output occurs, treatment should be stopped.

Note: When patients are well hydrated and kidney function is normal the risk of nephrotoxic reactions with amikacin is low if the dosage recommendations (see "Dosage and Administration") are not exceeded.

Neurotoxicity — Neuromuscular blockade and muscular paralysis have been demonstrated in the cat with high doses of amikacin (188 mg/Kg). The possibility of neuromuscular blockade and respiratory paralysis should be considered when amikacin is administered concomitantly with anesthetic or neuromuscular blocking drugs. If blockade occurs, calcium salts may reverse this phenomenon.

Other — Cross-allergenicity among aminoglycosides has been demonstrated. As with other antibiotics the use of amikacin may result in overgrowth of nonsusceptible organisms. If this occurs, appropriate therapy should be instituted.

Pregnancy — Reproduction studies have been performed in rats and mice and have revealed no evidence of impaired fertility or harm to the fetus due to amikacin. There are no well-controlled studies in pregnant women but investigational experience does not include any positive evidence of adverse effects on the fetus. Although there is no clearly defined risk, such experience cannot exclude the possibility of infrequent or subtle damage to the fetus. AMIKIN should be used in pregnant women only when clearly needed.

It is not known whether this drug is excreted in human milk. As a general rule, nursing should not be undertaken while a patient is on a drug since many drugs are excreted in human milk.

ADVERSE REACTIONS

Ototoxicity — See "Warning" box.

Nephrotoxicity — Albuminuria, presence of red and white cells, casts, azotemia and oliguria have been reported.

Other — In addition to those described above, other adverse reactions which have been reported on rare occasions are skin rash, drug fever, headache, paresthesia, tremor, nausea and vomiting, eosinophilia, arthralgia, anemia, hypotension.

Overdosage — In the event of overdosage or toxic reaction, peritoneal dialysis or hemodialysis will aid in the removal of amikacin from the blood.

A Prospective Randomized Trial of Regional *Versus* Systemic Continuous 5-Fluorodeoxyuridine Chemotherapy in the Treatment of Colorectal Liver Metastases

ALFRED E. CHANG, M.D., PHILIP D. SCHNEIDER, M.D., PH.D., PAUL H. SUGARBAKER, M.D., COLLEEN SIMPSON, R.N., MARY CULNANE, R.N., and SETH M. STEINBERG, PH.D.

From the Surgery Branch and Biostatistics and Data Management Section, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

Sixty-four patients were entered into a randomized trial that evaluated intra-arterial (I.A.) *versus* intravenous (I.V.) 5-fluorodeoxyuridine (FUDR) for colorectal liver metastases. There was a significantly improved response rate for I.A. (62%) compared with I.V. (17%) treatment ($p < 0.003$). However, the improved response rate for patients in whom I.A. therapy was used did not translate to a significantly improved survival rate. The 2-year actuarial survival rates for the groups for which I.A. and I.V. therapy was used were 22% and 15% respectively, with the survival curves not differing significantly ($p = 0.27$). These results may have been due to the inclusion of patients with tumor in draining hepatic lymph nodes. The presence of tumor in hepatic lymph nodes was associated with a poorer prognosis. Analysis of a subgroup of patients with negative hepatic lymph nodes suggested an improved actuarial survival rate in patients for whom I.A. *versus* I.V. therapy was used ($p < 0.03$). The toxicity of I.A. FUDR was considerable, and side effects included chemical hepatitis (79%), biliary sclerosis (21%), peptic ulcers (17%), and gastritis/duodenitis (21%). The only major effect of toxicity of I.V. FUDR was severe diarrhea (59%). Regional I.A. FUDR allowed more drug delivery to liver tumors, which resulted in increased tumor responses when compared with use of systemic therapy. However, the small gain in survival seen in a select subgroup of patients with negative hepatic nodes appeared to be offset by the toxicity of I.A. FUDR.

REGIONAL CONTINUOUS INFUSION CHEMOTHERAPY *via* the hepatic artery for liver tumors has several theoretic advantages. Anatomic studies in a variety of animal species including humans have demonstrated that hepatic tumors derive most of their blood supply from the hepatic artery as opposed to the portal vein.[1,2] This phenomenon, along with the ability of the liver to metabolize certain chemotherapeutic drugs, allows a much higher local concentration of drug to reach the tumor with reduced systemic effects. Besides increasing local tumor concentrations of a chemotherapeutic agent, continuous infusion allows prolonged

drug exposure to the tumor cells and thus potentially increases the cell-kill fraction.[3]

Extensive clinical experience with regional infusion chemotherapy of hepatic tumors has been reported since it was described in 1964.[4] Much of this experience has been with percutaneously placed hepatic artery catheters connected to extracorporeal pumps. These systems have been associated with mechanical and infectious complications.[5] An implantable pump that allows for continuous drug infusion was developed in 1972.[6] The first use of this device to deliver chemotherapeutic drugs to hepatic tumors was reported in 1980.[7] It has proven to be very reliable, without mechanical complications, and it is rarely subject to the problems seen with percutaneously placed catheters that are left in place for prolonged infusion.

Several Phase II studies have examined the use of this implantable pump to deliver 5-fluorodeoxyuridine (FUDR) in patients with colorectal hepatic metastases.[7-14] Response rates from 29 to 88% have been reported, with an overall survival rate from the time of pump implantation ranging from 8 to 18 months. The therapy can be associated with major toxicity. The monetary costs of this treatment and reported toxicity underscored the need for controlled studies to establish the impact of regional infusional chemotherapy on survival rate. This report describes a randomized prospective trial conducted by the Surgery Branch of the National Cancer Institute comparing the efficacy of regional *versus* systemic continuous FUDR chemotherapy *via* the implantable pump for patients with colorectal liver metastases.

Materials and Methods

Patients with isolated unresectable colorectal liver metastases were evaluated for study entry. To be eligible for entry, patients were to have no evidence of extrahepatic disease by radiologic assessment, a serum bilirubin level of less than 2 mg/dL, and a performance status of 0 or 1 (Eastern Cooperative Oncology Group Scale). Evaluation before operation included a history and physical examination, chest roentgenography, abdominal and chest computerized tomographic (CT) scans, a bone scan, a complete blood count, a chemistry profile, and carcinoembryonic antigen levels (CEA).

Sixty-four patients were randomized, 32 for regional intra-arterial (I.A.) infusion and 32 for systemic (I.V.) infusion. The protocol was closed to patient accrual on April 1, 1986, and all patient results were updated as of March 1, 1987. Median potential follow-up for all patients in the protocol is 23 months. Forty-nine of the 64 patients (76%) have died. Various patient characteristics are summarized in Table 1. There were no significant differences between the two groups regarding sex, age, stage of primary colon tumor, percentage hepatic replacement by tumor, symptoms, prior chemotherapy, CEA, lactic dehydrogenase, alkaline phosphatase, or disease-free interval.

Patients were randomized for their therapy after it was determined that their liver metastases were unresectable. Patients selected for I.A. therapy had a pump placed if there was no evidence of extrahepatic disease outside the regional draining hepatic (portal/celiac) nodes at the time of laparotomy. Previous reports had documented no benefit of I.A. FUDR therapy in the presence of extrahepatic disease.[12,14] The pump catheters were inserted as described by Neiderhuber et al.[15] A cholecystectomy was routinely performed to avoid chemically induced cholecystitis. When standard arterial anatomy was present, the catheter was inserted into the gastroduodenal artery and positioned at the junction to the common hepatic artery. Ligation of the distal gastroduodenal artery, right gastric artery, and any other

branches supplying the stomach or duodenum arising from the common hepatic distal to the gastroduodenal take-off was performed. Total liver perfusion was confirmed during operation with injection of 3 mL of fluorescein dye visualized by a Woods lamp. After operation a ^{99}technetium-labeled macroaggregated albumin scan through the sideport of the pump was performed to confirm adequacy of liver perfusion and repeated during follow-up evaluations. Patients selected for I.V. FUDR therapy had catheters placed into the superior vena cava *via* the cephalic vein. A subcutaneous pocket was created in the infraclavicular region to place the pump.

Of the 32 patients selected at random for I.A. therapy 21 had pumps placed for treatment. Eleven were not treated because of patient refusal after randomization (two patients) or the presence of extrahepatic disease outside hepatic lymph nodes (nine patients). Of the 32 patients selected at random to receive I.V. treatment, 29 received therapy and three did not. The latter occurred because of a death after operation from liver failure (one patient) and development of extrahepatic disease (carcinomatosis) that precluded treatment (two patients).

FUDR was administered continuously for 14 days, alternating with 14 days of water and heparin (17,500 U/50 mL) in the pump. Patients received I.A. FUDR at a starting dose of 0.3 mg/kg/day. Chemistry profiles were obtained every 2 weeks to monitor for hepatic toxicity. Doses were held for any abnormal liver function tests (LFTs) above baseline. Subsequent doses were administered at reduced doses when toxicity resolved. Doses were reduced 25, 50, and 75% for mild (≤2× LFT), moderate (>2, ≤3× LFT; gastritis symptoms), or severe (>3× LFT; or peptic ulcer disease), respectively. All patients were maintained on cimitidine or ranitidine while receiving I.A. FUDR. Midway through the trial the starting dose was reduced to 0.2 mg/kg/day in attempts to avoid severe hepatic toxicity. This did not appear to impact on incidence of toxicity nor response rates.

I.V. FUDR was started at a dose of 0.125 mg/kg/day. Diarrhea was the major toxicity of I.V. FUDR. Doses were reduced 25, 50, and 75% for mild (≤6 loose stools/day), moderate (7–12 loose stools/day), or severe (>12 loose stools/day) diarrhea, respectively. No bone marrow suppression occurred with this dose regimen.

Patients were treated with three cycles of drug and were re-evaluated for response by CT scan. Chest roentgenographs were performed every 3 months, and chest CT scans every 6 months. A complete response was indicated by disappearance of all disease by CT scan and normalization of CEA levels. A partial response was defined by greater than or equal to 50% reduction in the sum of the products of the perpendicular diameters of all sentinel lesions identified by CT scan. Progressive disease was defined as a greater than 25% increase in the size of evaluable tumor or the presence of any new lesion in the liver or at extrahepatic sites. Patients were treated for another three cycles if tumor responded or remained stable and were re-evaluated for response. FUDR was discontinued for patients who progressed. Once a patient progressed, there was no cross-over to the other arm of the study.

Survival from the time of randomization was the primary endpoint of the study. Estimates of the survival curves were computed by use of the method of Kaplan and Meier.[16] The test of Mantel and Haenzel was used for comparison of survival rates in the two treatment arms.[17] In comparing proportions in two groups, we have used the Fisher exact test.[18] All p values are two tailed.

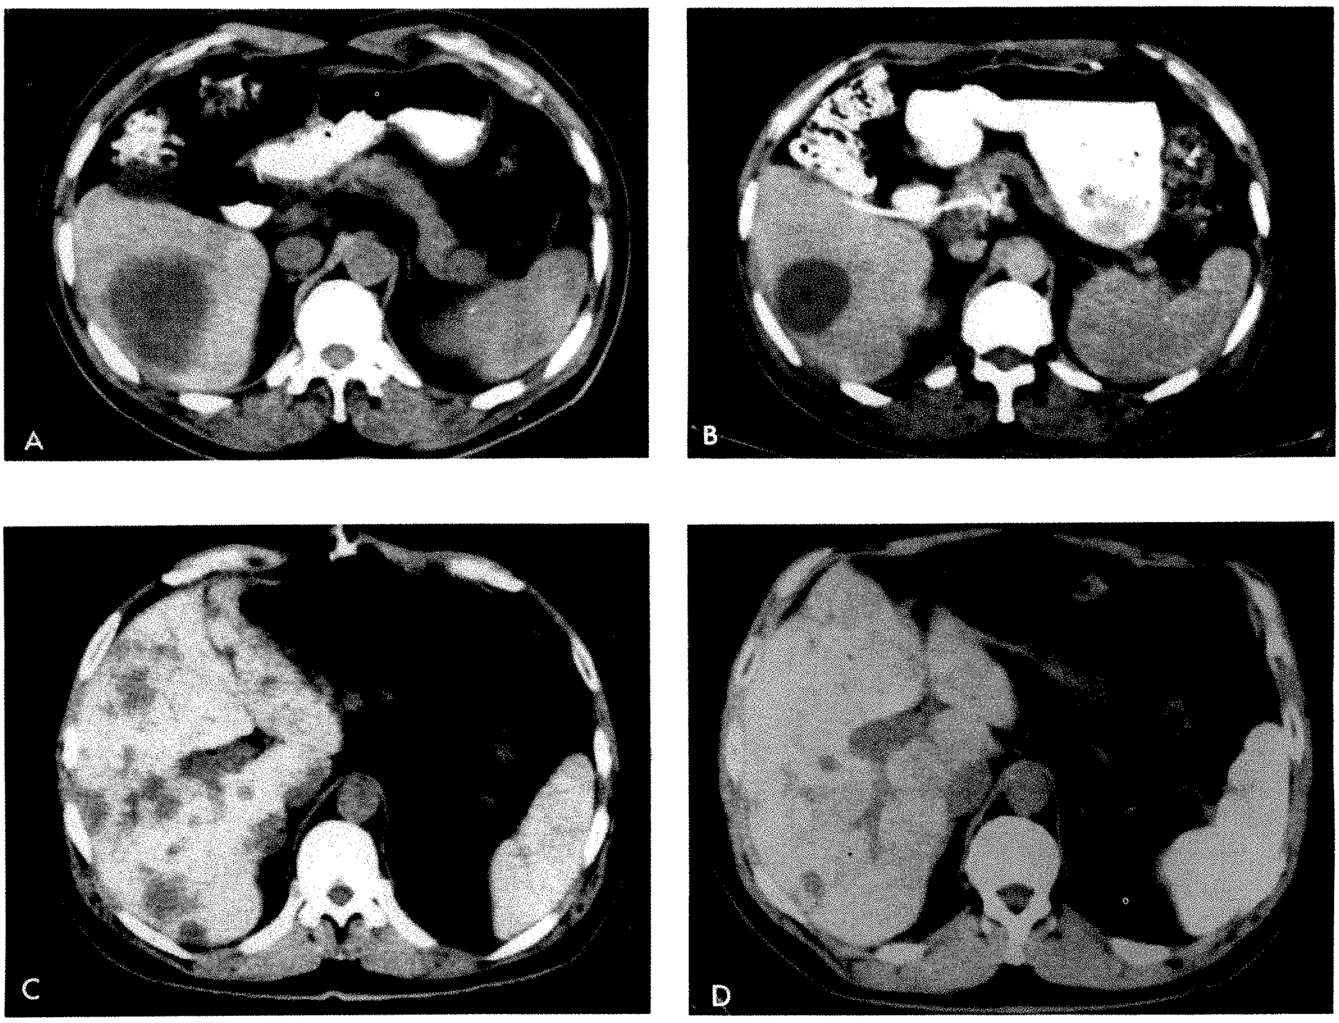
Results

Response Rates

The response rates for all randomized treated patients are indicated in Table 2. The overall response rate (complete and partial) for I.A. therapy was 13 of 21 patients (62%) and was significantly better than the rate of five of 29 patients (17%) seen for I.V. therapy ($p < 0.003$). There were two complete responses, one in each randomized group. Figure 1 illustrates the nature of the responses that were seen in two patients who had I.A. therapy.

The duration of response and sites of first failure are indicated in Table 3. The median duration of response was 7 and 9 months for I.A. and I.V. therapy, respectively. Of the 13 patients responding to I.A. therapy, six had their site of first relapse in extrahepatic sites compared with one of five in the I.V. treatment responders.

CEA levels were monitored every 2 weeks in all patients. Figure 2 is a graph of the percentage change in median CEA compared with pretreatment levels in patients who had I.A. and I.V. treatment and had elevated



FIGS. 1A–D. Responses documented by CT scan. *A*. Patient 10 had multiple liver metastases with a large tumor noted in the right lobe before therapy and a CEA level of 47 ng/mL. *B*. The same patient demonstrated a significant response in all tumors by CT scan with a decrease in CEA level to less than 2 ng/mL after receiving three cycles of I.A. FUDR therapy. *C*. Another patient (Patient 12) had bilobar metastases documented by CT scan and a CEA level of 37 ng/mL. *D*. After three cycles of I.A. FUDR, Patient 12 had a dramatic response in all liver lesions with a decrease in CEA level to less than 5 ng/mL. Both patients subsequently had relapses (see Table 3).

pretreatment CEA determinations. Three patients with normal pretreatment CEA values of less than 5 ng/mL (1 IV, 2 IA) were not included in the plot because CEA values were not reflections of their tumor burden. After the third cycle of chemotherapy, when patients were evaluated for response, the median percentage of pretreatment CEA levels was 28% and 168% for I.A. and I.V. treatment groups, respectively. Alternatively, after the third cycle, 12 of 20 patients who had I.A. therapy had their CEA levels decrease by more than 50% compared with 3 of 28 who had I.V. treatment ($p < 0.001$). CEA levels alone were not used to define a tumor response.

Survival

The survival of all randomized patients is depicted in Figure 3. The 2-year actuarial survival rates for the randomized I.A. and I.V. treatment groups were 22% and 15%, and the two curves were not significantly different from one another ($p = 0.27$). As was previously indicated, not all patients received treatment (see "Materials and Methods"). Patients found to have extrahepatic disease outside regional hepatic lymph nodes at the time of laparotomy for I.A. pump insertion did not have a pump placed. This would have allowed selection of a more favorable patient population in the I.A. treatment group because patients randomized for I.V. therapy were not required to have a laparotomy for staging purposes. Figure 4 depicts the survival of all randomized patients that received the assigned treatment. Patients who had I.A. and I.V. treatment had 2-year actuarial survival rates of 34% and 17%, respectively, with some evidence of difference between the curves ($p = 0.06$). This demonstrated a trend toward an improved survival rate in the selected group patients who had I.A. therapy.

The presence of tumor in hepatic lymph nodes did not exclude patients from receiving treatment. Biopsies were performed routinely on these nodes in patients randomized for I.A. therapy and also in patients who were chosen for I.V. therapy after an abdominal exploration revealed their liver metastases to be unresectable. The presence of positive hepatic lymph nodes appears to be a significant prognostic indicator (Fig. 5). For all treated patients who had I.A. therapy (including three pilot patients who satisfied the eligibility criteria), the median survival rate for patients with negative and positive hepatic nodes was 27 and 17 months, respectively, with the curves differing significantly (p = 0.024). Therefore, patients with negative hepatic nodes had improved survival rates compared with patients whose nodes were positive.

An analysis with patients who had I.A. and I.V. treatment was performed in randomized patients with negative hepatic nodes documented at laparotomy. As shown in Figure 6, patients who had I.A. treatment did significantly better than the group that had I.V. treatment (p = 0.03), with 2-year actuarial survival rates of 47% and 13%, respectively. A separate analysis that included the three pilot patients with I.A. treatment, all of whom had negative hepatic nodes, revealed a significant improved survival in patients who had I.A. treatment compared with I.V. therapy (data not shown).

Toxicity

Toxicity to I.A. therapy was significant. Table 4 lists the toxicity seen in all patients who had I.A. (including three pilot patients) and I.V. treatment. "Chemical" hepatitis, which was manifested as elevations in baseline liver function tests, was seen in 79% of patients with I.A. therapy compared with 7% of those with I.V. treatment. The usual changes seen were a transient elevation of liver functions seen 2 weeks after chemotherapy was started. These changes would often revert to baseline values after another 2–4 weeks. Minimal liver function abnormalities resulting from I.V. FUDR were seen. Eight of 24 patients who had I.A. treatment had elevations of total bilirubin greater than 3 mg/dL compared with none of 29 patients with I.V. therapy during some time interval of their treatment. Biliary sclerosis documented by percutaneous transhepatic cholangiograms was seen in five of 24 patients with I.A. treatment. All five patients had tumor responses (two complete, three partial) at the time the diagnosis of biliary sclerosis was made. One of these patients died of liver failure secondary to biliary cirrhosis with only two small metastatic nodules remaining in the liver.

Gastrointestinal toxicity was seen in both treatment groups but was manifested in different forms. In the group that had I.A. treatment, peptic ulcers developed

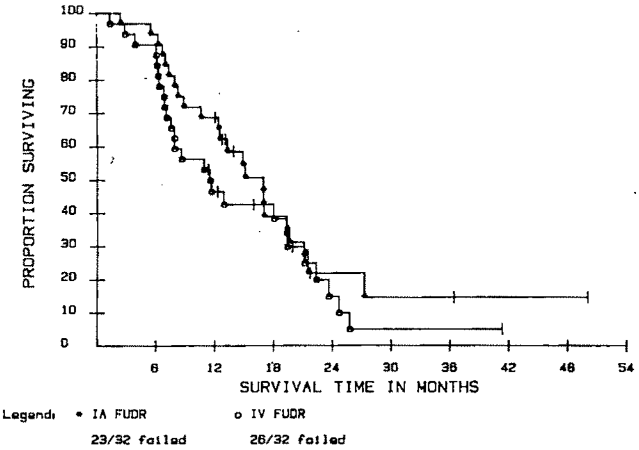

FIG. 3. Hepatic metastases infusion: survival of all randomized patients. The 2-year actuarial survival rates for randomized I.A. and I.V. groups were 22% and 15%, and the two curves were not significantly different (p = 0.27).

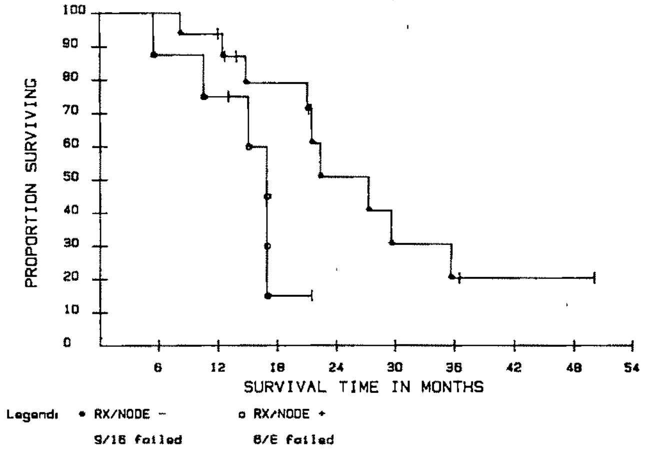

FIG. 5. Survival of all patients who had I.A. treatment with respect to hepatic node status. The median survival for patients with negative and positive hepatic nodes was 27 and 17 months, respectively, with the curves differing significantly (p = 0.024).

in the stomach or duodenum in four of 24 patients that were documented by upper gastrointestinal studies or endoscopic examination. One patient presented with a perforated ulcer requiring immediate operative intervention. Symptoms of gastritis and/or duodenitis were seen in five of the patients who had I.A. treatment. In the patients who had I.V. therapy there were no problems with peptic ulcers and minimal problems with gastritis. However, with I.V. therapy, 59% of patients complained of diarrhea that was severe enough to require six patients to be hospitalized for hydration.

The dose of FUDR given over repeated cycles in all treated patients is depicted in Figure 7. The dose of I.A. FUDR drug was significantly greater than systemic doses during the first five cycles of treatment. As can be seen, I.A. drug dose had to be decreased over successive courses. Dose modifications of I.A. therapy were mainly required because of hepatic toxicity and by the sixth cycle were not significantly different from I.V. doses. Dose modifications for I.V. therapy were less frequent, and the mean FUDR dose administered was relatively constant over time.

Discussion

This randomized, controlled trial has addressed the issue of whether regional continuous arterial perfusion FUDR therapy *via* the implantable pump offers any

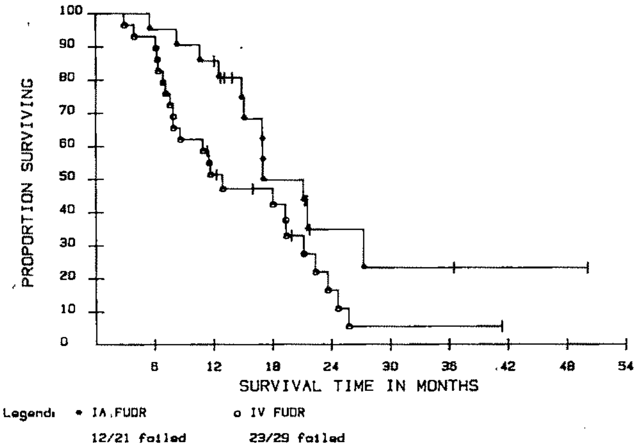

FIG. 4. Hepatic metastases infusion: survival of all randomized patients who received the assigned treatment. The 2-year actuarial survival rates for I.A. and I.V. treatment groups were 34% and 17%, respectively, with some evidence of difference between the curves (p = 0.06).

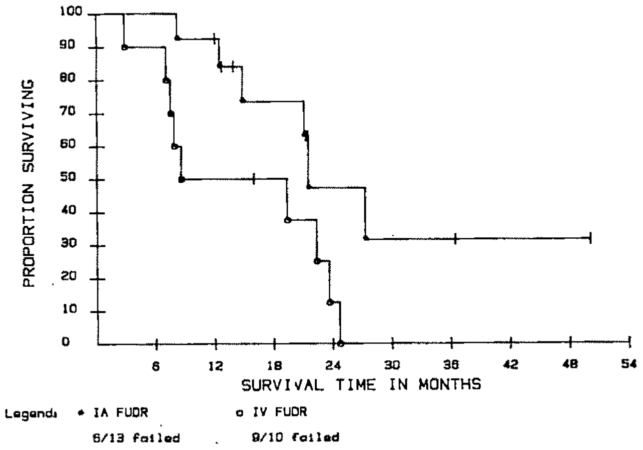

FIG. 6. Survival of patients with documented negative hepatic lymph nodes who were randomized for I.A. and I.V. treatment. The 2-year actuarial survival rates for I.A. and I.V. treatment groups were 47% and 13%, respectively, with the curves differing significantly (p = 0.03).

benefit in survival to patients with unresectable colorectal liver metastases. Previous reports for which FUDR was administered *via* the implantable pump have demonstrated significant tumor response rates in the range of 30–88% when various response criteria have been used.[7–14] We have confirmed that higher response rates are achieved when FUDR is administered intra-arterially *versus* intravenously at maximum tolerated doses. The response rates for the groups that had I.A. and I.V. treatment were 62% and 17%, respectively, which were significantly different. This most likely reflects the ability to deliver higher concentrations of the drug to the tumor regionally for several reasons. First, the hepatic extraction of FUDR is greater than 98% and allowed higher doses of I.A. drug to be administered without development of systemic toxicity.[19] Secondly, even at comparable doses, I.A. therapy should theoretically deliver higher doses of drug to the tumor because macroscopic hepatic tumors are mainly supplied by the hepatic artery. Also, inflow drug concentrations to the liver should be higher for arterial infusion *versus* systemic infusion when equal amounts of drug are administered because of the large blood volume dilution that occurs during systemic infusion. During the study, doses of I.A. drug were either greater than or equal to I.V. drug doses (see Fig. 7).

The most critical analysis is the impact of treatment on overall survival. After randomization, patients selected for I.A. treatment and who were found to have extrahepatic disease beyond hepatic lymph nodes did not have pumps placed. This was done because it was known that this potentially toxic treatment was not beneficial to patients with documented extrahepatic tumor.[12,14] These patients have been kept in the randomized group for analysis. Patients randomized for I.V. therapy were not required to have staging laparotomies and would have potentially occult extrahepatic tumor treated by systemic drug. With the use of this strategy, there was no difference in overall survival rate between patients randomized for I.A. or I.V. therapy with 2-year actuarial survival rates of 22% and 15%, respectively (Fig. 3). When one analyzes the survival data of patients who received treatment, excluding patients who did not, there was a trend in improved survival in the group with I.A. treatment compared with those who had I.V. treatment (Fig. 4). With more patients this may have resulted in an improved survival rate for the I.A. treatment group; however, this should be attributed to the selection of patients for I.A. treatment (*i.e.,* exclusion of patients with extrahepatic disease beyond hepatic lymph nodes).

An interesting observation was the effect of hepatic lymph node involvement on the survival of patients. Among all the patients who had I.A. treatment (21 selected at random and three pilot patients), hepatic lymph node involvement was not associated with response but was associated with survival. Those who had I.A. treatment and had negative hepatic lymph nodes (62% of the group) did significantly better than patients with positive hepatic lymph nodes (Fig. 5). Patients who had I.A. therapy and had positive hepatic nodes did not do significantly better than untreated patients excluded from therapy because of occult intra-abdominal extrahepatic disease (data not shown). This suggests that the presence of tumor in hepatic lymph nodes could have significant prognostic implications. Fortner et al. has also reported that a tumor in hepatic lymph nodes was associated with a poorer prognosis in a personal series of 109 evaluable patients receiving intrahepatic chemotherapy for colorectal liver metastases.[20] A tumor in these lymph nodes represents "remetastasis" from liver metastases.[21] Patients with involvement of hepatic nodes should not be considered for regional therapies because it appears to be a harbinger of systemic disease. This principle also applies to patients being considered for resection of colorectal liver metastases. Hughes et al.

TABLE 4. *Toxicities of FUDR Infusion*

Toxicity	IA Treatment (%) (N = 24)	IV Treatment (%) (N = 29)
Chemical hepatitis	19 (79)	2 (7)

reported a collected review of 859 resections for colorectal liver metastases in which there were no long-term survivors in a group of patients documented to have involvement of hepatic nodes.[22]

In a subgroup analysis of patients whose hepatic lymph nodes were documented to be negative, a significant survival advantage to I.A. therapy was found (Fig. 6). Two-year actuarial survival rates in the I.A. and I.V. groups were 47% and 13%, respectively. However, this was a small group of patients, and the results need to be confirmed in a larger series. Even if patients are adequately staged and found to be appropriate for regional infusion therapy, the toxicity of therapy needs to be considered.

I.A. FUDR was associated with major toxicity. The most common effect of toxicity was to the hepatobiliary system, with chemical injury to normal hepatocytes and ductal structures. The hepatic toxicity was similar to that encountered by others.[3,4] Our incidence of biliary sclerosis was 21% and led to a treatment-related death resulting from liver failure. This entity was first described by Hohn et al.[23] This complication may be related to the specific drug, FUDR, because there have been no other reports of this complication with other drugs delivered through the hepatic artery. Other effects of toxicity associated with I.A. FUDR are gastrointestinal problems such as peptic ulcers and gastritis/duodenitis, seen in 38% of patients. This coincides with the incidence reported by Kemeny et al.[13] Histamine H_2 receptor antagonists did not prevent these problems because all patients were treated with these medications. Resolution of these side effects required FUDR dose reduction or cessation.

This is one of only a few prospective, randomized studies that have been reported or are being conducted to evaluate arterial infusion therapy for colorectal hepatic metastases.[25] The first report in 1979 by Grage et al. was a Central Oncology Group study evaluating I.A. *versus* I.V. 5-fluorouracil (5-FU).[26] Sixty-one evaluable patients were entered into that trial. Only one "induction" dose of I.A. 5-FU was administered, followed by weekly systemic 5-FU in patients randomized for I.A. therapy. This was a major drawback with the study because repeated courses of I.A. drug were not given. There were no differences in response or survival rates between the randomized groups in that study. Since the introduction of the implantable pump, catheter complications related to prolonged hepatic artery infusion have been greatly reduced. Several randomized, prospective studies have been initiated evaluating I.A. FUDR *versus* a control group receiving systemic therapy. Preliminary results of a study at Memorial Sloan-Kettering Cancer Center have been reported by Kemeny and Daly.[27] Fifty evaluable patients were randomized for I.A. *versus* I.V. FUDR therapy; patients who progressed were crossed-over to the other arm. For I.A. therapy, a 43% response rate was noted compared with 32% for I.V. treatment. Survival data will be difficult to interpret because patients were crossed-over to the other arm. Hohn et al. reported their preliminary results in a similarly designed study.[28] Patients were randomized for I.A. *versus* I.V. FUDR therapy, with a cross-over when patients progressed. In 110 evaluable patients, I.A. therapy was associated with a 37% major response rate that was significantly better than 10% for the I.V. treatment group. Survival data were not analyzed in that report. Other randomized trials have not been reported to date.

Our experience indicated that I.A. FUDR is associated with significantly improved response rates of colorectal liver metastases compared with continuous I.V. FUDR. However, in our randomized study there was no impact on overall survival rate. This may be a significant observation that relates to all locoregional approaches to cancer. Despite adequate control of disease in one site, the patient may manifest disease elsewhere. For recurrent colon cancer, isolated hepatic recurrences are seen only 6% of the time compared with 80% of recurrences that are in multiple sites.[29] The status of hepatic lymph nodes was a major prognostic factor and when involved by tumor should be a contraindication to regional chemotherapy to the liver. This was seen in approximately 40% of our patients. In a subgroup of patients with negative hepatic nodes, I.A. therapy appeared to improve survival compared with I.V. therapy. However, because of the major hepatobiliary and gastrointestinal toxicity associated with I.A. FUDR therapy the improved survival advantage was not worthwhile in the best selected patient population. Another drawback was the morbidity experienced by patients who were explored and could not be treated because of extrahepatic disease.

Survival is certainly the most critical endpoint in evaluating new treatments. However, palliation of the patient and impact on their quality of life should also be considered. Even if survival is not prolonged, the high response rates associated with regional chemotherapy may potentially be an effective palliative approach to patients with unresectable colorectal liver metastases. Patt et al. reported an improved performance status in patients who respond to I.A. chemotherapy.[30] Future studies should define the impact of I.A. therapy on palliation and quality of life. This underscores the need to find treatments that are not associated with significant toxicities. Our present efforts are involved in a Phase I study of a different chemotherapeutic agent, iododeoxyuridine (IUdR), given by continuous I.A. administration to patients with colorectal liver metastases. This is a tumoricidal drug with radiosensitization properties that can be combined with radiation therapy.[31]

Adjuvant Postoperative Radiation Therapy for Colonic Carcinoma

CHRISTOPHER G. WILLETT, M.D.,* JOEL E. TEPPER, M.D.,* STEVEN J. SKATES, B.S.,* WILLIAM C. WOOD, M.D.,†

One hundred thirty-three patients with Stage B2, B3, and C colonic carcinoma had resection for curative intent followed by adjuvant postoperative radiotherapy to the tumor bed. The 5-year actuarial local control and disease-free survival rates for these 133 patients were 82% and 61%, respectively. Stage for stage, the development of local regional failure was reduced for patients receiving postoperative radiotherapy compared with a historic control series. Local recurrence occurred in 8%, 21%, and 31% of patients with Stage B3, C2, and C3 tumors who had radiation therapy, respectively, whereas the local failure rates were 31%, 36%, and 53% in patients treated with surgery alone. There was a 13% and 12% improvement in the 5-year disease-free survival rate in the patients with Stage B3 and C3 lesions who had radiotherapy compared with the historic controls. For patients with Stage C disease, local control and disease-free survival rates decreased progressively with increasing nodal involvement; however, local control and disease-free survival rates were higher in the patients who had radiotherapy than in those who had surgery alone. Failure patterns in the patients who had radiotherapy did not show any notable changes compared with those for patients who had surgery alone. Postoperative radiation therapy for Stage B3, C2, and C3 colonic carcinoma is a promising treatment approach that deserves further investigation.

Harvard Medical School, Boston, Massachusetts

RECENT REPORTS have described the failure patterns and identified patients at high risk for recurrence after attempted curative resection of colonic (nonrectal) carcinoma.[1-4] Subsets of patients at risk for local-regional failure include all patients with tumors extending through the bowel wall with adherence or invasion of adjoining structures or lymph node involvement with extension through the bowel wall.

Since 1976, patients with advanced stage colonic carcinoma have been offered treatment with postoperative radiation therapy to the tumor bed at the Massachusetts General Hospital. Duttenhaver et al. have described the indications and technical details of treatment and have analyzed local control and survival of the first 80 patients treated with relatively short follow-up.[5] This analysis indicated that postoperative irradiation to doses of 5000 cGy or greater improved local control and perhaps survival. The objective of this report is to assess long-term follow-up and failure patterns of patients treated with adjuvant postoperative radiation therapy.

Materials and Methods

From April 1976 to August 1985, 133 patients had resection with curative intent of a primary colonic neoplasm followed by postoperative radiation therapy in the Department of Radiation Medicine at the Massachusetts General Hospital. A colonic tumor was defined as one that arose from the large bowel above the peritoneal reflection without extension into the rectum. All patients were evaluated for at least 1 year after surgery, with mean and median follow-up periods of 44 months and 39 months, respectively, with a range of 12–110 months. Of the 133 patients, 60 were men and 73 were women. The mean age at surgery was 67.5 years, with a range of 21–85 years.

Primary lesions were described in terms of stage and of location in the bowel wall. In addition, the presence or absence of complete obstruction or perforation at the primary site was noted.[4] Pathologic staging was based on the Gunderson-Sosin modification of the Astler-Coller staging system and is described in Table 1.[6] The anatomic locations of the tumors within the large bowel were as follows: cecum, 27 patients; ascending colon, 12 patients; hepatic flexure, seven patients; transverse

Submitted for publication: April 11, 1987.

colon, three patients; splenic flexure, nine patients; descending colon, six patients; and sigmoid colon, 69 patients.

Postoperative radiation therapy was delivered *via* a Clinac 18 or 35 linear accelerator (Varian, Palo Alto, CA) by parallel opposed fields or appropriate arrangement of fields to treat the tumor bed with approximately a 5-cm margin with a total dose of 4500 cGy with 180 cGy fractions. This was followed by a shrinking field technique, sparing small bowel, to 5040–5500 cGy. Draining lymph nodes were included in the radiation field if they were felt to be at high risk of involvement. Technical aspects of treatment have been previously described.[5] Twenty-two patients were treated with adjuvant chemotherapy, generally with 5-fluorouracil (5-FU) alone.

Patients were evaluated for local failure, distant metastases, disease-free survival, and overall survival. Local failure was defined as a recurrence in the tumor bed and in adjacent organs by direct extension or in regional nodal groups. Regional nodal groups included lymph nodes up to the take-off of the colic vessels. Distant metastases were divided into abdominal and extra-abdominal failures. Abdominal failures included recurrences in the liver, peritoneal surfaces, para-aortic, and portahepatic lymph nodes (abdominal lymph nodes) but did not include tumor bed or regional nodal recurrences because these were classified as local rather than metastatic failures. Extra-abdominal failures included tumors in the lung, bone, central nervous system, or extra-abdominal lymph nodes. The 133 patients receiving postoperative radiotherapy were compared with a previously reported series of 395 patients with Stage B2, B3, C2, and C3 tumors who had surgical resection only at the Massachusetts General Hospital from 1970 to 1977.[3] The patients who had radiation therapy were unfavorably biased against radiation, however, because most were referred because of concern about the adequacy of local control with surgery alone. Actuarial local control and survival analyses were done by use of the Kaplan Meier method.[7]

TABLE 1. *Gunderson-Sosin Modification of stler-Coller Staging System*

Stage	Characteristics
A	Tumor limited to mucosa with nodes normal
B1	Extension through the muscosa but still within the bowel wall with nodes normal
B2	Extension through the entire bowel wall with nodes normal
B3	Extension through the entire bowel wall with adherence or invasion of adjacent organs or structures with nodes normal
C1	Lymph nodes with positive findings and tumor limited to the bowel wall
C2	Lymph nodes with positive findings and tumor through the entire bowel wall
C3	Lymph nodes with positive findings and extension through the entire bowel wall with adherence or invasion of adjacent organs or structures

Results

The 5-year actuarial local control, disease-free survival, and overall survival rates of all 133 patients receiving postoperative radiotherapy were 82%, 61%, and 62%, respectively. Table 2 shows by stage the 5-year actuarial local control, disease-free survival, and the overall survival rates for the patients who had postoperative radiotherapy and the patients who had surgery alone. With the exception of patients with Stage B2 disease, local control was at least 15% higher in the patients with Stage B3, C2, and C3 disease who had radiation therapy *versus* similarly staged surgical patients. Local control rates for patients with Stage B3, C2, and C3 disease receiving postoperative radiotherapy were 92%, 79%, and 69%, whereas these figures were 69%, 64%, and 47%, respectively, in patients having surgical resection only. Patients with Stage B3 and C3 disease receiving postoperative radiotherapy experienced a 13% and 12% increase in disease-free survival, respectively, relative to the group that had surgery alone. There was no improvement in disease-free survival rate for patients with Stage B2 or C2 disease.

The influence of the number of lymph nodes involved with carcinoma in the original specimen is shown in

TABLE 3. *Five-year Actuarial Local Control, Disease-free Survival, and Overall Survival Rates after Surgery Alone* Versus *Surgery and Radiation Therapy (RT) of Patients with Stage C Disease According to Number of Lymph Nodes Involved*

No. of Nodes	Treatment	No. of Patients	Local Control Rate (%)	Disease-free Survival Rate (%)	Overall Survival Rate (%)
1	Surgery	68	66	58	58
	Surgery and postoperative RT	21	92	71	65
2–5	Surgery	65	58	36	32
	Surgery and postoperative RT	40	76	42	45
6–14	Surgery	16	26	20	13
	Surgery and postoperative RT	9	50	28	16

Table 3. Higher rates of local control, disease-free survival, and overall survival were seen in patients receiving postoperative radiotherapy as compared with surgery alone. However, the magnitude of the improvement was greatest in patients with involvement of only one lymph node.

Twenty-one patients had evidence of complete obstruction or perforation at the tumor site and received postoperative radiotherapy. There was an improvement in the local control and survival rates for the 13 patients with Stage B3 disease who had radiation therapy compared with the group that had surgery only (Table 4). The limited number of patients with Stage B2, C2, and C3 disease with obstruction or perforation receiving radiotherapy precludes any comparison.

Local failure occurred predominantly in the tumor bed in both the patients who had radiation therapy and those who did not. Nineteen patients had local failure after surgery and postoperative irradiation, with 17 of these occurring in the tumor bed and two concurrently in regional nodes and the tumor bed. This is similar to the failure pattern observed in patients who had resection alone.[3] Tables 5 and 6 show the pattern of failure in patients with surgery alone *versus* those with surgery plus postoperative radiotherapy. The development of distant metastases only was higher in the patients who had radiotherapy; however, the overall distant metastatic rates were similar in both groups (Table 5). The incidence of extra-abdominal and hepatic metastases, peritoneal seeding, or abdominal lymph node metastases was similar in the patients receiving and not receiving postoperative radiation therapy (Table 6).

Discussion

In rectal carcinoma, the natural history and failure patterns after resection are well known, and adjuvant radiation therapy has been shown to decrease local failure rates and increase survival rates.[8,9] Data supporting the use of adjuvant radiation therapy for the treatment of colonic carcinoma (tumors above the peritoneal reflection) are less clear. A number of studies have analyzed the failure patterns after surgical resection alone to identify subsets of patients at increased risk for local regional failure.[1-3] Gunderson et al. reported on 91 patients with Stage C1–C3 colonic carcinoma who had single and multiple reoperative procedures after initial resection and observed a 48% incidence of local regional failure.[1] Russell et al. reported the cases of patients with Stage A, B1, and C1 tumors having local failure rates of 10%; Stage B2 and C2 lesions, 11%; and Stage B3 and C3 tumors, 35%.[2] In the Massachusetts General Hospital surgical series, local failure was uncommon in Stage A, B1, B2, and C1 tumors, but for Stages B3, C2, and C3 the local failure rates were at least 30%.[3] From these data it would appear that adjuvant radiotherapy may be indicated for advanced stage colonic carcinoma, Stages B3, C2, and C3.

Published reports on the use of adjuvant postoperative radiation therapy for colonic carcinoma are limited by the small number of patients treated and short follow-up period. However, the data do suggest that local failure rates are reduced by postoperative radiotherapy and in some studies there was an improvement in survival rate when compared with that for historic controls. Loeffler reported on 10 patients with Stage B3–C3 cecal carcinomas who received adjuvant regional postoperative radiotherapy to doses of 6500–7500 cGy who were treated with two daily fractions of 70–75 cGy and observed no local failures.[10] However, five patients had distant metastases develop with follow-up of 7–76 months. Brenner et al. described 21 patients with Stage C colonic carcinoma who received whole abdominal radiotherapy to 2000 cGy in eight fractions with a boost dose of 2000–3000 cGy in 3 weeks to areas at high risk and concurrent weekly doses of 5-FU at 350 mg/m^2 intravenously (I.V.).[11] The patients who had radiation therapy were compared with a matched control group that had surgery alone, and a statistically significant improvement in the disease-free survival rate of 55% was observed in patients receiving radiation *versus* 12% in those who had surgery alone. Shehata et al. reported on 19 patients with Stage B2 (14 patients) and Stage C2 (five patients) cecal carcinoma treated with regional postoperative radiation therapy to 4500 cGy and weekly doses of 5-FU (600 mg/m^2 I.V.) and matched to a similar group treated with right hemicolectomy only and noted no statistical difference in the median survival or incidence of distant metastases.[12] However, the incidence of local failure was 5% in the patients who had radiation therapy *versus* 19% in the group that had surgery alone. Forty-eight patients with Stage B1–C2 colonic carcinoma received adjuvant postoperative local irradiation at the Princess Margaret Hospital.[13] For patients with Stage B1 and B2 tumors the local failure rate was three of 20 (15%), whereas for patients having Stage C1 and C2 lesions local failure was seen in nine of 23 patients (32%).

In this study, postoperative radiotherapy to the tumor bed to doses of at least 4500 cGy has reduced the incidence of local failure to 18% overall for these advanced staged patients. Stage for stage, the development of local regional failure was reduced for patients receiving postoperative radiotherapy compared with the historic control series. Local recurrences occurred in 8%, 21%, and 31% of patients with Stage B3, C2, and C3 tumors who had radiation therapy, whereas the local failure rates were 31%, 36%, and 53% in patients treated with surgery only. In addition, there was a 12–13% improvement in the 5-year disease-free survival rate in the patients with Stage B3 and C3 disease who had radiation therapy compared with historic controls. Although local failure rate was reduced in patients with Stage C2 carcinoma who had radiation therapy, there was no notable difference in the 5-year disease-free survival rate from the patients who had surgery only. However, there is a po-

TABLE 6. *Patterns of Distant Metastases after Surgery Alone* Versus *Surgery and Postoperative Radiotherapy*

			Extra-abdominal Failures		Liver		Peritoneal Seeding		Abdominal Lymph Nodes	
Stage	Treatment	No. of Patients	Only	Total	Only	Total	Only	Total	Only	Total
B2 and B3	Surgery	246	11 (4%)	28 (11%)	15 (5%)	35 (14%)	4 (2%)	9 (4%)	1 (1%)	5 (2%)
	Surgery and postoperative radiation therapy	58	2 (3%)	3 (5%)	8 (14%)	8 (14%)	1 (2%)	1 (2%)	0 (0%)	0 (0%)
C2 and C3	Surgery	149	7 (5%)	35 (23%)	13 (9%)	44 (30%)	4 (3%)	23 (15%)	2 (1%)	12 (8%)
	Surgery and postoperative radiation therapy	75	4 (5%)	13 (17%)	6 (8%)	17 (23%)	4 (5%)	11 (15%)	2 (3%)	8 (11%)

tential bias in this series in that patients referred for radiation therapy were those who were thought by the surgeon to have a higher risk of local failure. This can be seen by an analysis of the patients with Stage C disease, where 46% of the patients who had surgery alone had the good prognostic factor of only one positive lymph node compared with 30% of the patients who had radiation therapy. For the entire patient population, Stage B2 diseases represented 41% of the group that had surgery but only 16% of those who had radiation therapy and Stages C2 and C3 represented 25% and 12% of the patients who had surgery, respectively, but 35% and 21% of the group that had radiation therapy. Thus, by most parameters, there was a selection process for the patients with poorer prognoses to be sent for the adjuvant therapy.

The analysis of patients with Stage C disease by the number of lymph nodes with carcinoma in the specimen showed that the patients with only one node involved who had radiation therapy had similar local control and disease-free survival rates as patients receiving postoperative radiotherapy for Stage B3 disease, which were clearly superior to those of the patients who had resection only. With increasing nodal involvement, local control and disease-free survival rates decreased progressively; however, local control and disease-free survival rates appeared higher with irradiation.

Local failures after resection and postoperative radiotherapy or surgery alone occurred predominantly in the tumor bed and not in regional nodes. Rates of failure in liver, peritoneal surfaces, abdominal lymph nodes, and extra-abdominal sites were similar among the two groups of patients.

For patients with Stage B2 disease there did not appear to be a notable gain in local control or disease-free survival rates in the patients who received radiation therapy *versus* the historic control patients. This is as expected, because the more recent analyses of failure patterns after surgery alone have not shown a high local failure for patients with Stage B2 disease without obstruction or perforation. In view of the reduction in local failure and improved disease-free survival rates in patients who had radiation therapy, we think that adjuvant postoperative irradiation for patients with Stage B3, C2, and C3 tumors is a promising approach that needs to be investigated through a prospective randomized trial.

Despite improvements in local control in the patients who had radiation therapy, the local failure rates were still significant for patients with Stage C disease with involvement of two or more lymph nodes (24% or greater). At the present time, all patients having postoperative irradiation are receiving 3 days of concurrent 5-FU at 500 mg/m^2/day I.V. for 3 days at the start and the completion of radiation therapy. Because the adjuvant studies of rectal carcinoma have shown the greatest survival and local control advantage with the combined use of radiation and chemotherapy, it is very possible that this combination will also be effective in colonic carcinoma.[8] Consideration of intraoperative radiation therapy for selected high-risk patients may also be used as a means of increasing the dose to the tumor bed to reduce further local failure and perhaps to increase disease-free survival. Ongoing studies will clarify the value of these treatment modalities.

ZANTAC® Injection
(ranitidine hydrochloride)

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see **DOSAGE AND ADMINISTRATION**). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).
Pregnancy: *Teratogenic Effects: Pregnancy Category B:* Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC® Headache, sometimes severe, seems to be related to ZANTAC administration. Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain have been reported. There have been rare reports of malaise, dizziness, somnolence, insomnia, vertigo, tachycardia, bradycardia, premature ventricular beats, and arthralgias. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.

Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.

Although controlled studies have shown no antiandrogenic activity, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Incidents of rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia, have been reported, as well as rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative is available as follows:
(NDC 0173-0362-38) 2-ml single-dose vials (Tray of 10)
(NDC 0173-0363-39) 10-ml multidose vials (Singles)
Store below 30°C (86°F). Protect from light.

ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

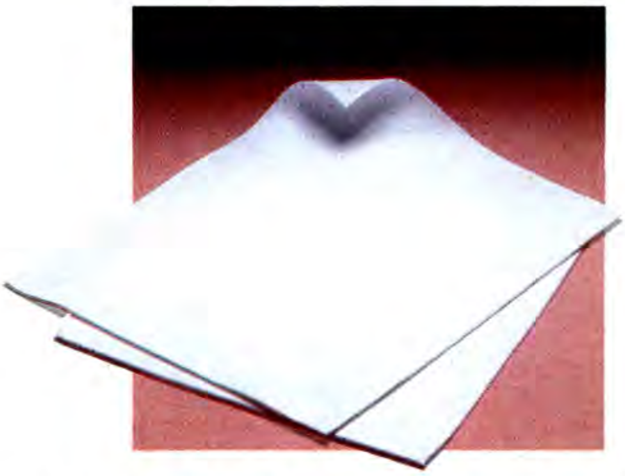
The Natural Choice



The best is not always good enough. The first choice, a patient's own tissue, cannot always be used for surgical reconstructions. When this happens the Soft Tissue Patch becomes the natural choice.

Since its introduction five years ago, the Soft Tissue Patch has performed exceptionally well in over 12,000 clinical cases. These cases include a wide variety of applications:

- Abdominal wall defects
- Large and small hernia repairs
- Thoracic wall defects
- Related pediatric reconstructions
- Rectal prolapse
- Vaginal prolapse
- Gastric banding

The excellent performance of the Soft Tissue Patch is due to its:

- soft, conformable nature
- high, balanced strength
- resistance to the spread of infection
- biocompatibility
- lower incidence of visceral adhesions/tissue erosion

GORE-TEX Soft Tissue Patch, the superior biomaterial, the natural choice.

For more information, return the business reply card or coupon. To order call **800-638-4804.**

GORE-TEX™ Soft Tissue Patch

Pyogenic Liver Abscess

Diagnostic and Therapeutic Strategies

EDWIN J. GYORFFY, M.D., CHARLES F. FREY, M.D., JOSEPH SILVA, JR., M.D., and JOHN McGAHAN, M.D.

From the Departments of Medicine, Surgery, and Radiology,
University of California, Davis, Medical Center,
Sacramento, California

A retrospective review of 26 adult patients admitted to University of California, Davis, Medical Center (UCDMC) with pyogenic liver abscess (1980–1986) was performed to ascertain the impact of rapid diagnosis and percutaneous drainage. Ultrasonographic examinations and computed tomography (CT) scans were highly sensitive and noninvasive imaging modalities. Sixteen patients had solitary abscesses and seven had multiple microscopic abscesses. The median time interval from admission to diagnosis and therapy was 2 and 3 days, respectively. Origin of the abscess was determined in 22 patients, the biliary tree being the most common source. Medical therapy was successful in three patients with microabscesses but failed in two. Nine patients had percutaneous drainage; two required repetitive percutaneous catheter placement, and two proceeded to surgical drainage. Twelve patients had surgical drainage; one required repetitive surgical drainage. Postdrainage complications were minimal in all groups. Overall mortality role was 11.5% (two patients). Deaths were related to delay in diagnosis, gram-negative sepsis at presentation, and biliary origin of the abscess.

RECENT REPORTS have emphasized the changing epidemiology, treatment, and prognosis of pyogenic liver abscess.[1-6] The availability of imaging modalities, ultrasonography, and computerized tomography (CT) and the successful application of closed percutaneous drainage of pyogenic liver abscess have changed approaches to diagnosis and therapy. We report our 6-year experience with pyogenic liver abscess with emphasis on diagnostic and therapeutic strategies.

Patients and Materials

Between January 1, 1980, and June 30, 1986, 26 patients older than the age of 16 years of age were admitted to University of California, Davis, Medical Center (UCDMC) with a final diagnosis of pyogenic liver abscess confirmed microbiologically and/or pathologically. UCDMC is a 453-bed University-based teaching hospital. Pediatric patients (N = 4) with pyogenic liver abscess and adult patients with amebic liver abscess (N = 14) identified during this time period were excluded from analysis. The case records of these 26 patients were reviewed with particular care devoted to ascertaining clinical features, time interval to diagnosis and therapy, imaging studies, microbiology, initial treatment, necessity for retreatment, and outcome.

Results

Clinical and Laboratory Features

Nineteen patients were men and seven were women. Their ages ranged from 21 to 76 years, with a mean of 47. Six patients were referred from other institutions. APACHE II scores, a physiologic measure of the severity of illness, ranged from 0 to 33, with a mean of 9.3.[7] More common signs and symptoms are shown in Table 1, and initial laboratory findings are shown in Table 2. Fourteen of the 26 patients had one or more co-morbid factors (biliary disease, malignancy, drug-related immunosuppression, diabetes mellitus, recent abdominal surgery, or chronic alcoholism). The initial chest roentgenogram abnormalities included atelectasis, hemidiaphragmatic elevation, or pleural effusion at the right base in 13 patients.

Diagnosis

Twenty-five of the 26 patients were diagnosed before death. The median number of days the patients had symptoms before hospitalization was 14 (range: 1–120 days). In six patients the diagnosis was made before hos-

Submitted for publication: April 29, 1987.

TABLE 1. *Clinical Features (N = 26)*

	No.	(%)
Symptoms		
Fever	23	(88)
Nausea/malaise	18	(69)
Weight loss	15	(58)
Abdominal pain	10	(38)
Signs		
Fever	25	(96)
RUQ tenderness	16	(62)
Hepatomegally	10	(38)
Jaundice	3	(12)

pitalization. In the remaining patients, the most common types of tentative diagnoses and symptoms cited on admission were cholecystitis, fever and abdominal pain, and sepsis of unknown source. Diagnosis was usually made after ultrasonography or CT scan for evaluation of abnormal liver enzymes, right upper quadrant tenderness, or chest roentgenographic abnormalities. Median length of patient hospital stay before a diagnosis was established was 2 days (range: 0–8 days). Thirteen patients had diagnostic aspiration or drainage before definitive therapy. Purulent material was aspirated in all patients, and there were two complications (one ruptured abscess necessitating immediate surgery and one hemorrhage necessitating transfusion).

Noninvasive Imaging

The initial imaging study is shown in Table 3. Ultrasonographic examination performed in 17 patients and the findings were positive in 15. In one patient a single abscess was missed and in another the ultrasonographic examination showed a single abscess in a patient with multiple abscesses. Both of these patients had nonhomogeneous liver scans secondary to co-existing liver disease. The initial procedure was CT scan for six patients and sulfur colloid scanning in two patients. There were no false-negative results in either group. One patient had an exploratory laparotomy that had normal findings. After operation an ultrasonographic examination was performed that indicated an abscess.

Most patients had multiple imaging studies during therapy. Both ultrasonographic examination and CT scan were highly specific, and we found little difference in terms of information obtained from the two modalities when used in follow-up examinations.

Abscess Characteristics

Three patients had multiple microabscesses (less than 1.5 cm), all of whom had a clinical picture of ascending cholangitis. Sixteen patients had solitary liver abscess, and seven patients had multiple abscesses (29 macroscopic abscesses in 23 patients). Twenty-three of the 29 macroabscesses were located in the right lobe. Eleven abscesses were between 1.5 and 5 cm, 12 abscesses between 5 and 8.0 cm, and six abscesses were greater than 8.0 cm. Twelve of 29 abscesses appeared loculated by ultrasonographic examination or CT scan, although these loculations were confirmed at subsequent drainage in only two patients.

Microbiology

All 26 patients had positive abscess culture results despite that they had received broad-spectrum antibiotics at the time of the initial culture of the liver abscess (Table 4). A total of 56 different organisms were isolated in 26 patients. Eight patients (31%) had monomicrobial cultures. Two organisms were isolated in 10 patients, three organisms in five patients, four organisms in two patients, and five organisms in one patient. As expected, the bacteriologic study showed a predominance of gram-negative aerobes (22 of 56) and anaerobes (27 of 56). Blood culture results were positive in nine of the 19 patients from which they were obtained.

Origin of Pyogenic Abscess

The origin of the pyogenic liver abscess was eventually determined in 22 (85%) patients (Table 5). In 14 patients the source was evident at diagnosis and was known before therapy was initiated. Clinical history and ultrasonographic or CT imaging were most helpful in determining origin, especially as it pertained to the biliary tree. In the remaining 12 patients the source was not evident at the time of therapy but was determined in

eight patients during the course of therapy. A barium enema was performed in six patients, which showed recent evidence of perforated diverticulum in two patients and extensive diverticular disease in another. Endoscopic retrograde cholangiopancreaticography was performed in four patients and had normal findings in all cases. The origin could be determined at laparotomy in three patients, with further clinical evaluation in one patient, and at necropsy in an additional patient.

Nine liver abscesses (35%) originated in the biliary tree, seven from cholecystitis and/or cholangitis and two from malignant obstruction of the biliary tree. Of the five cases originating from the colon, the origin was only evident in two patients on admission. Local penetrating trauma accounted for three cases and seeding from a source of infection in a distant location in three other patients. No source could be determined in four patients, despite a thorough investigation.

Therapy and Outcome

All patients generally received broad-spectrum antibiotics before diagnosis. The median time from admission to initiation of antibiotic therapy was 1 day (range: 0–8 days). The median time from admission to a drainage procedure was 3 days (range: 1–8 days). The initial treatment and requirement for retreatment for the 26 patients are shown in Table 6. In one patient, a diagnosis of liver abscess was not made before death. The patient received continuous antibiotics as the sole treatment, and an abscess was discovered at necropsy. One patient had a single aspiration followed by antibiotics. The abscess re-accumulated and was successfully treated by closed continuous percutaneous drainage.

Nine patients, three of whom had multiple abscesses, were initially treated by closed, continuous percutaneous drainage. All were clinically and hemodynamically stable. Diagnostic aspiration was followed by placement of a 7–12 Fr pigtail catheter by use of a modified Seldinger technique.[8] Catheter placement was carried out under guidance with either ultrasonography or CT scan. Once the catheter was adequately positioned, saline irrigation was performed and the drains were placed to gravity drainage. One drain was placed per abscess cavity. Patients were monitored by CT scan or ultrasonography to ensure complete drainage. The drains were left in for an average of 8 days (range: 4–18 days) and removed when the abscess cavity had collapsed around the catheter. Percutaneous drainage was considered to have failed if any of the following were noted: (1) complications related to catheter insertion that necessitated surgical intervention; (2) lack of improvement or worsening condition after 72 hours of percutaneous drainage; and (3) recurrence of the abscess within 3 months of therapy. Four patients' percutaneous drainage failed (Fig. 1). Two of these were treated successfully by placement of a second percutaneous catheter, and one patient went directly to successful surgical drainage. A blood clot was found in the abscess cavity. Another patient had successful surgical drainage after failure of a second percutaneous catheter drainage attempt. There were no

deaths in this group. Two complications were seen in the 13 patients who had diagnostic aspiration; abscess spillage necessitating immediate surgery occurred in one patient and hemorrhage necessitating transfusion in another. No complications arising from therapeutic drainage were seen.

Twelve patients had surgical drainage as initial therapy. Four patients with cholecystitis recognized on admission were successfully treated with cholecystectomy and operative drainage of the abscess. The other eight patients had operative drainage for a variety of reasons. In two of these patients, a single aspiration followed by treatment with antibiotics had failed at another hospital. One patient had an acute abdomen, one had spillage during diagnostic aspiration, and for four, two of whom were gravely ill, it was the clinician's choice. There was one treatment failure and two deaths in the patients that had surgical drainage. One patient had successfully repetitive surgical drainage 10 days after the first drainage, when the abscess failed to resolve. Another patient, in whom diagnosis was delayed, died after surgical drainage. The other patient died during operation for multiple abscesses. Two of the three patients with microabscesses were successfully treated with cholecystectomy, T-tube drainage, and antibiotics. The other patient was treated by antibiotics and removal of a T-tube previously placed.

The overall deaths were three of 26 (mortality rate: 11.5%). Analysis of the three deaths showed three common features: significant delay in diagnosis and treatment, high APACHE II scores, and origin of the abscess from the biliary tree. The patient that was diagnosed after death had an acute abdomen and sepsis. Exploratory laparotomy did not reveal any abnormalities. Blood cultures were positive for *Escherichia coli,* and the patient died from sepsis on the 10th hospital day. Necropsy showed a pyogenic abscess deep in the liver parenchyma associated with cholangitis. Culture of the biliary tree and abscess grew a pure culture of *E. coli.* In the other two deaths, there was a significant delay in diagnosis (7 and 8 days). One patient died during operation for multiple abscesses that surrounded the inferior vena cava, and the other patient died from multiorgan failure 14 days after surgical drainage. The mean APACHE II scores of the patients that died was 26.3 compared with 7.1 for the group of patients that were cured. Of the 23 surviving patients, follow-up information was available in 17 patients at 6 months without evidence of recurrence.

Discussion

In this review, we have been able to assess the impact of both imaging modalities (CT scanning and ultraso-

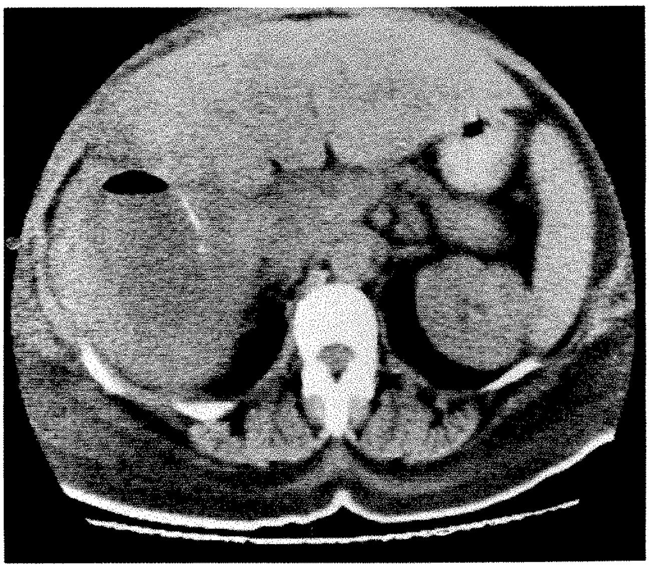

FIG. 1. Pyogenic abscess for which two efforts at percutaneous drainage failed.

nography) in expediting the diagnosis and the effect of percutaneous drainage on the clinical course and outcome of patients with pyogenic liver abscess. Most previously reported series include patients from several decades before the advent of these new techniques.[1-3,5,10]

The clinical presentation of pyogenic liver abscess remains insidious and may be protracted. Often the signs on physical examination and symptoms of a liver abscess are nonspecific; in our experience, the cholestatic pattern of liver function enzyme abnormalities is suggestive but not specific of a hepatic abscess. Fever, right upper quadrant tenderness, elevated venous leukocyte count, and hypoalbuminemia are present in most patients. The use of the APACHE II scoring system proved useful in identifying patients with a poor outcome.

The microbiologic findings for this group of patients showed the usual predominance of anaerobes and gram-negative aerobic bacilli. Since the advent of anaerobic cultures, non–spore-forming anaerobic bacteria have been recognized as important pathogens in pyogenic liver abscess and are recovered in 25–45% of cases.[11] We observed polymicrobial isolates in 69% of patients. Earlier studies have reported an increase in mortality rate with polymicrobial isolates,[3] although we did not observe this event in this small series. Bacteriologic results are generally not helpful in identifying the source of the pyogenic liver abscess, although multiple anaerobic isolates point to the colon as a source and a single isolate of *E. coli* often indicates the biliary tree as a nidus.

The optimal choice of antibiotics in liver abscess is unknown, although experimental evidence supports the use of agents active against both gram-negative aerobes and anaerobes. Most anaerobes originating in the abdomen are susceptible to similar antibiotics, and sensitivity testing is unreliable in routine anaerobiologic laboratories. The traditional use of an aminoglycoside combined with clindamycin or metronidazole is still recommended.[13] Both metronidazole and clindamycin have wide anaerobic coverage, excellent penetration to abscess cavities, and minimal side effects with short-term use. Third-generation cephalosporins have excellent activity but lack coverage for some gram-negative aerobes and anaerobes, especially *Bacteroides fragilis* (which was present in seven of our patients). The final choice of antibiotics should be guided by a culture. The duration of antibiotic therapy is controversial, but we agree with many reports that recommended therapy for 6 weeks.[14,15] When there is adequate drainage, we also feel that antibiotics should be given for 7 days after resolution of the abscess cavity and clinical signs of toxicity.

With the use of modern imaging procedures, the ability to diagnose pyogenic liver abscess is markedly improved from the past. In early studies, as many as 30% of patients with hepatic abscesses were diagnosed after death, whereas in this study 25 of 26 patients were diagnosed before death. The median time from admission to diagnosis was 2 days, which is a significant improvement from even recent studies that report the time to diagnosis range from 6.5 to 23 days.[3,16] We attributed this improvement to the sensitivity and accuracy of ultrasonography and CT scanning and aspiration of the abscess. Diagnosis is now possible with a high degree of certainty without surgical confirmation. Ultrasonography has a reported sensitivity of detecting pyogenic liver abscesses in the range of 85–95% and CT scanning of 95–100%.[17,18] Ultrasonography has the advantage of accurately visualizing the biliary tree and is better than CT scanning in distinguishing solid from cystic structures, but ultrasonography is limited by technical factors. Certain areas of the liver are difficult to visualize by ultrasonographic examination. These include areas adjacent to the hemidiaphragm, where visualization is difficult when the liver is anatomically situated high under the rib cage. Extremely obese patients and those who are uncooperative are difficult to scan with ultrasonography. Two false-negative results by ultrasonography in this study were in patients with nonhomogenous livers. In this regard, the CT scan is more sensitive and can distinguish subtle differences in density. CT scanning also has the advantage of visualizing the posterior, superior aspect of the liver. The CT scan best demonstrates surrounding structures, but both ultrasonography and CT scanning may be used to look for sources of sepsis outside the liver (i.e., kidney). Because of the common association of pyogenic liver abscesses with biliary disease, both ultrasonographic examination and CT scans may be useful to identify cholelithiasis or biliary obstruction. The technetium scan[17] adds little to the information available from ultrasonographic examination and CT scan and should never be used alone in assessing suspected liver abscesses.

Neither ultrasonography or CT scanning are accurate in differentiating loculations from multiple separate liver abscesses. Because it is requisite to drain all liver abscesses when there is more than one, any significant loculation may necessitate placement of a second catheter to improve drainage. Gerzoff et al.[19] and Bernardino et al.[20] reported that most loculations seen by ultrasonographic examination or CT scans are pseudoloculations and communicate freely within the abscess cavity. When significant loculations occur, they can potentially be a source of an inadequate percutaneous drainage and treatment failure but are not contraindications to percutaneous drainage.[21]

Determination of the origin of pyogenic liver abscess is important because it impacts on therapy. In this study the origin was determined in 14 of 26 patients at the time of therapy and later in the other eight patients. Barium enema was useful in this small series in detecting occult colonic disease, especially peridiverticular abscess. The source of the abscess was not apparent even after extensive investigation in four patients. So-called cryptogenic liver abscesses account for approximately 20% of cases, even in recent studies.[10] Biliary tract disease accounted for nine cases and is the most common underlying origin being reported.[1,22] Malignant biliary tract obstruction is becoming an increasingly significant source for pyogenic liver abscess.[3]

The source and characteristics of the abscess and the patient's underlying clinical condition are important parameters in determining therapy.

It appears that multiple microabscesses will predictably respond to systemic antibiotics.[23] However, it is important to determine the source of such abscesses because multiple small abscesses usually occur with co-existing cholangitis. In this series all three patients with multiple microscopic abscesses had ascending cholangitis necessitating additional corrective surgery on the biliary tree.

For single or multiple macroscopic abscesses, it is becoming increasingly clear that continuous drainage is necessary, either surgically or percutaneously. Since the report of McFazedean et al.[24] report in 1953, there has been controversy over the role of medical management alone in the treatment of pyogenic liver abscess. Subsequently, there has been a number of case reports[14,25–28] of the successful therapeutic management of pyogenic liver abscess without a drainage procedure (antibiotics alone or a single aspiration followed by antibiotics). In this series the one patient who did not have a drainage procedure because of failed diagnosis died later, despite continuous antibiotic therapy. In another patient, single aspiration followed by antibiotics was unsuccessful. In two referred patients single aspiration followed by antibiotic treatment had failed. McKorkell and Niles[29] reported on a series of 14 patients that medical management was successful in only one patient and concluded that medical management is not likely to be successful. In other studies[4,9,10,16] mortality rates for patients not receiving drainage procedures ranged from 70 to 100%. Although medical management may be successful in a small percentage of patients, we believe that continuous drainage is required for optimal therapy.

The experience with the use of closed continuous percutaneous drainage of pyogenic liver abscess continues to expand.[5,13,19,20,30–33] Initial studies reported a high success rate with few complications. Nine of our patients had percutaneous drainage as the initial procedure, and it was unsuccessful in four (44%). In three of these patients the failure of the abscess to resolve necessitated the placement of a second percutaneous catheter. The failure rate and complications of percutaneous drainage of pyogenic liver abscess have been reviewed in the English literature,[19] with a reported failure rate of approximately 15% and a complication rate of 4%. Because of the high success rate, particularly in gravely ill patients, closed continuous percutaneous drainage should be the initial drainage procedure, provided there is no other indication for laparotomy and percutaneous drainage is technically feasible.[34] For those patients in whom the source of the abscess is not obvious, percutaneous drainage can be used as a temporizing measure. The optimal time of catheter removal is not known. We have adopted a policy of obtaining serial imaging studies and removing the catheter when the abscess cavity has collapsed around the catheter and drainage has ceased. Many studies reported the time to catheter removal to be between 16 and 20 days, although Johnson et al.[33] reported successful treatment of pyogenic liver abscess with only 3–4 days of catheter drainage.

Laparotomy with surgical drainage has an important role in the management of pyogenic liver abscess. Although studies from the era before CT scans and ultrasonic imaging reported a significant mortality rate with operative drainage, these historic observations are no longer valid because of improved preoperative, operative, and postoperative care as well as more timely diagnosis. Operative drainage is highly effective and now has a low mortality and morbidity rates in the management of patients with pyogenic liver abscess. There are no controlled studies comparing percutaneous with operative drainage of liver abscesses. In patients with an identified intra-abdominal source of the liver abscess as an indication for laparotomy, surgical drainage is the procedure of choice. For abscesses in which percutaneous drainage has failed or abscesses in which percutaneous drainage is not technically feasible, surgical drainage is the preferred treatment. Furthermore, surgery is often essential in eliminating the source of infections that seeded the liver, as was necessary in eight of the 12 patients coming to operation.

Overall, three of 26 patients in this study died (mortality rate: 11.5%). In an analysis of the three deaths, we found delay in diagnosis, a biliary source, and a high APACHE II score were significant factors. Other authors have reported a mortality rate of 10–20%, which has significantly improved even from reports of 10 years ago. We feel this improved mortality rate reflects the improved capability for early diagnosis and rapid application of therapy. Successful management of pyogenic liver abscess entails an individualized approach based on the underlying clinical condition and source of the abscess and rapid institution of therapy. The reduced mortality rate of pyogenic liver abscess reflects the improved capability of rapid diagnosis and individualized therapy based on underlying severity of illness and knowledge of the source of the abscess.

Gastrointestinal Sarcomas

Analysis of Prognostic Factors

PATRICK C. McGRATH, M.D.,* JAMES P. NEIFELD, M.D., WALTER LAWRENCE, JR., M.D., SAUL KAY, M.D., J. SHELTON HORSLEY III, M.D., and GEORGE A. PARKER, M.D.

From the Division of Surgical Oncology, Departments of Surgery and Pathology, and the Massey Cancer Center, Medical College of Virginia, Richmond, Virginia

Clinical and pathologic data from 51 patients with primary sarcomas of the gastrointestinal tract treated from 1951 through 1984 were reviewed to determine clinical presentation, histologic features, treatment, and prognostic factors. The most common signs and symptoms were abdominal pain (62%), gastrointestinal bleeding (40%), and/or abdominal mass (38%). The primary site was stomach in 50%, small bowel in 30%, colorectum in 15%, and esophagus in 5%. Virtually all the sarcomas were leiomyosarcomas. Distribution was uniform among the three histologic grades; although 88% of Grade 1 tumors could be completely excised, only 35% of Grade 3 tumors could be completely resected. The 5-year survival rate was 75% for Grade 1 tumors, 16% for Grade 2 tumors, and 28% for Grade 3 tumors ($p = 0.0013$, Grade 1 *vs.* 2 and 3). Thirty of the 51 patients (59%) had curative resection with an operative morbidity rate of 24% and an operative mortality rate of 12%; at 5 years the disease-free survival rate was 58% and the overall survival rate was 63% (48% at 10 years). Eleven patients (42%) had recurrent disease develop at a median interval of 2 years after complete tumor excision. Twenty-one patients (41%) had partial excision or biopsy only of their tumors with an operative morbidity rate of 28%, operative mortality rate of 8%, and median survival of only 9 months. Overall, patients whose tumors were confined to the site of origin had a 58% 5-year survival rate compared with 20% for those whose tumors had invaded adjacent organs ($p < 0.05$). If the tumor was less than 10 cm in size, the 5-year survival rate was 78%, significantly better than the 38% for tumors greater than 10 cm ($p = 0.03$). These data suggest that histologic grade, local invasiveness, size, and extent of resection are the most important prognostic factors for patients with primary gastrointestinal sarcomas. Patients who have resection of all gross tumor, especially if it is well differentiated and localized, have a good prognosis.

GASTROINTESTINAL SARCOMAS are uncommon tumors, constituting 1–2% of all gastrointestinal malignancies and about 10% of all sarcomas.[1,2] The literature consists mostly of isolated case reports, and only a few studies of gastric or intestinal leiomyosarcomas from any one institution are reported. There is wide variation in reported survival rates and no uniform therapeutic approach. However, in recent years there has been considerable progress made in the pathologic interpretation of soft tissue sarcomas in general, thus enabling a more accurate assessment of prognostic variables.

The purpose of this review is to analyze the management of primary gastrointestinal sarcomas at the Medical College of Virginia (MCV), to delineate their natural history, and to investigate the influence of various factors on prognosis.

Materials and Methods

Fifty-one patients were treated at MCV from 1952 to 1984 for primary gastrointestinal sarcomas. Pediatric rhabdomyosarcomas have been excluded from this study because of their different natural history since the advent of combined modality therapy.[3] Charts and histopathologic slides were reviewed to determine clinical presentation, histologic type and grade of the tumor, extent of surgical resection, operative morbidity and mortality rates, the use of radiation and/or chemotherapy in addition to surgery, pattern of recurrence and metastases, and survival data.

For the purpose of this review, resection was considered complete if all gross disease was removed and the microscopic margins were tumor-free. Partial resection included those cases in which the bulk of tumor was removed but gross or microscopic disease remained.

TABLE 1. *Histopathologic Grading of Gastrointestinal Sarcomas*

Grade 1	Well differentiated Moderate cellularity Lack of anaplasia 0–4 mitoses/10 high-power fields
Grade 2	Moderately differentiated Moderate cellularity Mild anaplasia 5–9 mitoses/10 high-power fields
Grade 3	Poorly differentiated Marked cellularity Marked anaplasia ≥10 mitoses/10 high-power fields

Survival curves were plotted by use of Cox's proportional hazards model.[4]

The histologic slides were characterized in terms of differentiation, cellularity, anaplasia or atypia, and mitotic index. These tumors were then graded according to the criteria indicated in Table 1.

Results

Clinical Presentation

The mean age of the patients with gastrointestinal sarcomas was 53 years (range: 9–83 years). There was a slight male predominance, with a ratio of 1.8:1. The most common presenting complaint was abdominal pain, which was present in 62% of the patients. Forty per cent of the patients had evidence of gastrointestinal blood loss. Thirty-six per cent of patients had significant weight loss, and 28% complained of anorexia, nausea, or vomiting. The average duration of symptoms was 4.4 months (range: less than 1–24 months). An abdominal mass was palpable on physical examination in 38% of the patients (Table 2).

The average diameter of tumors was 11 cm (range: 1.5–23 cm). The tumors were slightly smaller in those patients having complete resection, but this was not statistically significant.

The distribution of the gastrointestinal sarcomas according to location is shown in Table 3. More than half of the tumors were located in the stomach, with 14 in the small intestine, eight in the colorectum, and only three in the esophagus.

TABLE 2. *Presenting Signs and Symptoms of Patients with Gastrointestinal Sarcomas*

Signs and Symptoms	No. of Patients	Percentage
Abdominal pain	31	62
Gastrointestinal bleeding	20	40
Abdominal mass	19	38
Weight loss	18	36
Anorexia, nausea, and vomiting	14	28

TABLE 3. *Distribution of Gastrointestinal Sarcomas*

Site	Number	Percentage
Esophagus	3	6
Stomach	26	51
Duodenum	3	6
Jejunum	7	13
Ileum	4	8
Colon	5	10
Rectum	3	6
Total	51	100

Histopathology

Virtually all the tumors were leiomyosarcomas, of which 44 were spindle cell type and five were epithelioid cell type (also known as malignant leiomyoblastoma). There was one malignant fibrous histiocytoma located at the base of the appendix and one hemangiopericytoma located in the sigmoid colon, representing extremely rare locations for these histologic types.

Table 4 shows the distribution of histologic grade in terms of those patients having complete *versus* partial resection of their tumors. Although there was a near uniform distribution of tumors between the three tumor grades, there was a marked difference in the extent of surgical resection possible among the three groups classified by grade. Almost all the patients with Grade 1 tumors could have complete resections, whereas only one-third of the Grade 3 tumors could be resected completely.

Extent of Surgery

Thirty of the 51 patients (59%) had complete resection of their tumors. These patients had 33 operations in which their tumors were completely excised; 27% of these operations necessitated resection of adjacent organs to ensure adequate margins. The most frequent adjacent organs resected were spleen and tail of pancreas (in association with gastric sarcomas); there was one pancreaticoduodenectomy plus nephrectomy performed to completely excise a sarcoma of the duodenum. There was a 24% incidence of postoperative complications in these patients, the most frequent being wound infections and sepsis. There were four deaths (12% operative mortality rate) among those patients having complete excision; three of those resulted from

TABLE 4. *Histologic Grade of Gastrointestinal Sarcomas*

	Grade 1	Grade 2	Grade 3
Complete excision	14	11	5
Partial excision	2	10	9
Total	16	21	14

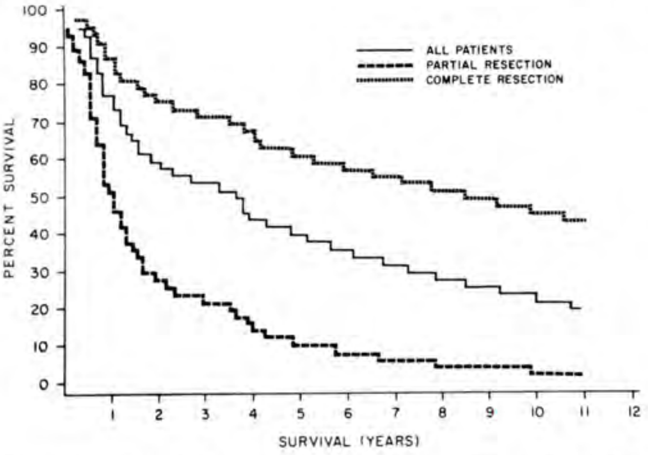

FIG. 1. Actuarial survival curves for patients having complete or partial resection of primary gastrointestinal sarcomas.

sepsis and occurred during the first 6 years of the review. The other death resulted from breakdown of the gastrojejunostomy and overwhelming sepsis in the patient who had a pancreaticoduodenectomy.

Twenty-one patients (41%) had 25 operations with partial excision or biopsy only of their tumors; the morbidity rate was 28% and operative mortality rate was 8% in this group of patients having palliative operations.

Pattern of Recurrence and Metastases

Twelve of the 26 patients (46%) who survived complete resection had recurrent disease develop. The recurrence was initially local in three patients; 10 of the 12 patients eventually had distant metastatic disease develop. The median interval from initial resection to detection of recurrence in these 12 patients was 2 years (range: 6–98 months). The three patients whose recurrence was local had complete excision of the recurrent tumor, with one patient surviving 16 years with no evidence of disease and the other two patients dying from recurrent tumor 12 and 31 months after re-excision.

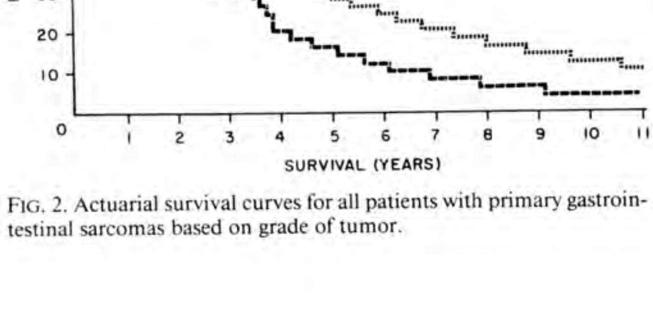

FIG. 2. Actuarial survival curves for all patients with primary gastrointestinal sarcomas based on grade of tumor.

Twenty-eight of the 51 patients (55%) had documented distant metastases or subsequently had them develop. The most common sites of metastases were liver (65%), peritoneum (43%), regional nodes (28%), and omentum (18%). There were only three cases of extra-abdominal metastases, and these were all located in the lung. Among all patients with gastrointestinal sarcomas, there was a 15% incidence of metastases to regional lymph nodes.

Survival

The 5-year survival rate for all patients with gastrointestinal sarcomas treated at MCV during the period of study was 40%. When the data were analyzed according to the extent of resection, it is clear that complete excision afforded the only hope for long-term survival. The 5-year survival rate for patients who had complete resection was 63%, as compared with 10% surviving at 5 years after partial excision ($p < 0.0001$). At 10 years the overall survival rate for patients having complete tumor resection was 48% (Fig. 1). The 5-year disease-free survival rate of patients having complete resection was 58%.

Various prognostic factors were analyzed to determine their effect on survival. Analysis of survival data based on grade of tumor revealed a significantly better 5-year survival rate of 75% for patients with Grade 1 tumors, as compared with 16% and 28% for Grade 2 and 3 tumors, respectively ($p = 0.0013$); there was no significant difference between Grades 2 and 3. The 10-year survival rate for Grade 1 tumors was 60% but was less than 10% for Grades 2 and 3 (Fig. 2). Those patients with tumors smaller than 10 cm had a significantly better 5-year survival rate of 78% as compared with 38% for those patients whose tumors were greater than or equal to 10 cm ($p = 0.03$) (Fig. 3). There was also a significant improvement in the 5-year survival rate (58%) in those patients whose tumors were confined to the site of origin when compared with patients whose tumors invaded adjacent organs (20%) ($p = 0.05$). There were no 5-year survivors among those patients who had distant metastases, and their median survival was only 10 months (Fig. 4). There were no statistically significant differences in terms of survival between sarcomas located in the stomach, small bowel, or colorectum. Other factors, such as sex of the patient or duration of symptoms, also did not correlate with survival.

Radiation and/or Chemotherapy

Of the 21 patients who had partial resection of their tumors, 12 (57%) also received therapeutic radiation

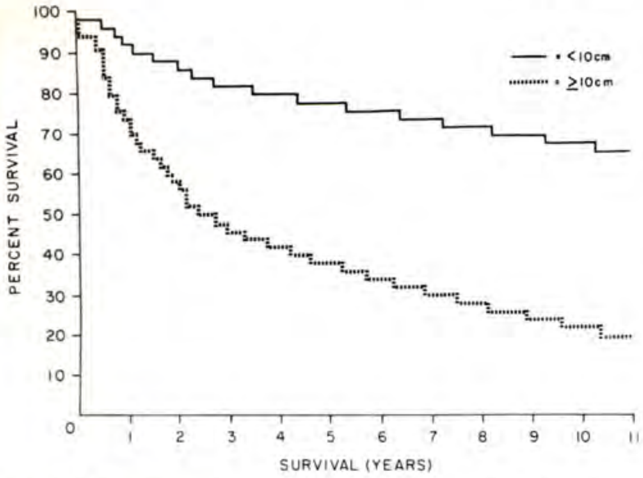

FIG. 3. Actuarial survival curves for all patients with primary gastrointestinal sarcomas based on size of the primary tumor.

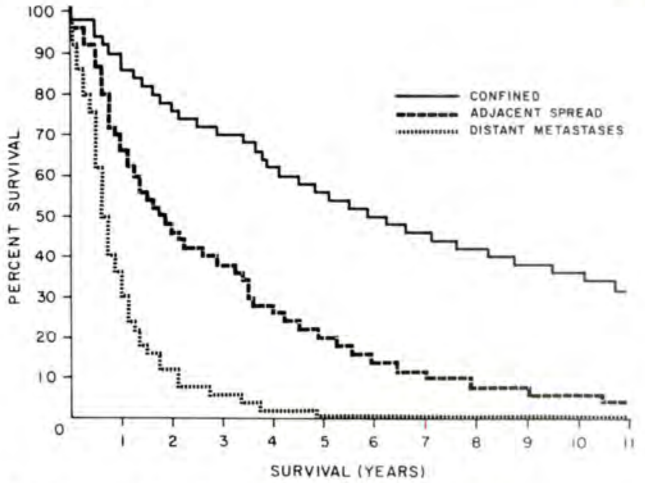

FIG. 4. Actuarial survival curves for all patients with primary gastrointestinal sarcomas based on extent of disease.

and/or chemotherapy; there was no difference in survival when compared with those patients who had operation alone (Table 5). The most frequently used chemotherapeutic regimen was doxorubicin HCl (Adriamycin®; Adria, Columbus, OH) and DTIC, alone or in combination with vincristine and cyclophosphamide. Total radiation doses ranged from 4500 to 5400 rads.

Discussion

Gastrointestinal sarcomas are uncommon malignant tumors that occur throughout the entire alimentary tract. The distribution of these tumors in our series is similar to the review of the 725 gastrointestinal leiomyosarcomas in the literature as of 1965, which reported the distribution as follows: esophagus 5%, stomach 47%, small bowel 35%, and colorectum 12%.[2] Because the alimentary tract has more smooth muscle than any other part of the body, it is not surprising that virtually all gastrointestinal sarcomas are leiomyosarcomas. The malignant fibrous histiocytoma of the appendix and the hemangiopericytoma of the colon in our series represent extremely rare cases.

The most frequent clinical presentations are abdominal pain, gastrointestinal bleeding, and/or an abdominal mass. Of note is that more than two-thirds of the patients that had gastrointestinal bleeding could have complete resection of their tumors, suggesting that small tumors causing early symptoms had a more favorable prognosis. In the past the diagnosis of gastrointestinal sarcomas was usually made at the time of a laparotomy, prompted by either radiologic studies with abnormal findings, intestinal obstruction, or gastrointestinal bleeding. With the advent of fiberoptic endoscopy, a tissue diagnosis may be made before operation for gastric and colorectal tumors, which could aid in pretreatment management decisions.

Surgical resection is the treatment of choice for gastrointestinal sarcomas, and appropriate surgical management requires every effort for complete excision of the tumor with an adequate margin of normal tissue. Resection of adjacent organs is often necessary to ensure complete excision. Several reviews have shown that small tumors (<5 cm) of the stomach can be adequately treated by wedge gastric resection with a generous margin of normal gastric wall.[5–7] Larger gastric sarcomas may require subtotal or total gastrectomy, and this should include omentectomy and resection of juxtagastric nodes. There is a discrepancy in the literature regarding the prevalance of nodal spread of gastrointestinal sarcomas, with some reports indicating little or no spread to regional lymph nodes[6–9] and others reporting a 10–15% incidence of nodal spread.[5,10–12] Our patients demonstrated a 15% incidence of spread to regional lymph nodes from all gastrointestinal sarcomas. The incidence of metastases to regional lymph nodes was only 6% for Grade 1 tumors as compared with 19% for Grade 2 tumors and 21% for Grade 3 tumors. Although it may not be necessary to include regional nodes in the resection of Grade 1 tumors, the grade of the tumor cannot be accurately assessed until the entire specimen is resected. Thus, because of this small but definite incidence of spread to regional nodes, and because including these nodes in the resection does not increase the morbidity

TABLE 5. *Results of Therapeutic Radiation (RT) or Chemotherapy (CT) on Survival of Patients with Gastrointestinal Sarcomas*

	Patients		Median Survival (Months)

rate, we recommend a wide segmental resection with associated mesentery and/or omentum for all gastrointestinal sarcomas.

Reported survival data after operations for gastrointestinal sarcomas have been extremely variable, especially with respect to gastric sarcomas. The rates for curative resection for gastric sarcomas have ranged from 68 to 90%, with an overall 5-year survival rate between 19% and 56% and a 5-year survival rate after curative resection ranging from 32 to 63%.[6,7,10,13,14] Reports on sarcomas of the small and large intestine have been more consistent with 5-year survival figures of between 40% and 50% for all patients and those receiving complete excision.[9,15-17] This review reports a 5-year survival rate of 40% for all patients with gastrointestinal sarcomas and 63% for those able to have complete excision of their tumors. There was no significant difference in survival rate between sarcomas located in the stomach as compared with those in the small or large intestine.

Several prognostic factors were analyzed to determine their effect on survival, and the most significant factor affecting survival was the histologic grade of sarcoma. The method of grading sarcomas in this review was similar to that initially described for soft tissue sarcomas[18,19] and that recently reported for use with gastrointestinal sarcomas.[6,7,20] Grading was determined by a composite observation of the mitotic rate, degree of atypia or anaplasia, degree of cellularity, and degree of differentiation. The mitotic count appears to be the most objective and reproducible feature when determining the grade of malignancy; however, as noted by Appelman and Helwig, this needs to be related to the histologic appearance of the tumor.[5] More recently, Appelman has tended to downgrade the value of using mitotic counts in evaluating malignancy in stromal tumors of the gut. He found that the site of the primary tumor may be more valuable in tumor behavior prediction than a set number of mitotic counts.[21,22] Nevertheless, our results show that once the diagnosis of sarcoma is established, no difference in survival occurred on the basis of tumor location. This review clearly demonstrates that low-grade sarcomas (Grade 1) had a much better prognosis than higher grade sarcomas (Grades 2 and 3). This observation is related to the fact that nearly all (88%) Grade 1 sarcomas could be completely excised and, of those, only 14% eventually had metastases develop, whereas only 35% of Grade 3 sarcomas could be resected for cure and for half of those metastatic disease eventually developed. Other factors that were associated with a better prognosis were smaller tumors (<10 cm) and tumors confined to the site of origin, as noted in previous reports.[7,10,16]

Our study demonstrated no benefit from therapeutic radiation and/or chemotherapy; however, the number of patients treated was small and the role of radiation or chemotherapy cannot be adequately assessed with so few cases. Review of the literature has also failed to reveal a significant benefit from these nonsurgical modalities in an adjuvant or therapeutic setting.[6,7,15] However, the 42% recurrence rate in patients with curative resection in this review and reports that up to 78% of patients will eventually have distant metastases develop[5,6,20] warrant further investigation into the role of adjuvant therapy.

Only one H_2 antagonist controls pH for up to 12 hours on a single dose

PEPCID® I.V. (Famotidine, MSD) is indicated in some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or as an alternative to the oral dosage forms for short-term use in patients who are unable to take oral medication.

The recommended dosage is 20 mg q12h. Dosing intervals may need to be prolonged or dosage reduced in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine. PEPCID I.V. is contraindicated in patients who are hypersensitive to any component of this medication. The adverse reactions reported for PEPCID Tablets may also occur with PEPCID I.V. In addition, transient irritation at the injection site has been observed with PEPCID I.V.

A double-blind, placebo-controlled study[1] involving eight volunteer hypersecretor subjects. The pH of gastric aspirates was measured hourly for 12 hours following single intravenous doses. PEPCID I.V. maintained the mean gastric pH above 4.0 at all time points throughout the 12-hour period with one 20-mg I.V. dose.

(Famotidine for
Oral Suspension|MSD)
40 mg per 5 mL

INJECTION
Pepcid® IV
(Famotidine|MSD)
20 mg per 2 mL

Contraindications: Hypersensitivity to any component.

Precautions: *General:* Symptomatic response to therapy does not preclude the presence of gastric malignancy.

Patients with Severe Renal Insufficiency: Longer intervals between doses or lower doses may be needed in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine (see Clinical Pharmacology and Dosage and Administration sections of Prescribing Information).

Information for Patients: The oral suspension should be shaken vigorously for 5-10 seconds prior to each use, and unused constituted oral suspension should be discarded after 30 days.

Drug Interactions: No drug interactions have been identified. Compounds tested in man include warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In rats and mice given oral doses up to approximately 2500 times the recommended human dose for active duodenal ulcer, there was no evidence of carcinogenic potential, no evidence of a mutagenic effect, and fertility and reproductive performance were not affected.

Pregnancy: *Pregnancy Category B*—There are no adequate or well-controlled studies in pregnant women. Use during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether famotidine is secreted into human milk; however, it is secreted into the milk of lactating rats. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: No dosage adjustment is required based on age but may be necessary in severe renal impairment (see Clinical Pharmacology section of Prescribing Information).

Adverse Reactions: The adverse reactions listed below have been reported during domestic and international clinical trials in approximately 2500 patients. In the placebo-controlled clinical trials, the incidence of adverse experiences with PEPCID Tablets, 40 mg at bedtime, was similar to that with placebo.

Incidence Greater than 1%: The following adverse reactions have been reported to occur in more than 1% of patients on therapy with PEPCID in controlled clinical trials and may be causally related to the drug: headache (4.7%), dizziness (1.3%), constipation (1.2%), and diarrhea (1.7%).

Causal Relationship Unknown: The following other adverse reactions have been reported in clinical trials. While a causal relationship could not be established for these infrequently reported events, causality cannot be excluded. *Body as a Whole*—Fever, asthenia, fatigue. *Cardiovascular*—Palpitations. *Gastrointestinal*—Nausea, vomiting, abdominal discomfort, anorexia, dry mouth, liver enzyme abnormalities. *Hematologic*—Thrombocytopenia. *Hypersensitivity*—Orbital edema, conjunctival injection. *Musculoskeletal*—Musculoskeletal pain, arthralgia. *Nervous System/Psychiatric*—Paresthesias; grand mal seizures (single report); psychic disturbances including depression, anxiety, decreased libido, hallucinations (single report); insomnia; somnolence. *Respiratory*—Bronchospasm. *Skin*—Alopecia, acne, pruritus, rash, dry skin, flushing. *Special Senses*—Tinnitus, taste disorder.

The adverse reactions reported for PEPCID Tablets may also occur with PEPCID Oral Suspension or PEPCID I.V.; in addition, transient irritation at the injection site has been observed with PEPCID I.V.

Management of Overdosage: There is no experience to date with deliberate overdosage. Up to 640 mg/day have been given to patients with pathological hypersecretory conditions with no serious adverse effects. In the event of overdosage, treatment should be symptomatic and supportive. Unabsorbed material should be removed from the gastrointestinal tract, the patient should be monitored, and supportive therapy should be employed.

Dosage and Administration: *Duodenal Ulcer:* The recommended adult oral dosage for active duodenal ulcer is 40 mg h.s.; most patients heal within 4 weeks, and it is rarely necessary to use the full dosage for longer than 6 to 8 weeks. A regimen of 20 mg b.i.d. is also effective. For maintenance therapy, the recommended oral dosage is 20 mg h.s.

Pathological Hypersecretory Conditions (e.g., Zollinger-Ellison Syndrome, Multiple Endocrine Adenomas): The dosage varies with the individual patient; the recommended adult oral starting dosage is 20 mg q6h, but some patients may require a higher starting dosage. Dosages should be adjusted to individual patient needs and continued as long as clinically indicated; up to 160 mg q6h have been administered to some patients with severe Zollinger-Ellison syndrome.

Oral Suspension: The Oral Suspension may be substituted for Tablets for those patients who cannot swallow tablets.

Directions for Preparing PEPCID Oral Suspension: Prepare suspension at time of dispensing. Slowly add 46 mL Purified Water. Shake vigorously for 5-10 seconds immediately after adding the water and immediately before use.

Stability of PEPCID Oral Suspension: Unused constituted oral suspension should be discarded after 30 days.

Intravenous Administration: In some hospitalized patients with pathological hypersecretory conditions or intractable ulcers, or in patients who are unable to take oral medication, the recommended intravenous dosage is 20 mg q12h. For preparation of solutions for injection or infusion and for compatible diluents, please see Prescribing Information. Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Concomitant Use of Antacids: Antacids may be given concomitantly if needed.

Dosage Adjustment for Patients with Severe Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance less than 10 mL/min), the elimination half-life of famotidine may exceed 20 hours, reaching approximately 24 hours in anuric patients. Although no relationship of adverse effects to high plasma levels has been established, to avoid excess accumulation of the drug, the dosage may be reduced to 20 mg h.s. or the dosing interval may be prolonged to 36 to 48 hours as indicated by the patient's clinical response.

How Supplied: Tablets, containing 20 mg or 40 mg famotidine, with hydroxypropyl cellulose, hydroxypropyl methylcellulose, iron oxides, magnesium stearate, microcrystalline cellulose, starch, talc, and titanium dioxide as inactive ingredients, in bottles of 30 and unit-dose packages of 100; Oral Suspension, containing per 5 mL after constitution with 46 mL Purified Water, 40 mg famotidine, with citric acid, flavors, microcrystalline cellulose and carboxymethylcellulose sodium, sucrose, and xanthan gum as inactive ingredients, and sodium benzoate 0.1%, sodium methylparaben 0.1%, and sodium propylparaben 0.02% added as preservatives, in bottles of 400 mg famotidine for constitution; Solution for intravenous injection, containing 10 mg famotidine per mL, with L-aspartic acid 4 mg, mannitol 20 mg, and water for injection q.s. 1 mL as inactive ingredients, and benzyl alcohol 0.9% added as preservative to the multidose vial, as 10x2-mL single-dose vials and as 4-mL vials.

Right Lower Quadrant Pain in Young Patients with Leukemia

A Surgical Perspective

JOHN M. SKIBBER, M.D., GREGORY J. MATTER, M.D., PHILLIP A. PIZZO, M.D.,* and MICHAEL T. LOTZE, M.D., F.A.C.S.

A retrospective review of cecal and appendiceal complications occurring in young patients with acute leukemia since 1969 was performed. The objective of this study was to determine the relative incidence of appendicitis and typhlitis among patients with acute leukemia who had operation or autopsy in this institution as well as to determine the risks of operative intervention. Fifteen patients with these complications were identified among the 400 patients with acute leukemia seen during this time period. Signs and symptoms of an acute abdomen were present despite immunosuppression. The incidence of sepsis at the time of presentation was 53%. Preoperative risk factors identified most frequently were coagulopathy and organ failure resulting from sepsis. Postoperative morbidity (25%) and mortality rates (8%) were related to the development of infectious complications. Appendicitis occurred in eight of the 15 patients studied, whereas typhlitis or its complications was found in seven patients. No preoperative factors could be found to differentiate typhlitis from appendicitis on clinical examination. It is suggested that operation can be safely performed in neutropenic patients who have acute right lower quadrant pain and signs of peritoneal irritation and may be the only effective way of differentiating appendicitis from typhlitis.

From the Surgery Branch and the Pediatric Oncology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland*

INCREASINGLY AGGRESSIVE CHEMOTHERAPEUTIC REGIMENS have brought about improved long-term survival rates of up to 60% in patients with acute lymphocytic leukemia.[1,2] These aggressive regimens expose the patients to complications and death related to bone marrow suppression and neutropenia with the attendant infectious complications. The mortality rate from gram-negative sepsis approaches 40%. In patients with polymicrobial sepsis with cancer, the mortality rate is 70%.[3]

Intra-abdominal and, specifically, right lower quadrant (RLQ) infectious complications often are the source of such sepsis.[4] The evaluation and treatment of these intra-abdominal infectious complications involve the surgeon. Evaluation is often difficult in these critically ill immunosuppressed patients. The otherwise straightforward evaluation of RLQ pain in a young patient is obscured by the patient's underlying disease or treatment.[5] The range of pathologic processes to be expected and the implications of signs and symptoms in these patients might differ from those of "normal" patients, therefore making clinical assessment difficult for the surgical consultant. Consideration of the risks of operation in such patients adds to the difficulty in management.[4-6]

We have reviewed our experience with RLQ complications in young patients having chemotherapy for leukemia in order to determine the incidence of typhlitis and appendicitis, relative to each other, and to assess the risks of operative intervention. We have also attempted to document the incidence of localized and diffuse abdominal pain exhibited by this group of patients. Additional diagnoses made in relation to abdominal pain were documented, as well as the incidence of laparotomies with normal findings.

Methods

Discharge diagnoses at the Clinical Center, National Institutes of Health (NIH), between 1969 and 1984 identified 400 patients admitted for acute leukemia (AL) that were between the ages of 3 and 21 years. Of this group of 400 patients, 129 sustained 135 episodes of documented abdominal pain. The diagnoses related to these episodes were based on clinical laboratory, radiologic, and/or pathologic results recorded in these charts. Ninety-six of these 129 patients had autopsies at this institution available for analysis. Sixteen of the patients

TABLE 1. *Leukemic Patients with Right Lower Quadrant Complications*

		Age	
	N	Range	(Median)
Group 1 (operation)	13	5–12	(12)
Group 2 (autopsy)	3	7, 10, 21	(10)

had RLQ pathologic conditions identified as cecitis, typhlitis, appendicitis, cecal or appendiceal perforation, and mesenteric adenitis. The records of these 16 patients were then reviewed for the status of the primary disease, initial symptoms and signs with the RLQ complications, hematologic values, radiologic findings, and initial microbiologic results with abdominal signs or symptoms. Charts were also examined to determine the drug therapy preceding this complication. Operative risk factors, defined as hemodynamic instability, coagulopathy, or respiratory failure, were evaluated. Indications for operation, operation performed, and operative findings, as well as operative complications and deaths, were recorded. The results reported in surgical pathology (13 patients) and autopsy reports (three patients) were evaluated. Minimum follow-up period was 14 months. Additional causes of abdominal pain documented in 113 patients were also recorded.

Results

Study Group

Of the 400 patients admitted with AL who were between the ages of 3 and 21 years, 129 (32%) had a total of 135 documented episodes of abdominal pain. Among the 129 patients, 16 (12%) had laparotomies for RLQ findings (Table 1). Thirteen patients had operation (group 1), and three (group 2) patients had their disease confirmed at autopsy. Ages were from 3 to 21 in the leukemic patients. Nine were male patients and seven were female patients. Eleven patients had acute myelogenous leukemia, and six had acute lymphocytic leukemia.

Eleven of the 16 patients with AL with RLQ findings had evidence of advanced disease, including positive bone marrow aspirate findings or evidence of visceral involvement. Seven patients were seen during initial induction chemotherapy, six during re-induction therapy for relapse, and two while their disease was in remission. Median survival for patients operated on was 7 months after surgery (range: 1 week to 5 years). All patients studied at autopsy died within 1 month of presentation with RLQ symptoms or signs.

Clinical Findings

A total of 125 patients studied had documented abdominal pain. Among the 135 episodes of AL, 60 were localized and 75 were diffuse. In 11 of 16 patients with AL with cecal or appendiceal pathologic conditions, the pain was localized to the RLQ of the abdomen, whereas four others had diffuse abdominal pain. Thirteen of 16 patients had fever and chills, whereas 10 had nausea and vomiting. All operated patients had abdominal tenderness to palpation that was localized to the RLQ. Thirteen of the 16 had documented peritoneal signs (rebound, abdominal wall rigidity, or involuntary guarding). All patients operated on had peritoneal signs. In 14 of the 16 operated leukemic patients, their temperatures were greater than 39 C for 2 consecutive days. One patient with AL had a palpable RLQ mass documented.

Laboratory and Radiologic Findings

Eight of the 16 patients with AL had leukocyte counts less than 2,000/mL, and four had counts between 2,000 and 10,000/mL. Three counts were greater than 15,000/mL. Ten of the 15 patients with AL were at their nadir leukocyte count at the time of their presentation. In 10 of the patients with AL the platelet counts were less than 70,000/mL (Table 2).

In two patients with AL intraperitoneal free air was seen on chest roentgenograph. Nine of 15 patients had abdominal roentgenographs showing dilated small bowel or air fluid levels.

Eight young patients with leukemia had positive blood culture results, despite the use of multiple prophylactic or empiric antibiotics in 14 of the patients. Six patients had gram-negative organisms cultured from their blood, one patient had anaerobic sepsis, and one

Group 1	13	5* (44%)	10
Group 2	3	3* (100%)	3

* Six of eight gram-negative enteric bacteria.

patient had polymicrobial sepsis, including fungemia (Table 3).

Only one of the patients with AL was not receiving or had not recently received antineoplastic therapy at the time of presentation. Five of these patients were being treated with chemotherapy at the time of complication, whereas nine patients had received chemotherapy within the preceeding 20 days. Eight patients with AL had received steroids within 15 days.

Operative Risk Factors

In a retrospective assessment of the operative risk factors at presentation of patients with AL, 10 patients had a coagulopathy (protime, plasma thromboplastin time > control and/or platelet count < 70,000), four had hemodynamic instability (defined as hypotension [blood pressure < 90] and requiring treatment with the volume expansion and/or vasopressors), and one was in respiratory failure. Of the 13 patients with AL operated on, indications for operation included acute abdominal pain with peritoneal signs in 11 and a suspected intra-abdominal abscess in one. A total of fourteen laparotomies were performed in 13 patients with AL. Nine had simple appendectomies, two had appendectomies with drainages of abscesses, and two had right hemicolectomies. At operation six patients had simple appendicitis, two had perforated appendices, two had cecal perforation, two had evidence of localized abscess formation, and one had a diagnosis of mesenteric adenitis. In the 13 leukemic patients operated on, there was one death resulting from overwhelming continued sepsis. There was one re-operation for cecal perforation in a patient after appendectomy. There were three wound infections, three cases of intra-abdominal sepsis, a single case of respiratory failure, and one wound dehiscence. All of these complications occurred among three patients. The leukemic patients for whom autopsies were performed all died with sepsis 2–14 days after the onset of symptoms (Table 4).

	N	Appendicitis	Typhlitis	Mesenteric Adenitis
Group 1	13	8	4	1
Group 2	3	0	3	0

Pathologic Findings

Pathologic examination at either operation or autopsy revealed eight cases of appendicitis (two of these with leukemic infiltrates and one with an associated abscess) among the leukemic patients. Two had normal appendices with cecal edema, and five had cecal necrosis (two with associated intra-abdominal abscesses) consistent with typhlitis. One had mesenteric adenitis documented by culture and biopsy (Table 5).

Additional Causes of Abdominal Pain in Leukemic Patients

Of the 129 young patients with acute leukemias, there were 135 documented episodes of abdominal pain; 60 were localized and 75 were diffuse. Aside from the patients with RLQ findings previously described, the clinical or pathologic diagnosis assigned to the cause of the abdominal pain was varied (Table 6). These were based on clinical, laboratory, radiologic, or pathologic findings recorded in the medical records. Autopsies were done on 92 of these 129 patients at this institution.

Discussion

The purpose of this study was to determine the relative incidence of appendicitis and typhlitis among young leukemic patients at our institution. The incidence of appendicitis and typhlitis lesions among young leukemic patients was roughly equal in a review of operated or autopsied patients. In 400 patients seen over a period of 15 years at the NIH, acute appendicitis was identified in eight and cecal edema, necrosis, or perforation consistent with typhlitis was noted in seven. One had a laparotomy with normal findings with the diagnosis of mesenteric adenitis by biopsy and culture. Cecal edema alone was found in two of the eight patients with typhlitis. The true incidence of these lesions in this population probably is higher because of the presence of less severe cases of typhlitis that do not come to operation or autopsy. The estimated incidence of clinically significant and pathologically proven cecal and appendiceal complications has been determined in this study to be at least 4% among all leukemic patients between the ages of 3 and 21 years. Among patients with AL to be operated on who had RLQ pain, appendicitis or typhlitis can be expected with equal frequency and will be found in 26% of those with localized RLQ pain.

Leukemic patients who presented with significant RLQ symptoms had sufficient indications for operation and had signs of peritoneal irritation documented despite having advanced disease or having received chemotherapy or steroids. All patients in our study had significant fever. These RLQ complications produced the clinical picture of an acute abdomen. Thirteen of 15 patients who had these problems did so during induction therapy for their leukemia. The low incidence of laparotomies with normal results in this group of patients probably reflects their perceived high operative morbidity and mortality rates.

Many of these patients appeared to be poor operative risks because of coagulopathy and hemodynamic instability. The incidence of sepsis in these young leukemic patients was high (53%) and usually resulted from gram-negative organisms. This occurred despite the liberal use of antibiotics. One-third of the leukemic patients demonstrated signs of major organ failure related to their sepsis.

The most common reported cause of death in leukemic patients is from sepsis.[8] In a study of 89 cases of perforated appendicitis at Los Angeles Children's Hospital, only 6% of blood cultures had positive results compared with 53% of our young leukemic patients.[9] Septicemia in patients with leukemia has been reported to result in a 20–40% mortality rate.[8] Studies of leukemic patients with surgical complications have demonstrated the incidence of sepsis to be as high as 75%.[4] Appendicitis and typhlitis, or their complications, appear to be associated with significant morbidity and mortality rates in leukemic patients.

The term typhlitis in this setting was first used by Wagner et al. in 1970.[10] It referred to a necrotizing colitis involving the cecum or the cecum and appendix and was found in leukemic children who were receiving therapy and were often in the terminal stages of their disease. Others have used the term neutropenic enteropathy or referred to these clinical pictures as the ileocecal syndrome.[7,11] In autopsy series, the incidence of these lesions ranges from 9.9 to 12%. Both appendiceal and cecal complications have been estimated as occurring with an incidence of approximately 5%.[4,12,13] Although occurring infrequently, appendicitis is associated with a high mortality rate in leukemic patients.[13–15]

The vaguely defined clinical diagnosis of typhlitis is difficult, and operative findings range from simple edema of the cecum to a frankly necrotic and perforated cecum.[10,12,13,16] Diagnosis of this disorder without pathologic examination is speculative and the differentiation from appendicitis is unclear.[17] The role of surgical management in appendicitis is clear. The role of surgical therapy in typhlitis is less well defined.[15,18,19] Recommendations for therapy range from nonoperative therapy to right hemicolectomy.[20–24] Pleas for nonoperative therapy are often based on the patient's poor outlook for survival because of his or her underlying disease, a fear of surgical complications, or even hopes that the patient will be able to localize a cecal perforation.[25,26] Although conservative therapy can be successful in some instances of typhlitis, there are no prognostic signs that differentiate it from appendicitis or that predict progression to cecal necrosis. A review of 65 cases of appendiceal and cecal complications in young (<30 years) patients with ALL reported in the medical literature in 13 articles show only two nonoperative survivors. Of 26 operated patients, there were 21 who survived for more than 30 days (Table 7). A well-described syndrome of cecal necrosis or perforation in immunosuppressed patients receiving therapy with steroids or chemotherapy can also occur.[27,28]

In our patients, appendectomy was performed with minimal complications. Progression of the appendicitis to perforation or abscess formation puts the patient at high risk for subsequent infectious complications, illness, and death. Despite the poor preoperative risk status of these patients in terms of coagulopathy and associated organ failure, most of the complications seen in the operated patients were thought to be directly related to the patients' susceptibility to infection. The risk to the patient from surgically treatable intra-abdominal sepsis appears greater than the risk of complications from the surgical exploration in this setting. We are in

agreement with Schaller, who noted "that the sickest patients are the ones about whom the surgeon tends to procrastinate yet they are also the patients who may benefit most from early operation."[29]

Our study cannot address the larger questions of the outcome of abdominal pain in the great number of neutropenic patients with cancer who did not come to operation or autopsy who may have these disorders in milder forms. The relative efficacy of operative and nonoperative therapy on outcome of these patients can only be addressed in a prospective evaluation of these patients. In our leukemic patients operated on, median postoperative survival was significant (7 months), thus allowing the patient's survival to be determined by his response to chemotherapy. We are initiating a prospective evaluation of neutropenic patients with abdominal pain that will attempt to determine factors relevant to outcome.

Documented abdominal pain occurred in 32% of the young leukemic patients seen during the study period. Of the 135 episodes, 60 were localized and 75 were diffuse. When the clinical diagnosis of the cause for abdominal pain is evaluated, it can be seen that most of such episodes will respond to supportive cause and do not require operation.

Typhlitis and appendicitis appear to be equally common in the young leukemic patient with RLQ signs of peritoneal irritation. The preoperative differentiation between these two problems is difficult, and one cannot be secure in recommending nonoperative treatment. The classical signs of peritoneal irritation can be found in these patients despite their neutropenia and immunosuppressed condition and have the same implications as in the nonleukemic patient. The greatest risk to these patients appears to be from progressive local and systemic infection. This series and review of the literature suggests that appropriate surgical treatment in terms of drainage of purulent material and appropriate resection of compromised tissues should strongly be considered in young leukemic patients with these findings.

Summary

In this review of leukemic patients admitted at the NIH over a period of 15 years with cecal and appendiceal complications, we find that appendicitis and typhlitis ranging from cecal edema to necrosis were equal in incidence among patients with signs of RLQ peritoneal irritation. Despite substantial preoperative risk factors, including coagulopathy and organ failure, operation could be performed safely with adequate supportive measures. Sepsis was common at the time of presentation, occurring in 53% of our patients. There were no discernable factors that differentiated appendicitis from typhlitis before operation or before autopsy. Operative death and complications were related to the patients' susceptibility to infection. We believe that neutropenic patients presenting with RLQ findings of peritoneal irritation can be operated on safely. In addition, this may be the only effective way to differentiate appendicitis from typhlitis.

Acknowledgment

The authors thank Susan Privot for her assistance in the preparation of this manuscript.

See brief summary of prescribing information on adjacent page.

The antiemetic physicians prescribe most*

COMPAZINE®

brand of

prochlorperazine

See complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

Indications: For control of severe nausea and vomiting.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; pediatric surgery; use in children under 2 years of age or under 20 lbs.; use in children for conditions for which dosage has not been established.

Warnings: The extrapyramidal symptoms which can occur secondary to 'Compazine' may be confused with the central nervous system signs of an undiagnosed primary disease responsible for the vomiting, e.g., Reye's syndrome or other encephalopathy. The use of 'Compazine' and other potential hepatotoxins should be avoided in children and adolescents whose signs and symptoms suggest Reye's syndrome.

May cause tardive dyskinesia in some patients on neuroleptic (antipsychotic) therapy, usually long-term. This syndrome consists of potentially irreversible, involuntary dyskinetic movements. The risk of tardive dyskinesia and likelihood of irreversibility are thought related to duration of treatment and total cumulative dose of neuroleptic drugs.

Use in patients with bone marrow depression only when potential benefits outweigh risks. Patients who develop a hypersensitivity reaction (e.g., blood dyscrasias or jaundice) to a phenothiazine generally should not be reexposed to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy. Prochlorperazine may intensify or prolong the action of other C.N.S. depressants.

Use in pregnancy is not recommended except in cases so serious and intractable that, in the physician's judgment, drug intervention is required and potential benefits outweigh possible hazards. There have been instances of prolonged jaundice, extrapyramidal signs, hyperreflexia or hyporeflexia in newborn infants whose mothers received phenothiazines. There is evidence that phenothiazines are excreted in the breast milk of nursing mothers.

Precautions: The antiemetic action of 'Compazine' may mask the signs and symptoms of overdosage of other drugs and may obscure the diagnosis and treatment of other conditions such as intestinal obstruction, brain tumor and Reye's syndrome (See Warnings). Postoperative aspiration of vomitus has occurred in a few surgical patients who received prochlorperazine as an antiemetic. When used concomitantly with cancer chemotherapeutic drugs, may obscure vomiting as a sign of these agents' toxicity. Deep sleep and coma have been reported with prochlorperazine, usually with overdosage.

Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent *in vitro*, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Permanently stop neuroleptic therapy if neuromuscular reactions occur in pregnant women or in children.

In children with acute illnesses or dehydration, use only under close supervision. Avoid high doses and parenteral administration when cardiovascular system is impaired since hypotension has occurred. Use cautiously in patients with glaucoma. Use with caution in persons who will be exposed to extreme heat since phenothiazines may interfere with thermoregulatory mechanisms. Phenothiazines can diminish the effect of oral anticoagulants. Phenothiazines can produce alpha-adrenergic blockade. Thiazide diuretics may accentuate orthostatic hypotension that may occur with phenothiazines. Antihypertensive effects of guanethidine and related compounds may be counteracted when phenothiazines are used concomitantly. Concomitant administration of phenothiazines with propranolol results in increased plasma levels of both drugs and may also precipitate phenytoin toxicity. Phenothiazines may lower the convulsive threshold; dosage adjustments of anticonvulsants may be necessary. Presence of phenothiazines may produce false positive phenylketonuria (PKU) test results. Patients should not receive 'Compazine' 48 hours before or 24 hours after myelography with the contrast medium metrizamide.

Adverse Reactions: Drowsiness, dizziness, amenorrhea, blurred vision, skin reactions. Hypotension. Cholestatic jaundice, leukopenia, agranulocytosis. Fatty changes in the liver have been observed in a few patients who died while receiving the drug (no causal relationship has been established). Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, tardive dyskinesia, and a variant, tardive dystonia. Contact dermatitis is a possibility if 'Compazine' Injection (solution) inadvertently gets on hands or clothing.

Other adverse reactions reported with 'Compazine' or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., severe hypotension in mitral insufficiency or pheochromocytoma). Grand mal and petit mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat and organophosphorus insecticides; dryness of mouth, nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, ejaculatory disorders/impotence, priapism, atonic colon, urinary retention, miosis and mydriasis; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; pancytopenia, thrombocytopenic purpura, eosinophilia, hemolytic anemia, aplastic anemia; biliary stasis; hyperglycemia, hypoglycemia, glycosuria, lactation, galactorrhea, gynecomastia, menstrual irregularities, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema; angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; mild fever after large I.M. doses; increased appetite; increased weight; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; neuroleptic malignant syndrome, which may be fatal; with prolonged administration of substantial doses. skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits.

EKG changes have been reported. Discontinue long-term, high-dose therapy gradually.

Note: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported.

Supplied: Tablets—5, 10 and 25 mg., in bottles of 100; Spansule® capsules—10, 15 and 30 mg., in bottles of 50; Injection—5 mg./ml. in 2 ml. ampuls, 10 ml. vials and 2 ml. disposable syringes; Suppositories—2½, 5 and 25 mg.; Syrup—5 mg./5 ml.; Single Unit Packages of 100 (intended for institutional use only)—5 and 10 mg. tablets; 10, 15 and 30 mg. 'Spansule' capsules.

WE HAVE ONLY GOOD THINGS TO SAY ABOUT CANCER OF THE COLON.

If detected early, the cure rate for colorectal cancer is very high. It can be as high as 75%.

Because we now know how to detect it early. And we know how to fight it once we detect it.

There are three simple checkup guidelines for men and women without symptoms.

One, get a digital exam every year. This is recommended for everyone over 40.

Two, get a stool blood test every year if you are over 50.

Three, after two initial negative tests one year apart, get a procto exam every three to five years if you are over 50.

These guidelines are the best protection against colorectal cancer you can have.

If you're not over 50, please give this information to friends and loved ones who are.

In any case, please help spread the word.

Good news doesn't always travel fast.

MEFOXIN® (Cefoxitin Sodium, MSD) is indicated for the treatment of intraabdominal, gynecological, lower respiratory tract, and skin and skin-structure infections due to designated susceptible organisms including members of the *Bacteroides fragilis* group. (See Brief Summary for complete listing of Indications.)

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with caution to penicillin-sensitive patients.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST|| reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage# vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

"I'D LIKE TO MAKE AN APPOINTMENT WITH THE DOCTOR"
COLORECTAL CANCER
Kit For Early Detection

Be prepared, Doctor. More patients will be asking about colorectal cancer. According to a survey* conducted by the American Cancer Society, many people would like to receive more information about colorectal cancer, and 83% said they would want to be checked for it. Further, they are learning that this cancer can be detected *before* symptoms appear. The present cure rate is 44%. The cure rate *could* be as high as 75%, with early detection and appropriate management.

For asymptomatic persons the Society recommends annual digital rectal examination at age 40 and over; at age 50 and over, an annual stool blood test, as well as sigmoidoscopy every three to five years, following two initial annual negative sigmoidoscopies.

We're here to help. You can reach us at your local American Cancer Society office or write to our Professional Education Department at National Headquarters, 90 Park Avenue, New York, N.Y. 10016. Ask about the Society's Colorectal Check program of professional and public education for the early detection of colorectal cancer.

Exocrine and Endocrine Stomach after Gastrobulbar Preserving Pancreatoduodenectomy

HWI-CHA KIM, M.D., TAKASHI SUZUKI, M.D., TAKEHIRO KAJIWARA, M.D.,* TAKASHI MIYASHITA, M.D.,
MASAYUKI IMAMURA, M.D., and TAKAYOSHI TOBE, M.D.

Exocrine and endocrine stomach was studied serially in 13 patients who had gastrobulbar preserving pancreatoduodenectomy (GPPD). In most of them, acid output temporarily increased just after operation but recovered. Gastrin response level decreased transiently but returned to the preoperative level. A negative correlation was observed between the acid and gastrin levels, which suggests that the negative feedback mechanism between parietal cells and G cells was maintained. Acid and gastrin levels in GPPD were higher than those in conventional pancreatoduodenectomy (cPD) but not remarkably different from those of the controls. No peptic ulcer was detected after the operation. These findings indicated that GPPD poses little problem concerning offensive factors. Postoperative ulcer formation is considered to be prevented by the authors' procedure, which is devised to best preserve defensive mechanisms so that duodenectomy is minimized and the gastrointestinal continuity is reconstructed physiologically from mouth to anus by end-to-end duodenoduodenestomy, end-to-side pancreatojejunostomy, and end-to-side choledochojejunostomy.

*From the First Department of Surgery, Faculty of Medicine, Kyoto University, Kyoto, Japan, and the Department of Surgery, Kobe Central Civil Hospital, Kobe, Japan**

PANCREATODUODENECTOMY (PD) involves resection of the duodenum and the upper jejunum, an area in which inhibitory factors in gastric secretion are considered to be concentrated. The operation, moreover, causes impairment of pancreatic exocrine function, a reduction in buffering capacity because of biliary diversion, and maldigestion and malabsorption of lipids. As a result, the mucosa of the anastomosis sites is generally considered to become vulnerable to the attacks of both offensive and defensive factors. In PD, therefore, extensive gastrectomy including the pyloric sphincter[1–4] in combination with vagotomy is recommended for reduction in acid secretion.[5] In fact, there are many reports of marginal ulcers and hemorrhage of the gastrointestinal tract occurring after this operation.[6–9] In 1978, however, Traverso and Longmire performed PD without gastrectomy but by preserving the pyloric ring, with the whole stomach being supplied by the vagus nerve for postoperative functional preservation, with good results. They performed this stomach-preserving PD in a large series of patients, in some cases together with total pancreatectomy, but observed no postoperative hyperacidity or marginal ulcers.[11] However, some authors reported instances of hyperacidity followed by marginal ulcers in patients who had this operation,[12] and much remains to be elucidated about the pathogenic mechanism of this postoperative problem. We devised gastrobulbar preserving pancreatoduodenectomy (GPPD) with Billroth I type reconstruction on the basis of our hypothetical origin of this condition and studied exocrine and endocrine function of the stomach, a key factor in this problem, in patients who had GPPD and those who had conventional pancreatoduodenectomy (cPD).

Materials and Methods

Since the report of the first case in 1981,[13] we performed GPPD in more than 20 patients admitted to Kyoto University Hospital and its affiliate hospitals. Most patients with co-existing peptic ulcer or hyperacidity were excluded from indication of this surgery. Of those treated by GPPD, changes of exocrine and/or endocrine function of the stomach were examined in 13 (Table 1). The patients were eight men and five women, ranging in age from 29 to 74 years (mean: 56.1 years), including one who had total pancreatectomy. The final diagnoses of these patients were chronic pancreatitis in

‡ Total pancreatectomy.

five, leiomyoma of the duodenum in one, anomalous arrangement of the pancreatobiliary duct in one, myosarcoma of the pancreas and duodenum in one, myosarcoma of the duodenum in one, cancer of the head of the pancreas (*en bloc* resection was added 1.5 months after GPPD) in one, cancer of the papilla of Vater in one, cancer of the ascending colon (formation of duodenal fistulas) in one, and mucin-producing pancreatic cancer in one. This operation was indicated, in principle, for benign diseases but was also performed in patients with sarcomas that infrequently show lymph node metastasis or localized early carcinomas unlikely to have metastasized, as well as in elderly persons and poor-risk cases. The patients were evaluated for 1.5 months to 3 years and 10 months (mean: 2 years and 1 month). Hyperacidic patients were, in principle, excluded from this surgery.

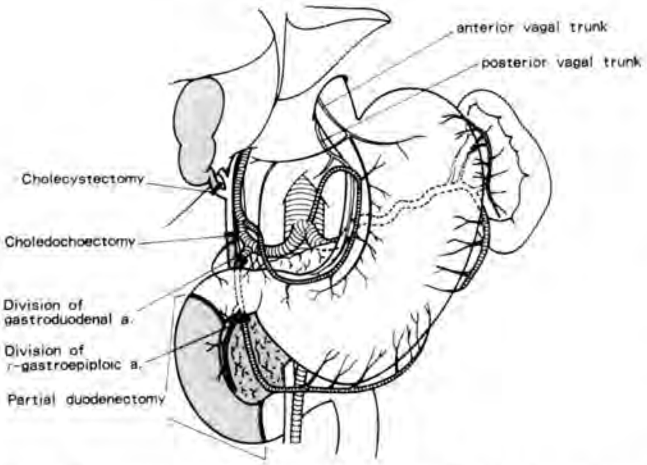

FIG. 1. Duodenectomy and vascular dissections. The duodenum is cut by access through the mouth at the upper margin of the second portion and through the anus at the third portion. The right gastroepiploic artery is ligated and cut just attached to the anterior surface of the pancreas, and the gastroduodenal artery is cut at the upper margin of the pancreas. Shaded area represents the area resected.

As shown in Figure 1, the duodenum was cut by entrance through the mouth at the upper margin of the second portion to leave the duodenal bulb intact, and by entrance through the anus, in principle, in the third portion oral from the area covered by the ligament of Treitz, preserving the distal duodenum and entire upper jejunum as much as possible. The head of the pancreas was usually cut above the portal system, and the gallbladder was resected. Caution was also exercised to preserve the vagus nerve, especially its pyloric and antral branches, left and right gastric arteries and veins, and other nerves and vessels supplying the entire stomach, including the gastroduodenal junction. The gastrointestinal tract was reconstructed retrocolically from the mouth to the anus by end-to-end duodenoduodenostomy, end-to-side pancreatojejunostomy, and end-to-side choledochojejunostomy by Billroth I procedure at intervals of about 10 and 5 cm (Fig. 2). No Braun's anastomosis was made. The pancreatic duct tube was led extracorporeally through the anterior wall of the stomach. Figure 3 is a roentgenogram of a patient's upper gastrointestinal tract 2 months after the operation. All patients survived the operation and were discharged.

The similar study was made in eight patients with cPD in whom 50–80% of distal stomach was resected. They consisted of five men and three women, ages 38–76 years (mean: 59.1 years): to be specific, six with cancer of the head of the pancreas, one with cancer of the papilla, one with pancreatic arteriovenous malformation, and one with chronic pancreatitis were studied 1 month to 3 years and 2 months (mean: 10.7 months) after the operation. None of these patients exhibited ulcer.

Nine male and four female healthy volunteers, ages 20–63 years (mean: 36.5 years), served as the normal controls.

Gastric Analysis

After patients had a 12-hour fast, gastric juice was collected through a gastric tube inserted nasally into the stomach so that changes in gastric secretion before and after pentagastrin injection (6 μg/kg, intramuscularly [I.M.]) could be studied. The gastric juice was collected at 10-minute intervals. The basal acid output (BAO) level was determined during the first 30 minutes, and after pentagastrin injection the maximum acid output (MAO) level was determined during the following hour. BAO and MAO levels represent 1-hour acid output. The examination was repeated from the time before to a maximum of 3 years and 10 months after the operation. Because there was some variation in the time of the examination among patients, changes in the acid level were serially studied in the same patients by division of the follow-up period into seven periods, namely, before; half a month; 1 month; 1 month to 1 year; 1–2 years; 2–3 years; and 3 years or more after the operation. The acidity of the gastric juice was titrated to an end point of pH 7.0 by use of a pH stat with 1/10 N NaOH and expressed as mEq.

Gastrin Determination

Blood was drawn from the antecubital vein early in the morning and 15, 30, 60, 90, and 120 minutes after the beginning of ingestion of a test meal consisting of ham, toast, one boiled egg, milk, and sugar (total weight, 365 g; protein, 21.6 g; fat, 19.7 g; carbohydrates, 58.4 g; total calories, 504). The serum was isolated and stored at −20 C until evaluation. The serum gastrin level was

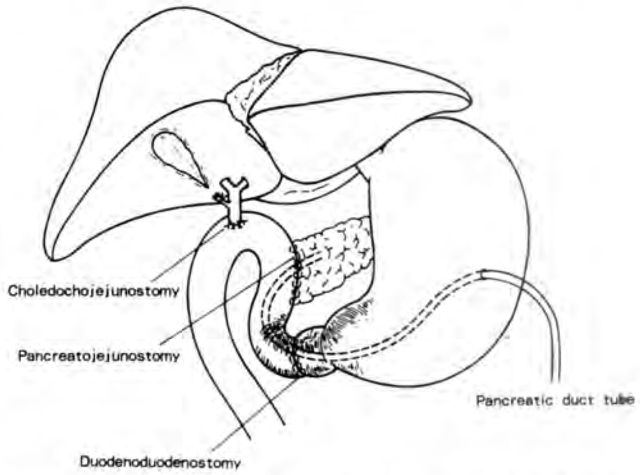

FIG. 2. Reconstruction of the digestive tract by our method. End-to-end duodenoduodenostomy, end-to-side pancreatojejunostomy, and choledochojejunostomy are performed from the mouth to the anus. The pancreatic duct tube is led extracorporeally through the anterior wall of the stomach. No Braun's anastomosis is made.

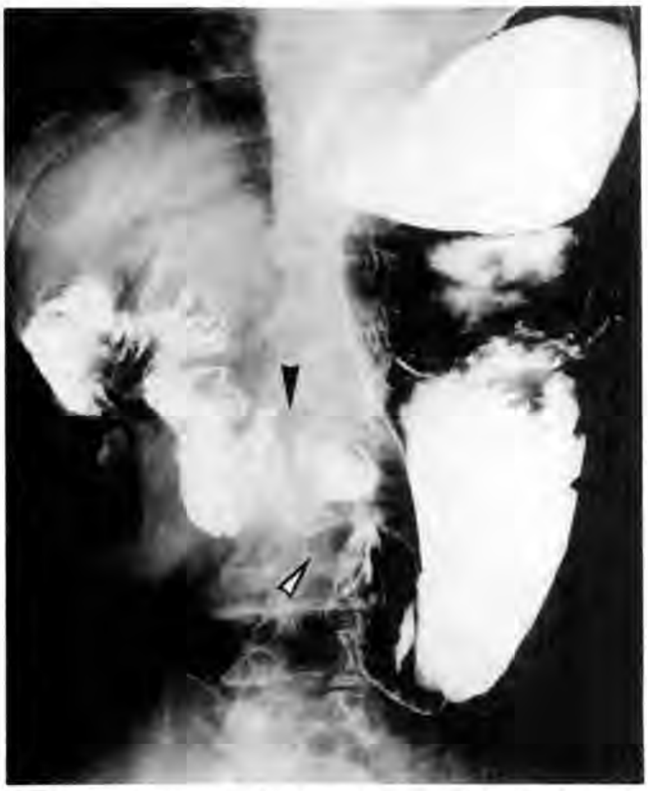

FIG. 3. A roentgenogram of the upper gastrointestinal tract 2 months after GPPD; ◁ = pyloric ring; ◀ = site of duodenoduodenostomy.

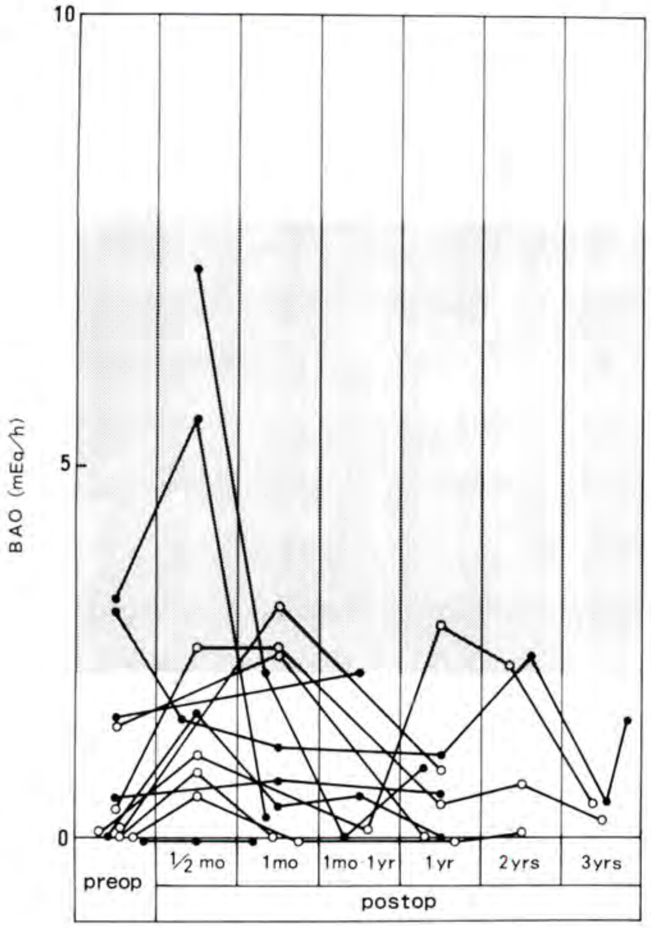

FIG. 4. Serial changes in BAO levels before and after GPPD. Shaded area represents the normal range; ○ = patients with chronic pancreatitis; ● = patients with nonchronic pancreatitis.

determined by use of a radioimmunoassay kit (CEA-IRA-SORIN Association, Gif-Sur-Yvette, France), and the basal gastrin level during fasting and the integrated gastrin response during 120 minutes after ingestion of the meal (IGR, the product of the mean gastrin level at each measurement after the meal and the interval until each measurement minus the product of the gastrin level before the meal and the total of all intervals) were calculated. Its changes were evaluated before as well as 1 month, 1–2 years, 2–3 years, and 3 years or more after the operation.

Postoperative Evaluation of the Gastrointestinal Tract

Symptoms and signs related to mucosal damage of the digestive organs including the sites of anastomosis were examined in all patients, and roentgenographs of the upper gastrointestinal tract were evaluated periodically. Endoscopic examination was also performed in four patients evaluated for more than 2 years and one patient evaluated for more than 1 year after the operation.

All values were expressed as mean plus or minus standard deviation (SD) and examined by unpaired Student's t-test. Correlations were calculated by parametric linear regression analysis, and $p < 0.05$ was considered to be statistically significant.

Results

Changes in Acid Output

BAO levels ranging from 2 to 8 mEq/h and MAO levels ranging from 5 to 21 mEq/h were regarded as normal (normoacidic). Values above or below these ranges were considered to indicate hyperacidity or hypoacidity, respectively.

Preoperative acid output. According to BAO levels, none of the patients was hyperacidic, two were normoacidic, seven were hypoacidic, and three were anacidic; according to MAO levels, one was hyperacidic, three were normoacidic, and eight were hypoacidic. The BAO or MAO level could not be determined in one patient with duodenal stenosis because of retention of a large volume of food in the stomach.

Postoperative changes in BAO levels (Fig. 4). BAO levels increased half a month after the operation but decreased after 1 month to a level comparable to the preoperative value in all patients except one, who showed duodenal stenosis before operation and in whom the BAO level tended to decrease immediately after the operation. The values were equal to or below the preoperative level 1 year after the operation and remained stable after more than 2–3 years. BAO levels were markedly increased in one patient 1 and 2 years after the operation, but the value remained in the normal range and decreased sharply after more than 3 years. BAO levels showed similar changes in those with and without chronic pancreatitis.

Postoperative changes in MAO levels (Fig. 5). MAO levels increased moderately half a month after the operation but decreased after 1 month, except in one patient with duodenal stenosis in whom the MAO level was high before the operation but rapidly decreased after the operation. The values were comparable to the preoperative levels 1 year after the operation, and no major changes were noted after more than 2–3 years. A marked increase was observed in one patient immediately after the operation, but the value decreased from a peak 1 year after the operation and remained within the normal range. Similar changes were observed in both those with and those without chronic pancreatitis.

Postoperative changes in BAO and MAO levels were similar.

Changes in Serum Gastrin Level

Changes in the basal gastrin level and IGR level during 120 minutes after the ingestion of test meal were studied in patients who could be examined repeatedly.

Basal gastrin levels ranging from 31.8 to 71.4 pg/mL and IGR levels ranging from 7.0 to 16.0 ng • min/mL were considered to be normal.

Changes in basal gastrin level (Fig. 6). Two patients with atrophic gastritis were markedly hypergastrinemic, two with chronic pancreatitis were mildly hypergastrinemic, and the other two showed normal gastrin levels before the operation.

The basal gastrin level decreased in most of the patients 1 month after the operation but increased 1 year after the operation and remained stable thereafter near the preoperative level. The basal gastrin level increased in two patients with chronic pancreatitis shortly after the operation but returned to normal after 2–3 years.

Changes in IGR levels (Fig. 7). One patient with atrophic gastritis was markedly hypergastrinemic, two with chronic pancreatitis were slightly hypergastrinemic, but the other two showed normal IGR levels before the operation.

IGR levels were reduced in all patients 1 month after operation but increased 1 year after operation in most patients and remained stable thereafter, near the normal level. In those with chronic pancreatitis, IGR levels were normal before the operation, increased abnormally after the operation, but returned near the normal level 3 years after the operation.

Relationship Between Gastric Acid Output and Gastrin Levels

The relationship between acid output and gastrin levels was examined in those available for evaluation by the use of all data from before and 1 month to 3 years after the operation. One patient with chronic pancreatitis (Patient 9), in whom both gastric acid output and gastrin level were abnormally enhanced after the operation, was excluded.

BAO and basal gastrin levels (Fig. 8). A significant negative correlation was observed for BAO and basal gastrin levels ($Y = -40.08X + 125.7$, $r = -0.479$, $p < 0.05$).

MAO and basal gastrin levels (Fig. 9). A significant negative correlation was observed for MAO and basal gastrin levels ($Y = -5.16X + 126.1$, $r = -0.476$, $p < 0.05$).

MAO and IGR levels (Fig. 10). A significant negative correlation was observed MAO and IGR levels ($Y = -0.66X + 17.26$, $r = -0.476$, $p < 0.05$).

Comparisons Between GPPD and cPD

Gastric acid output levels (Fig. 11). Gastric acid output levels were compared between 35 patients who had GPPD and nine patients who had cPD.

BAO levels. After operation, BAO levels were significantly higher ($p < 0.001$) in the group that had GPPD

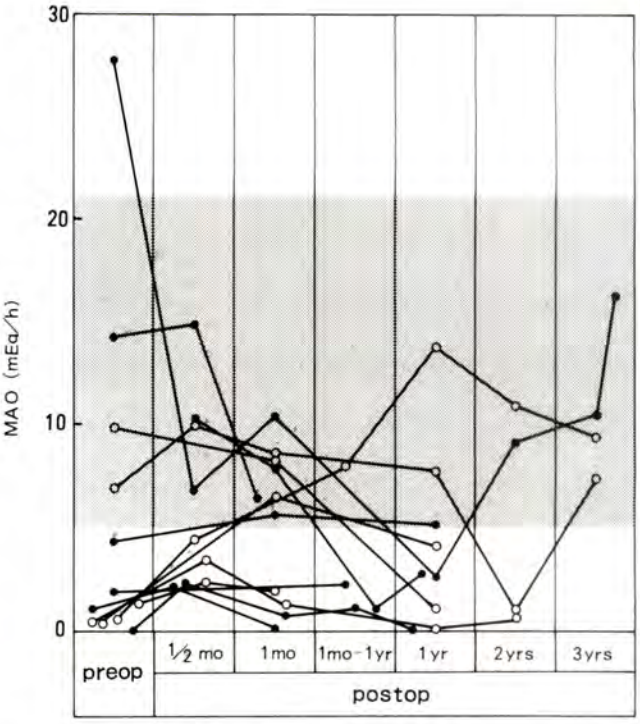

FIG. 5. Serial changes in MAO levels before and after GPPD. Shaded area represents the normal range; ○ = patients with chronic pancreatitis; ● = patients with nonchronic pancreatitis.

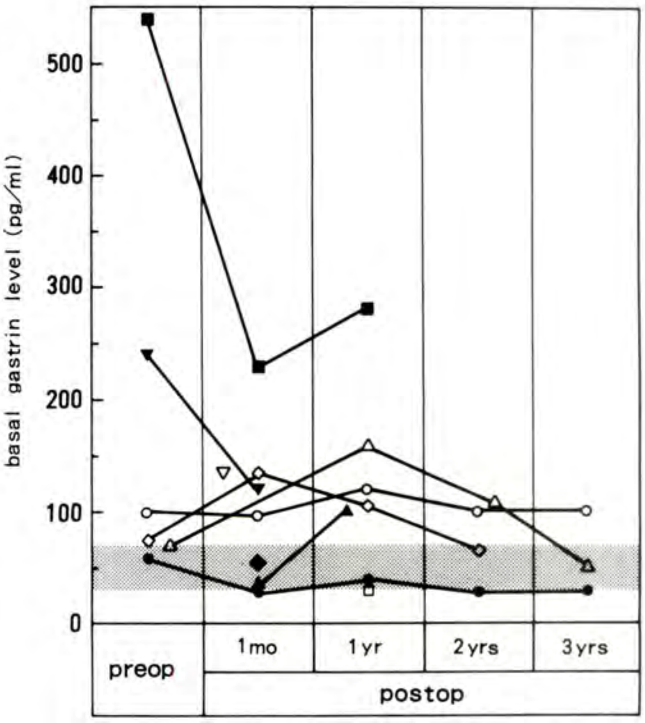

FIG. 6. Serial changes in basal gastrin levels before and after GPPD. Shaded area represents the normal range. Open symbols indicate patients with chronic pancreatitis. Closed symbols indicate patients with nonchronic pancreatitis.

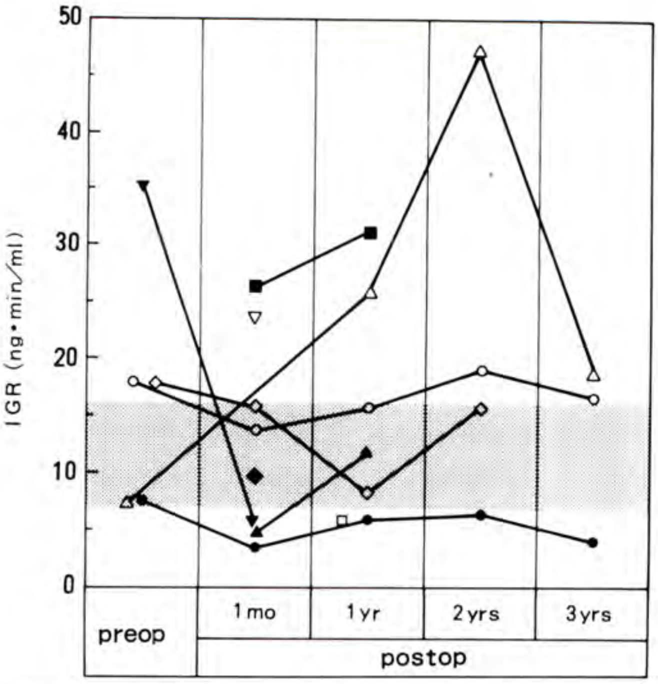

FIG. 7. Serial changes in IGR levels before and after GPPD. Shaded area represents the normal range. Open symbols indicate patients with chronic pancreatitis. Closed symbols indicate patients with nonchronic pancreatitis.

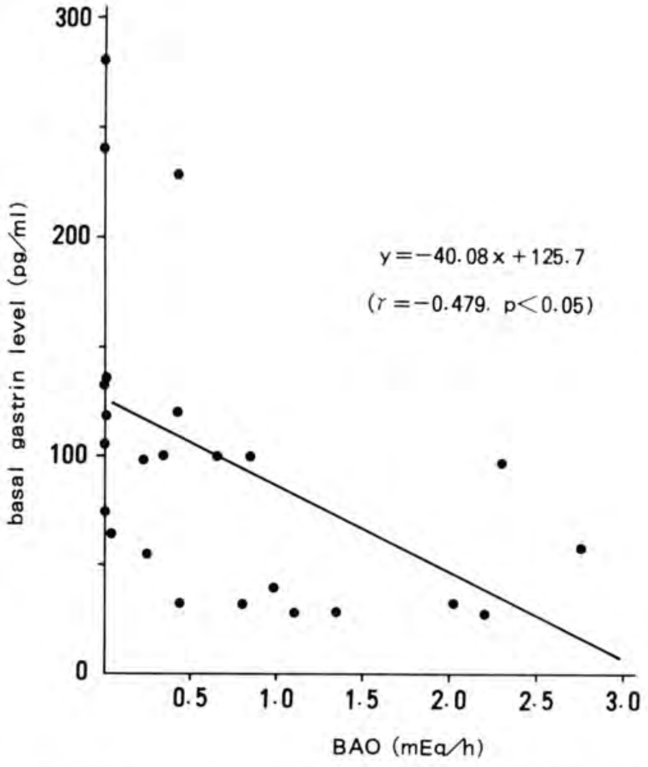

FIG. 8. Relationship between BAO and basal gastrin levels after GPPD.

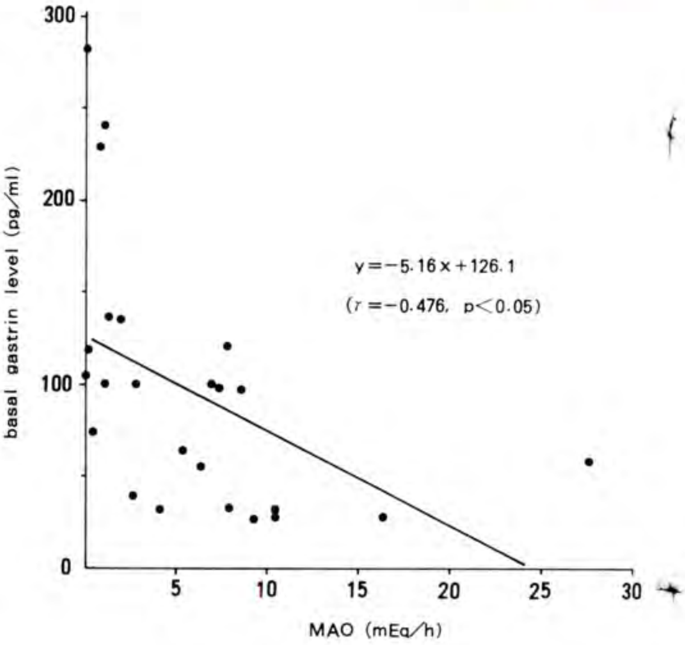

FIG. 9. Relationship between MAO and basal gastrin levels after GPPD.

(1.17 ± 1.55 mEq/h) than in the group that had cPD (0.04 ± 0.02 mEq/h) but were below the normal range.

MAO levels. After operation, MAO levels were significantly higher ($p < 0.001$) in the group that had GPPD (5.12 ± 4.29 mEq/h) than in the group that had cPD

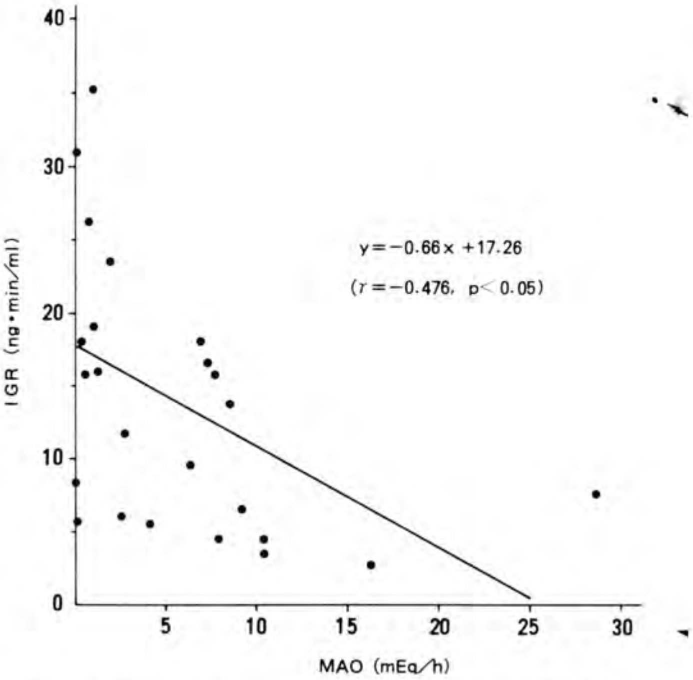

FIG. 10. Relationship between MAO and IGR levels after GPPD.

(0.54 ± 0.26 mEq/h), but the mean value was near the lower margin of the normal range.

Serum gastrin levels. Serum gastrin levels were compared among 20 patients who had GPPD, nine who had cPD, and 13 healthy controls.

Basal gastrin levels (Fig. 12). The basal gastrin levels were significantly higher after operation in the group that had GPPD (93.1 ± 66.6 pg/mL) than in both the group that had cPD (29.1 ± 6.5 pg/mL) and the control group (51.6 ± 19.8 pg/mL) ($p < 0.01$ and $p < 0.05$, respectively). The values in the group that had cPD were significantly lower ($p < 0.01$) than those of the control group.

IGR levels (Fig. 13). After operation, the IGR levels in the group that had GPPD (12.3 ± 7.9 ng•min/mL) were significantly higher ($p < 0.001$) than those in the group that had cPD (2.2 ± 1.5 ng•min/mL) but were not significantly different from those of the controls (11.5 ± 4.5 ng•min/mL). The values of the group that had cPD were significantly lower ($p < 0.001$) than those of the control group.

Postoperative Evaluation of the Gastrointestinal Tract

Most of the patients temporarily retained the gastric contents after the operation, but the condition was shortly resolved by repeated aspiration of the contents through an indwelling stomach tube. None of the patients had symptoms of mucosal damage of the digestive organs such as hematemesis and hematochezia throughout the observation period. Roentgenography was performed after operation in all patients, and endoscopic examination was done in those observed for a long time after the operation, but no signs of ulcer were observed in the stomach, duodenal bulb, or areas near the anastomoses. A patient (Patient 9) who showed marked enhancement of exocrine and endocrine stomach after the operation were examined more often and more closely than other patients, but no abnormalities were noted. One patient had GPPD with a diagnosis of chronic pancreatitis but was found by postoperative histologic examination to have pancreatic cancer and had *en bloc* resection of the upper gastrointestinal tract 1.5 months after the operation. Reddening was noted in the resected specimen of this patient in the jejunal mucosa anal from the anastomosis site, but there were no histologic findings suggestive of ulcer such as loss or rupture of the mucosa.

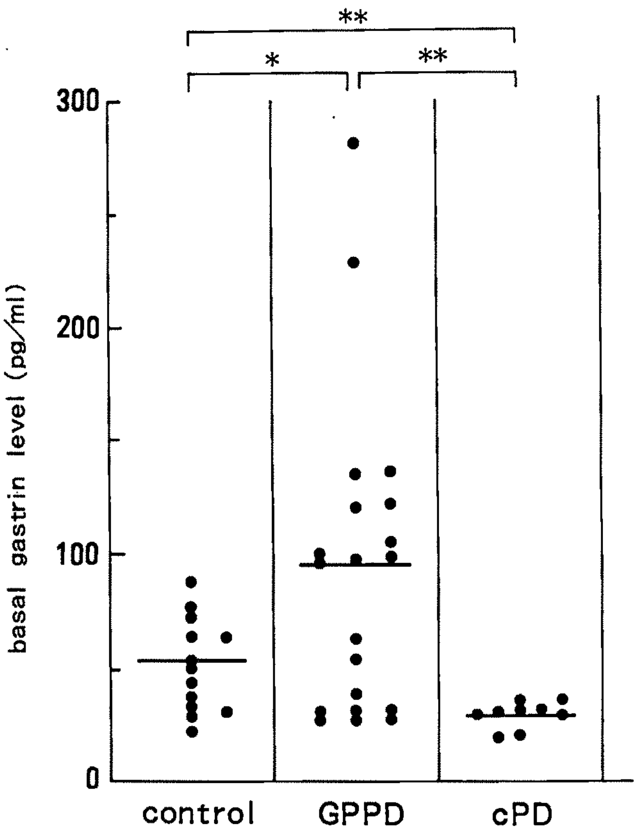

FIG. 12. Basal gastrin levels after GPPD and cPD. *p < 0.05; **p < 0.01.

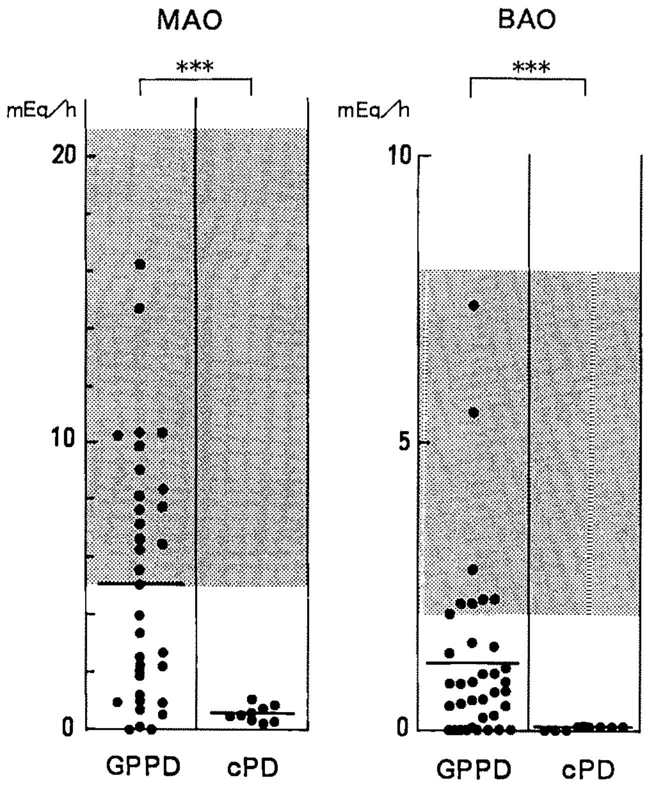

FIG. 11. BAO and MAO levels after GPPD and cPD. Shaded area represents the normal range; ***p < 0.001.

Discussion

Duodenectomy,[14,15] massive pancreatectomy (or pancreatic disorders),[16,17] and Mann-Williamson proce-

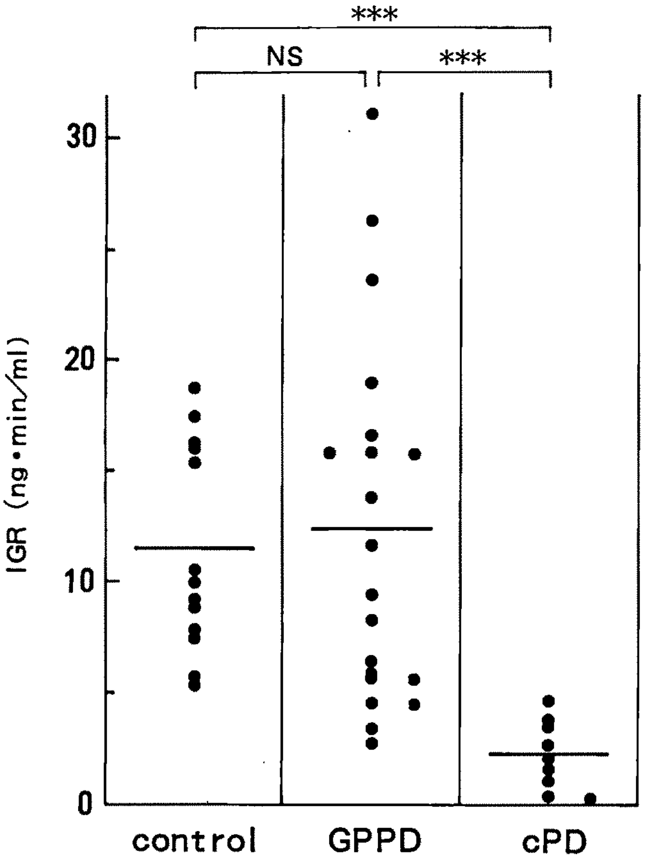

FIG. 13. IGR levels after GPPD and cPD. ***$p < 0.001$; NS = not significant.

dure,[18,19] in which bile and pancreatic juice are diverted through a duodenal segment to the distal intestine, frequently result in peptic ulcer in dogs. This condition is considered to result largely from increased acid secretion. Clinical pancreatoduedenectomy is considered to be associated with all these factors in peptic ulcer. Waddell et al.[1] studied changes in acid secretion after this operation and suggested that postoperative acid secretion increases, making the possibility of ulcer greater, as the extent of gastrectomy is smaller. In PD, therefore, some surgeons perform extensive gastrectomy, often in combination with vagotomy, to reduce acid secretion. However, there are still many patients who have marginal ulcers after this operation. The incidence of the condition is reported to be 6–36%,[4,6] and the mean interval between the operation and the onset of the disorder is reported to be 1.25 years by Grant et al.[4] and 3 years by Scott et al.[6] Contrary to this general view, Traverso and Longmire[10] attempted to preserve the entire stomach including the bulbar and pyloric regions in PD and found that the subsequent 18 patients treated by this procedure were free of ulcer and showed nearly normal acid secretion.[11] Among other studies, the incidence of the marginal ulcer after GPPD was reported to be low by Flautner et al. (0 of 37 patients, 0%),[20] Grace et al. (one of 37, 2.7%),[21] and Pearlman et al. (0 of 10, 0%),[22] but high by Braasch et al. (five of 87, 6%),[23] and particularly Gebhardt et al. (seven of 18, 38.9%), who reported the mean interval between the operation and the onset of ulcer to be 13 months. We studied changes in exocrine and endocrine stomach, a key factor in marginal ulcers after pancreatectomy and duodenectomy, with the occurrence of the condition in 13 patients from before to half a month to a maximum of 3 years and 10 months after GPPD (mean: 2.1 years).

As for gastric acid output, BAO and MAO levels showed similar changes after the operation. BAO and MAO levels temporarily increased half a month after the operation, decreased after 1 month, returned to the preoperative level after 1 year, and remained stable after more than 2–3 years. This temporary increase in acid output may be related to inadequate recovery of stomach muscle tone and peristalsis from the surgical insult[24] and poor gastric emptying secondary to disconnection of the proximal intestinal pacemaker,[25] in addition to partial loss of inhibitory factors in gastric acid secretion resulting from duodenectomy. As for gastrin level, both the basal gastrin level and IGR level after a test meal were reduced 1 month after the operation but returned nearly to the preoperative level after 1 year and remained near the normal level thereafter. Basso et al.[26] noted that, of those who had cPD, patients retaining antral mucosa after operation had marginal ulcers and bleeding stomitis develop and showed significant increases in bombesin-stimulated gastric acid output and gastrin level as compared with those without ulcer. Therefore, the long-standing postoperative control of gastrin level in our patients suggests that GPPD is advantageous for prevention of marginal ulcers and hemorrhage of the gastrointestinal tract.

The relationship between exocrine and endocrine stomach was studied next by use of all data from before to after GPPD, excluding one patient who showed marked increases in both acid output and gastrin levels. Negative correlations were observed between BAO and the basal gastrin levels, between MAO and the basal gastrin levels, and between MAO and IGR levels. The relationship between acid output and gastrin levels remains controversial, but Trudeau et al.[27] observed an inverse relationship between the basal gastrin level and both BAO and MAO levels in their subjects, who were patients with gastric ulcers, patients with duodenal ulcers, and healthy controls. Acid output levels were higher in patients with duodenal ulcer than in those with gastric ulcer or healthy controls, and the gastrin level in patients with gastric ulcer than in those with duodenal ulcer or healthy controls. They[28] also observed an increase in the gastrin level with the advance of age and ascribed this phenomenon to an age-associated reduction in acid secretion. Considering that none of our patients exhibited hyperacidity, gastric ulcer, or duodenal ulcer, acid output appears to be closely related to gastrin level except in those with hypoacidity resulting probably from old age. Gedde-Dahl[29] noted a negative correlation between pentagastrin-stimulated MAO and food-stimulated gastrin per cent increase response in normal humans. We, therefore, considered that a feedback mechanism is maintained between parietal cells and G cells during fast as well as after meals from before to after GPPD.

However, in one patient (Patient 9), who showed an abnormal increase in acid and gastrin levels after operation, negative correlation was not observed between those from before the operation. It is likely because of failure to maintain the feedback mechanism.

An increase in gastric acid secretion was observed in dogs in association with pancreatic exocrine dysfunction, and the condition was ascribed primarily to hypergastrinemia.[16,17] Gastric acid secretion has often been reported to decrease in patients with chronic pancreatitis.[30-32] Gulbo et al.[33] compared the basal gastrin levels and gastrin response levels after a meal between patients with chronic pancreatitis and normal controls but noted no significant difference between the two groups. As in other studies, almost all patients of this study were normoacidic or hypoacidic before the operation. Grant et al.[4] suggested that the incidence of post-PD ulcer is higher in patients with than without chronic pancreatitis, but we observed similar changes in acid secretion in both those with and those without chronic pancreatitis. As for gastrin levels, both the basal gastrin and IGR levels showed slight increases before the operation in the small number of patients examined, but the basal gastrin level increased but IGR showed no significant difference after the operation as compared with the controls. These differences in changes in acid and gastrin levels may result from to atrophic gastritis not involving the antrum, as suggested by Gulbo et al.,[33] or to hypoacidity secondary to other causes.

Next, postoperative acid output and gastrin response levels were compared between GPPD and cPD. Acid output levels were clearly lower in our patients than those of Pearlman et al.[22] In those who had underwent cPD, they were similar to those in the series of Sato et al.,[34] despite the difference in the method of stimulation, but were lower than in the series of Waddel et al.[1] In patients who had GPPD, both BAO and MAO levels were higher than in those who had cPD, but the mean value was near the lower margin of the normoacidic range. These findings indicate that acid output is maintained near the normal level after GPPD, whereas it is markedly reduced after cPD because of extensive gastrectomy. As for gastrin level, basal gastrin levels were significantly higher in those who had GPPD than in the controls, but IGR levels were not significantly different between the two groups. The higher basal gastrin levels in patients with GPPD than in the controls result from the presence of a few patients with hypergastrinemia associated with anacidity.[35,36] Both the basal gastrin and IGR levels were lower in those who had cPD than in those who had GPPD or the normal controls, clearly because of the antrectomy.

We periodically examined all patients by radiography and endoscopy of the upper gastrointestinal tract but did not encounter ulcer of the anastomosis sites or mucosal damage. These findings suggest that there are no major problems concerning offensive factors after GPPD.

Some investigators[37,38] considered that the primary pyloric function is to prevent reflux. Fisher et al.[37] postulated a sequence of events triggered by reflux of bile-containing duodenal contents into the stomach because of pyloric incompetence and resulting in gastric ulcer formation. Nahrwald[39] also demonstrated that in dogs, antral retention of bile and bile acid could release gastrin. Braasch,[40] moreover, considered that the loss of a pylorus could allow alkaline reflux, antral stimulation, subsequent parietal cell stimulation, and resulting increased gastric secretion and that pyloric preservation can prevent jejunal ulcer formation by preventing this possible chain of events.

The duodenal bulb is considered to play an even greater role than the pylorus in prevention of ulceration after this operation. The duodenal bulb possesses an acid-sensitive mechanism and plays a primary role in duodenal inhibition by releasing gastric inhibitory hormones such as somatostatin,[41] bulbogastrone,[42] and secretin,[43] as well as regulating gastric emptying.[44] A pacemaker is present within 1 cm from the pylorus to control the transport of the gastric contents.[45] The Brunner's glands distributed primarily in the bulb neutralize the gastric acid by secreting mucus and bicarbonates to protect the duodenal mucosa.[46]

Because we understand that ulceration is prevented by cooperative actions of the pylorus and the duodenal bulb, we called our procedure gastrobulbar preserving pancreatoduodenectomy.

However, despite these precautions, Braasch et al.[23] observed ulcer formation in five of their 87 patients, including 13 who had total pancreatectomy. Gebhardt et al.[12] noted the condition in seven of 18 patients, more frequently in those showing enhanced gastric acid secretion after the operation. They concluded that the duodenal bulb alone cannot adequately inhibit acid secretion. By their method of reconstruction, the oral extremity of the remaining intestine is left empty in a blind loop, and, apart from this site, a further anal portion of the intestine is anastomosed end-to-end with the duodenum. By this procedure, the portion of the intestine lacking protection for mucosa and containing less gastric inhibitory factors is directly exposed to the gastric juice. In addition, because the blind intestine is anastomosed end-to-side further anally from the site of the influx of gastric juice, the duodenal anastomosis site is not adequately neutralized by bile or pancreatic juice.

Kiriluk et al.[47] showed that in dogs the buffering capacity of the bowel contents is progressively reduced as the distance from the pylorus is increased. In the humans, unlike dogs, Brunner's glands are not only densely distributed in the proximal duodenum, but are considered to also be present in the distal duodenum,[46] giving this portion a buffering ability.[48] Moreover, Isenberg et al.[49] observed that bicarbonate secretion from the bulb is increased by stimulating the distal duodenum, not to mention the bulb, with acid.

We devised our GPPD for preservation of defensive factors, cutting the duodenum with access through the mouth in the second portion, to leave the bulb intact, and from the anus, in principle, in the third portion, to minimize the area of duodenectomy, and reconstructing the duodenum by end-to-end anastomosis. Just anal to this duodenodeodenostomy, end-to-side pancreatojejunostomy and then end-to-side choledochojejunostomy were made without any Braun's anostomosis. Thus, we tried, on the one hand, to reduce acid secretion and preserve defensive mechanisms, and, on the other, to neutralize gastric acids by maintaining adequate bile and pancreatic juice output levels *via* secretion of gut hormones distributed in this region.[50] Also, pancreatojejunostomy performed just proximally will permit rapid neutralization of acid by pancreatic juice and choledochojujunostomy distally will prevent reflux of bile into the stomach.

These surgical manipulations together with exclusion of patients susceptible for peptic ulcer, such as those showing ulcer or hyperacidity before the operation as well as those with a history of ulcer, are considered to have contributed to prevention of marginal ulcers in our patients.

Conclusion

In our GPPD, the extent of duodenectomy is minimized, the neurovascular supply to the pylorus and duodenal bulb is preserved, and the intestine is reconstructed by end-to-end duodenoduodenostomy that is Billroth I type. This procedure ensures rhythmic discharge of gastric acid first into the duodenal bulb, which is resistant to mucosal damage; its transport through the site of duodenoduodenostomy to the upper jejunum while stimulating release of gastric inhibitory factors; and adequate stimulation of bile and pancreatic secretion. As a result, acid is efficiently buffered and pancreatic enzymes thoroughly activated,[51] to allow smooth digestion and absorption of lipids, and the gastric inhibitory factor (enterogastrone)[52] is released to prevent abnormal increases in acid secretion.

Percutaneous Ultrasonography-guided Cutting Biopsy from Liver Metastases of Endocrine Gastrointestinal Tumors

T. ANDERSSON, M.D.,* B. ERIKSSON, M.D.,† P. G. LINDGREN, M.D.,* E. WILANDER, M.D.,‡ and K. ÖBERG, M.D.†

Ultrasonography-guided cutting needle biopsy of the liver was performed in 186 instances on 95 different patients with carcinoid and endocrine pancreatic tumors. In 171 cases, biopsy specimens were taken from liver metastases found on ultrasonography, and in 93% of these the obtained material was adequate for a correct diagnosis. In the 7% for which an incorrect diagnosis was made, all but one biopsy specimen contained normal liver tissue, indicating that the needle-guiding technique, and not the sampling technique, is the most critical part of the biopsy procedure. Tumor specimens were examined with silver stains and immunocytochemistry after application of monoclonal serotonin antibodies. The argyrophil silver stain of Grimelius could be applied on all specimens and had positive results in all but one case, demonstrating the neurohormonal endocrine origin of the metastases. The argentaffin reaction and/or serotonin immunoreactivity could be applied in 152 cases and had positive results in 115 of 122 (94%) of the mid-gut carcinoid tumors and negative results in 27 of 28 (96.4%) of the non–mid-gut carcinoid tumors and endocrine pancreatic tumors. Major complications occurred in 1.5%; none was lethal or required surgery. The results show that the technique used for tumor biopsy is very accurate and provides material sufficient for multiple histopathologic and immunocytochemical analyses without exposing the patients to high complication risks. It is further concluded that the staining techniques and immunocytochemical analyses applied on the biopsy specimens are valid for the prediction of the location of the primary endocrine tumor.

PERCUTANEOUS FINE-NEEDLE BIOPSY of liver metastases has been routinely used to confirm the diagnosis, because cytologic examination usually reveals whether or not a lesion is malignant.[1,2] Cutting biopsy, with needles of larger dimensions, has been used mainly for diagnosis of diffuse liver disease, where fine-needle cytologic procedures are insufficient.[3-5] Fine-needle biopsy is used, instead of cutting biopsy, in focal liver disease because of the lower risk of complications, for example, bleeding.[6]

From the Departments of Diagnostic Radiology, Internal Medicine,† and Pathology (Endocrine Laboratory),‡ Akademiska Sjukhuset, University of Uppsala, S-751 85 Uppsala, Sweden*

In patients with endocrine tumors derived from the neuroendocrine cell system, liver metastases are often present at the time of hospital admittance. Cutting biopsy specimens can be examined both with histopathologic and histochemical techniques and immunocytochemical analyses, making it possible, with a high degree of accuracy, to establish the histopathologic diagnosis and the topographic location of the primary tumor.[7]

The aim of this investigation was to examine whether ultrasonography-guided cutting biopsies are adequate to sample material for histologic and immunocytochemical analyses. The staining techniques for endocrine cells and hormones for predicting the location of the primary tumor were also investigated, as was the complication rate of the biopsy technique.

Materials and Methods

One hundred eighty-six liver biopsy specimens, taken from 95 different patients with carcinoid tumors or endocrine pancreatic tumors (EPTs), were examined. There were 40 men and 55 women; the mean age was 60.8 years and the median age 63 years (range: 18–78 years). All patients were examined with ultrasonography before liver biopsy was performed with ultrasonographic guidance.[7-9] All biopsies were taken with either a Tru-Cut (Travenol, France) or Biopty (Radioplast A.B., Sweden) needle with an external outside diameter of 2 mm (173 cases) or 1.2 mm (11 cases). In two cases biopsies were performed with both 2.0-mm and 1.2-mm needles. The needle was placed in an automatic biopsy de-

Submitted for publication: June 5, 1987.

vice (Fig. 1), making it possible to perform the biopsy with one hand while holding the ultrasound transducer with the other.[8] If the liver mass was large or showed ultrasonographic features of tumor necrosis, attempts were made to obtain the biopsy specimen from the periphery of the lesion. All patients were hospitalized during the biopsy procedure, and normal bleeding and coagulation parameters were required (platelet count, Normotest [NYCOMED A. S., Oslo, Norway] Activated Prothrombin Time [NYCOMED A. S.]) for a biopsy procedure. All patients were kept in bed for 4 hours after biopsy and stayed overnight in the hospital.

Light Microscopy

The biopsy specimens were divided and fixed in 10% buffered formalin or in Bouin's fluid, dehydrated, and embedded in paraffin. Sections, approximately 4-μm thick, were cut and stained with hematoxylin and eosin, van Gieson stain, the argentaffin reaction of Masson, and the argyrophil reactions of Grimelius and Sevier-Munger.

Immunocytochemical Analysis

Immunocytochemical analysis with monoclonal serotonin antibodies (Mas 055 clone YC5/45, HLK SeraLab Limited, Crawley Down, Sussex, England) was used for visualization of serotonin-containing endocrine tumor cells.[7]

Analysis of Complications

Notes of any complications were registered in the patients' medical records.

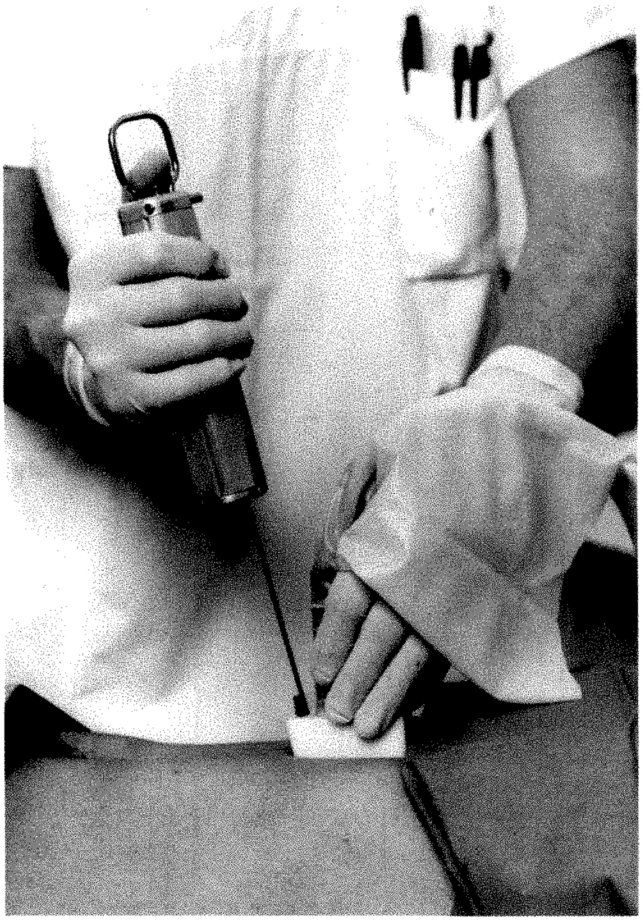

FIG. 1. The biopsy device is loaded with a specially designed cutting needle and introduced into the tissues through the needle guide unit attached to the ultrasound scan head. The device makes it possible to perform the sampling procedure swiftly with just one hand.

Results

Biopsy results were classified as "correct diagnosis" and "incorrect diagnosis" (Fig. 2), where biopsy results were considered correct if the biopsy diagnosis agreed with the final diagnosis. If the biopsy examination, for example, showed normal liver tissue and follow-up evaluation showed metastatic liver disease or the biopsy examination showed malignant tumor tissue but the endocrine nature of the tumor was not indicated, the biopsy results were classified as incorrect. In 10 cases no abnormality was detected with ultrasonographic examination, but biopsy was performed and examination showed (Fig. 2) normal liver tissue in nine cases and carcinoid tumor in one. In three of the cases with normal liver tissue in the biopsy specimens, two with EPTs and one with a carcinoid tumor, multiple metastases smaller than 1 cm were noted at angiographic examination and operation. The remaining six showed no signs of liver metastases with other examinations or at operation. In five ultrasonographic examinations, diffuse changes of the liver parenchyma were seen. In four of these, biopsy results and final diagnosis agreed (three steatosis and one diffuse carcinoid tumor infiltration) and in one case the biopsy specimen and ultrasonographic examination showed fatty infiltration, whereas angiographic examination revealed several small metastases, 4–6 mm in diameter. In the 171 cases where biopsy specimens were taken from focal masses in the liver, biopsy results and final diagnosis agreed in 159 cases (93%). In 12 cases the biopsy results were classified as incorrect. One of these biopsy specimens showed "low differentiated malignant tumor," whereas the final diagnosis was metastasis from an EPT. The remaining 11 biopsy specimens all contained normal liver tissue, and the tumor had consequently been missed. Eight of these tumors were smaller than 1.5 cm and none larger than 3 cm. Most also had an unfavorable location in the dome of the right lobe of the liver, close to the diaphragm. In the whole material of 171 liver metastases

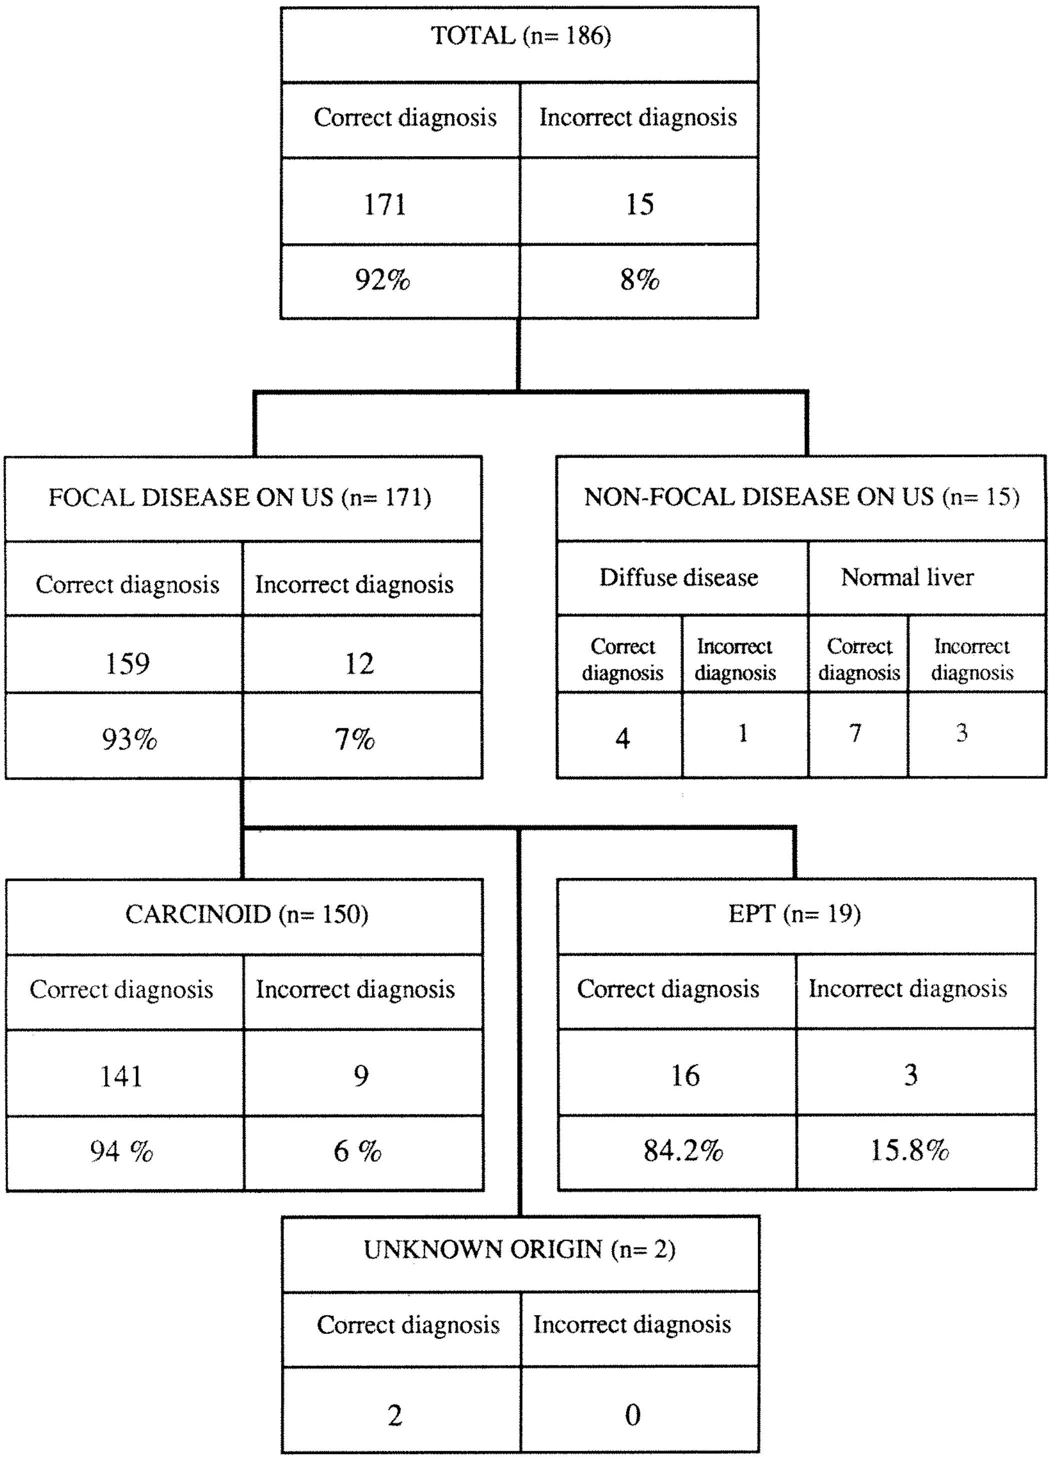

FIG. 2. The results of microscopic examinations of biopsy specimens; US = ultrasonography; EPT = endocrine pancreatic tumor.

for which biopsies were done, the tumor size varied between 1 and 20 cm (mean: 4.1 cm).

To test the accuracy of the analyses for identifying the topographic location of the primary tumor, the 162 specimens containing tumor tissue were compared with the known location of the primary tumor (Table 1). A tumor was classified as a "mid-gut carcinoid tumor" if the primary site was located between the duodenum and the left flexure of the colon. Carcinoid tumors from the gastrointestinal tract above the duodenum (foregut) and below the left colonic flexure (hindgut) and those with the primary site outside the gastrointestinal tract (lung) were classified as "non-mid-gut carcinoid tumors." In 10 biopsy specimens the amount of material was not

TABLE 1. *The Results from Silver Stains and Immunoreactivity to Monoclonal Serotonin Antibodies in Biopsy Specimens Correlated to the Location of the Primary Tumor*

Tumor	G+ M− SI−	G+ M/SI+	G− M− SI−	G+ M = 0 SI = 0	Number of Biopsies
Mid-gut	7	115	0	7	129
Non–mid-gut	11	1	0	1	13
EPT	15	0	1	2	18
Unknown origin	2	0	0	0	2
Total					162

G = Grimelius argyrophil stain; M = argentaffin reaction of Masson; SI = serotonin immunoreactivity; + = positive reaction; − = negative reaction; 0 = not tested; M/SI+ = positive argentaffin reaction and serotonin immunoreactivity or one of the reactions positive and the other not tested.

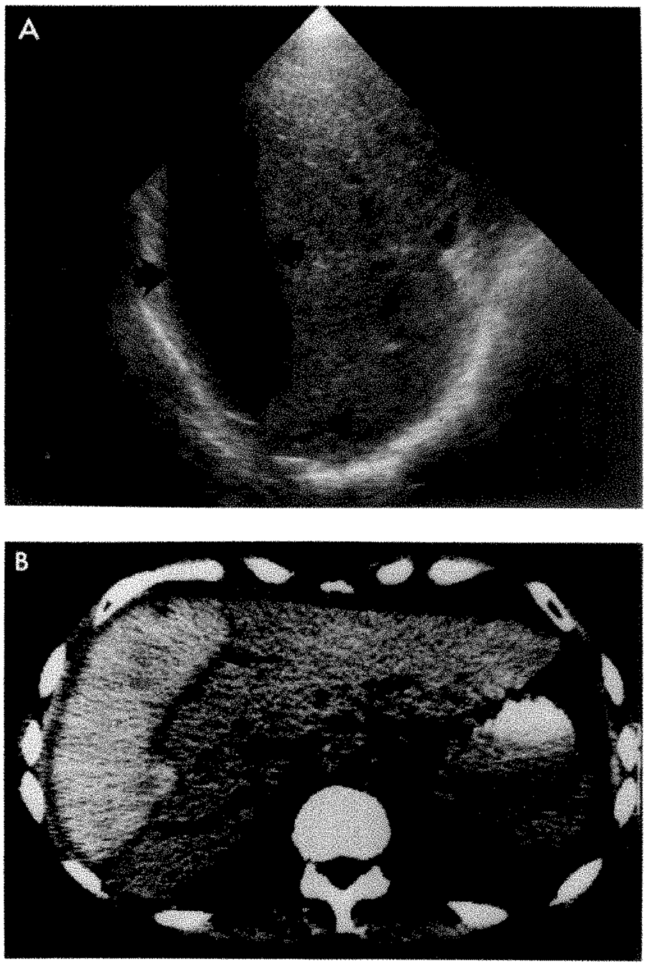
enough to allow all analyses to be performed, and neither the argentaffin reaction nor immunocytochemistry could be analyzed (seven mid-gut tumors, one non–mid-gut tumor, and two EPTs). In the remaining 152 specimens (122 mid-gut carcinoid tumors, 12 non–mid-gut carcinoid tumors, 16 EPTs, and two tumors of unknown origin), the material was sufficient for adequate analysis, but eight specimens (all mid-gut tumors) only permitted examination with one of the two methods indicating serotonin content. In the group of mid-gut tumors, seven specimens showed negative argentaffin reaction and/or negative serotonin immunoreactivity (5.7%), whereas one of the specimens from the non–mid-gut tumor group showed a weakly positive reaction. All but one of the patients with mid-gut tumors and a negative argentaffin reaction or serotonin immunoreactivity later had rebiopsies, and all these biopsy specimens showed a positive argentaffin reaction. In the group with EPTs, no specimen showed positive argentaffin reaction or positive serotonin immunoreactivity. In two cases the location of the primary lesion could not be established, both specimens showing negative argentaffin reaction. With one exception, all specimens containing tumor tissue showed a positive reaction for Grimelius argyrophil silver nitrate stain. This case with normal results was incorrectly classified as "low differentiated tumor."

In the 11 specimens obtained with the 1.2-mm needle, normal liver tissue was found in two and tumor tissue in nine. In all the nine specimens containing tumor tissue, the amount of material was sufficient to allow both a complete light microscopic examination and immunocytochemical analysis to be performed.

Three major complications occurred—all intrahepatic hematomas occurring after biopsy with the 2.0-mm needle (Fig. 3). In all three patients multiple biopsies (more than three) were performed. None of the patients required surgery. No other major complications were noted, but several patients had various degrees of pain lasting for minutes up to 10 days, most episodes lasting a few hours.

Discussion

The results show that percutaneous biopsy under ultrasonographic guidance is an extremely safe and reliable method for obtaining material from liver tumors for histopathologic examinations because adequate material was obtained in 93% of the tissue specimens, al-



FIGS. 3A and B. Ultrasonographic (*A*) and computed tomographic (*B*) scans of the liver in a patient with a postbiopsy hematoma in the right lobe (arrows).

lowing the pathologist to make the correct diagnosis. Among the 7% of the specimens from focal lesions not giving the correct diagnosis, only one case showed tumor material and the rest showed normal liver tissue. It is therefore probable that the guidance of the biopsy needle into the lesion is the most critical procedure where most failures occur. This is also supported by the fact that all but one of the patients with an incorrect diagnosis had small tumors (<3 cm) usually unfavorably located high up in the dome of the liver. The automatic biopsy device gave enough material to allow a tumor diagnosis in all cases where tumor tissue was present in the specimen, but in a small number of cases (10 of 162 specimens with tumor tissue) the amount of material was not sufficient for performance of all analyses. In the 14 cases where no focal lesion, or obvious diffuse tumor infiltration, was present, tumor tissue was obtained in only one case, whereas angiographic examination revealed metastases in an additional four cases. It therefore seems meaningless to take biopsy specimens blindly from a liver that appears normal on ultrasonographic examination.

There were no differences between the 1.2- and 2-mm biopsy needles in obtaining enough material for the histopathologic and immunocytochemical analyses. The use of the 2.0-mm needle is therefore abandoned, although the number of major complications was low (1.5%), because the use of a smaller needle may further reduce the risk for complications.

The silver stains employed on the biopsy specimens have an affinity for hormone secretory granules in normal and neoplastic endocrine cells and make it possible to visualize these structures on light microscopic examination.[10] The Grimelius argyrophil stain is specific for endocrine cells and tumors of the neurohormonal type but is nondiscriminatory, because a positive reaction is obtained in most carcinoid tumors and EPTs, irrespective of their hormone content.[10] The argentaffin reaction of Masson, on the other hand, is specific for carcinoid tumors with content of serotonin, which is characteristic of mid-gut carcinoid tumors (classic carcinoids).[11] These observations make it possible to differentiate mid-gut carcinoid tumors from non–mid-gut carcinoid tumors and EPTs. Our investigation confirms that the silver staining characteristics of the primary tumor are also found in the secondary lesions, making it possible to indicate the location of the primary tumor after examining biopsy specimens from liver metastases. The accordance between the topographic location of the carcinoid tumor and the presence or absence of proven serotonin content is not complete, however. In seven cases, negative argentaffin reactions and/or negative serotonin immunoreactivity were present in specimens from mid-gut carcinoid tumors. This may be because the serotonin content of classic mid-gut carcinoid tumors is unevenly distributed within the tumor and areas without serotonin may be found in between the serotonin-containing ones, which is supported by our observation that, in all but one case, subsequent biopsy specimens showed a positive argentaffin reaction. To reduce the number of biopsy specimens with serotonin-negative material, it may be justified to take two, or more, biopsy specimens from different areas of a metastasis. The use of the two different methods to show the serotonin content is recommended because the methods are valid on different tissue fixation specimens—the argentaffin reaction of Masson on formalin-fixed tissue and serotonin immunoreactivity on Bouin-fixed material. This means that if the obtained biopsy material fixed in one fluid is sparse, the tissue fixed with the other method possibly can be analyzed adequately, which occurred in eight cases with this material. The Grimelius argyrophil silver nitrate stain had a positive reaction on all tumor specimens but one, indicating that the method is extremely reliable in showing the endocrine origin of the metastatic lesions.

Although the risks with the biopsy method used are low, they could be minimized even more by use of a smaller needle and not performing more than three biopsies at the same investigation.

Portal Vein Injuries

Noninvasive Follow-up of Venorrhaphy

RAO R. IVATURY, M.D., F.A.C.S., MANOHAR NALLATHAMBI, M.D., F.A.C.S., DANIEL H. LANKIN, M.D.,
IRENE WAPNIR, M.D., MICHAEL ROHMAN, M.D., F.A.C.S., and WILLIAM M. STAHL, M.D., F.A.C.S.

The authors report their experience with 14 patients with portal vein injuries (1976–1986) treated at a level I trauma center. Seven patients (50%) survived and included six of 10 patients (60%) who had venorrhaphy and one in whom the portal vein was ligated. Associated injuries were present in all the patients (mean Abdominal Trauma Index: 39.5) and accounted for the high mortality rate. Follow-up data after repair or ligation of the portal vein seldom are reported in the literature. The authors studied all three patients who survived portal venorrhaphy since 1982 by real-time ultrasonography. Patency of the repair could be established in two patients. In the third patient postvenorrhaphy thrombosis was diagnosed by ultrasonographic examination. Sequential ultrasonographic examinations demonstrated resolution of the thrombus on anticoagulant therapy. Ultrasonography provides a noninvasive and easily reproducible method of studying the portal vein after repair.

From the Department of Surgery, New York Medical College and Lincoln Medical Mental Health Center, Bronx, New York

TRAUMA to the portal vein is rare. In the last three decades fewer than 200 such injuries have been described in the literature.[1-13] The largest series from a busy trauma center[10] spanned a period of 23 years and included only 46 patients. These injuries often are lethal; the reported mortality rate resulting from uncontrolled hemorrhage varies from 50 to 70%. The frequent occurrence of concomitant injuries to other major organs and vascular structures, along with the technical difficulty of isolating and controlling the lacerated portal vein, contributes to this high mortality rate. Lateral venorrhaphy is the preferred method of management of the injured portal vein. More recently, however, it has been suggested that ligation of the vein is a viable alternative in patients with unstable conditions.[7,8,10] Although there has been a significant survival rate after portal vein ligation, postvenorrhaphy thrombosis of the portal vein as a fatal complication has been reported by Fish[2] and Chisolm and Lenio.[3] Portal vein thrombosis after repair may complicate postoperative fluid and electrolyte management as a result of splanchnic bed sequestration.[12,14] Unfortunately, the real incidence of portal vein thrombosis after repair has not been investigated, probably because of the relative difficulty in investigating the portal system in critically injured and hemodynamically unstable patients.

In this report we present our experience with portal vein injuries, with particular emphasis on a noninvasive modality for the study of the repaired portal vein. To our knowledge, this is the first report of such a follow-up in a series of patients with portal vein trauma.

Clinical Materials and Methods

Between 1976 and 1986, 14 patients with portal vein injuries were treated at the Lincoln Medical and Mental Health Center, a level I trauma center. There were 12 men and two women, with an age range of 22–36 years. Seven patients were stabbed, and seven received gunshot wounds. All the patients had hypotension (systolic blood pressure less than 90 mmHg) on admission. Five patients had no palpable blood pressure. Two patients had emergency room thoractomies for resuscitation, and in two others thoracotomies were performed in the operating room for aortic compression in an attempt to reduce intra-abdominal hemorrhage. None of these patients who were *in extremis* survived.

Associated injuries were noted in all of the 14 patients (Table 1), the liver being the most common organ injured. An associated bile duct injury was found in three

TABLE 1. *Associated Injuries*

Visceral Injuries		Vascular Injuries		
Location	No. of Patients	Location	No. of Patients	(No. of Survivors)
Liver	10	Hepatic artery	2	(1)
Pancreas	3	Superior mesenteric	3	(0)
Duodenum	3	Inferior vena cava	3	(2)
Spleen	1	Aorta	3	(1)
Biliary tract	4	Renal vessels	3	(2)

patients. One patient, with a severe crush injury of the duodenum and the head of the pancreas, required a pancreatoduodenectomy as well as portal and vena caval repair. Major vascular injuries were common (eight of 14 patients, 57%) and involved the hepatic artery (two patients) and the aorta, vena cava, and their tributaries (12 injuries in six patients). The mean abdominal trauma index of 39.6 testifies to the severity of trauma sustained. The patients received a mean of 10 units of packed erythrocytes (range: 6–26 units).

The portal vein injury was managed by ligation in one patient and venorrhaphy in 10 patients. Three patients died from exsanguination before repair could be attempted. Seven of the 14 patients (50%) survived, including the patient treated by portal vein ligation. Six of the 10 patients who had venorrhaphy survived. None of the four patients who required resuscitative thoracotomy survived. Five of the seven deaths occurred during operation, and two patients died in the intensive care unit. All the deaths resulted from a combination of uncontrolled bleeding and coagulopathy. The survivors had a mean Abdominal Trauma Index of 28.1, whereas the Index was 51 for those who did not survive. Four of the eight patients with concomitant major vascular injuries survived.

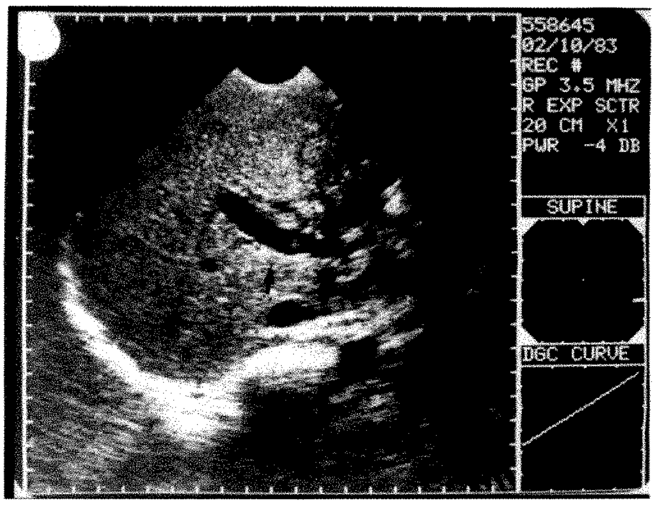

FIG. 2. Left oblique parasaggittal view after 5 weeks of anticoagulation showing resolution of the thrombus.

Follow-up of the Repaired Portal Vein

Since 1982, three of seven patients with portal vein injuries lived. In these patients, the portal vein was studied after operation by real-time ultrasonography. The first patient, who had sustained injuries to the portal vein and common hepatic duct that were treated by venorrhaphy and biliary ductal repair, had ultrasonographic examination of the abdomen on the 16th day after operation for a suspected intra-abdominal abscess. None was found. Instead, in the real-time study, blood could be seen swirling past an echogenic density that almost completely occluded the lumen of the portal vein (Fig. 1). Portal vein thrombosis was diagnosed. The patient was treated with continuous intravenous heparin therapy. In subsequent weeks, the patient improved clinically, and sequential ultrasonographic examination demonstrated resolution of the thrombus with complete restoration of the venous lumen of the vein by the 9th week (Figs. 2 and 3). He was discharged 3 weeks later. At the last follow-up visit, approximately 3½ years after injury, the portal vein was demonstrated to be normal on ultrasonographic examination. In the second patient, who had a pancreatoduodenectomy and portal vein and vena caval repair, ultrasonographic examination 2 and 5 weeks after the procedure proved the veins to be patent (Fig. 4). The third patient was a 17-year-old woman who had sustained injuries to the portal vein, abdominal aorta, and the renal vein. During an uneventful recovery

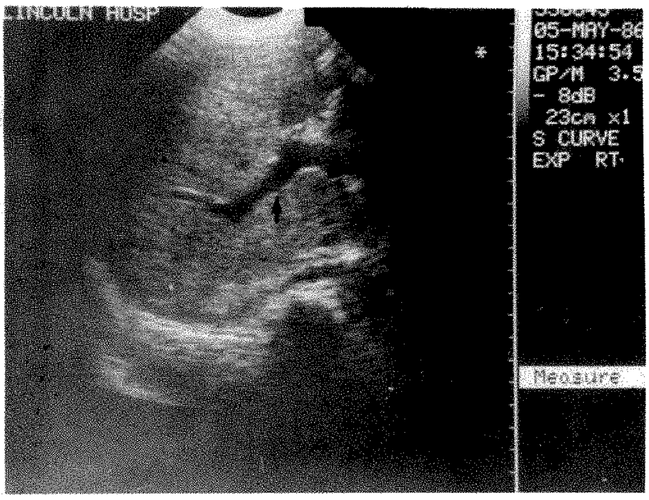

FIG. 3. Left oblique parasaggittal view 3½ years later: portal vein (arrow) completely normal.

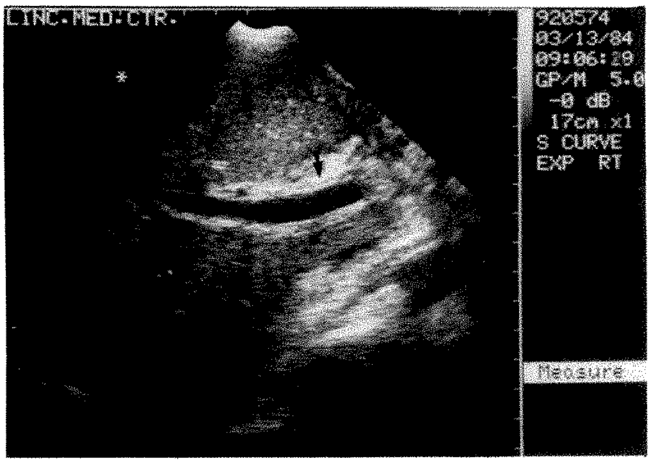

FIG. 4. Patient 2. Left oblique parasaggittal view 5 weeks after repair, showing patent portal vein (arrow).

from the repair of these injuries, ultrasonographic examination on the 10th day after operation established patency of the repaired portal vein (Fig. 5).

Discussion

The experience with portal vein trauma of each of several busy trauma centers is limited to fewer than 50 patients collected over several decades. Stone et al.,[10] for example, could find only 46 patients during a 23-year period. Despite this rarity, these lesions are of concern to the trauma surgeon because of their potentially lethal nature and the anatomic and physiologic importance of the portal vein.

The portal vein provides as much as 80% of the metabolic and oxygen needs of the liver and is the principal conduit for visceral efferent flow. The concealed location of the portal vein in the portal triad protects it from injury but presents numerous difficulties to adequate exposure and control. The frequent presence of concomitant injuries to other major vessels and organs contributes to massive blood loss. All of our patients presented with severe hypotension, and 57% of the patients had additional vascular injuries. Five (35%) were *in extremis* on admission, and each of four of them had a resuscitative thoracotomy and aortic occlusion before an attempt was made to control hemorrhage. As shown in this report and several others,[3-12] these factors contribute to a high mortality rate. Death occurred in 22 of the reported patients before the portal vein could be controlled.

The technical details of exposure of the portal vein and its tributaries are reviewed by Petersen et al.,[7] Stone et al.,[10] and, more recently, Sheldon et al.[12] and consist of mobilization of the right colon and small bowel mesentery as well as the pancreas and the splenic vein to provide access to the posterior aspect of the portal vein. Occasionally, division of the pancreatic neck may be the only feasible approach to the retropancreatic confluence of the splenic and superior mesenteric veins.[7] Packing, vascular clamps, and the Pringle maneuver are useful in temporarily staunching exsanguinating hemorrhage from the portal vein while other major vascular lesions are receiving attention.

Lateral venorrhaphy has been the preferred surgical approach and yields a significant survival rate (Table 2). In a few instances, an end-to-end anastomosis may be accomplished. For patients with injuries precluding portal vein reconstruction, portasystemic shunt has been proposed. However, the potential complication of hepatic encephalopathy and the inadvisability of per-

forming such a technically involved operation in a patient with an unstable condition argue against such a procedure. In his collective review of the literature in 1966, Fish[2] noted that encephalopathy developed in four of five patients treated by primary portacaval shunt. Other maneuvers, such as a saphenous vein interposition graft to the portal vein, have been employed sporadically (Table 2). Ligation of the traumatized portal vein is the other major option in management.

The Role of Ligation

After the initial observations of Child et al.[15] that ligation of the portal vein was compatible with survival, this procedure found increasing favor. Pachter et al.[8] reviewed 10 cases from the literature with five survivors and added another successful case of their own. In a more recent review, Stone et al.[10] presented a survival rate of 80% with planned ligation of the vein. A 2- to 36-month follow-up with angiography in five of the survivors of ligation showed excellent collateral flow to the liver and no evidence of portal hypertension. Similarly, a favorable survival rate was noted by Petersen et al.[7] Even though one of their patients had an elevated portal pressure level after ligation of the vein, none had esophageal varices develop. It is recommended, however, that these patients be subjected to a "second-look" operation 24 hours later to detect small bowel infarction from portal hypertension.[7,8,12]

The Fate of the Repaired Portal Vein

Although ligation is an acceptable option in the management of an unreconstructable portal vein laceration in the patient with an unstable condition, and although lateral venorrhaphy is the preferred mode of treatment, a relevant concern is the patency rate after repair. Unfortunately, this issue has not been addressed adequately in the surgical literature. Stone[14] and Petersen et al.[7] commented on the low patency of the portal vein after repair but did not provide specific data as to the number of patients studied *versus* the number of patent veins. In other large studies of portal vein trauma,[4,6,12] follow-up studies of the repaired veins were not provided. As indicated in Table 3, data regarding the status of the portal venous circulation after repair are available in only 10 of the 169 patients described in the literature. Seven of these patients had ligation of the portal vein.

The complication of postvenorrhaphy thrombosis of the portal vein is not without significant sequelae. Patton and Johnston[1] recorded instances of portal hypertension with variceal bleeding secondary to portal vein thrombosis. Fish[2] and Chisolm and Lenio[3] reported deaths resulting from this complication. Stone et al.[10,14]

and Pachter et al.[8] emphasized the gravity of splanchnic pooling secondary to portal thrombosis. The resultant excessive sequestration of intravascular fluid may cause hypovolemia and hypotension. Precise hemodynamic monitoring becomes essential. It seems desirable, therefore, to study the portal vein after repair. However, the difficulty and the potential complications of performing invasive studies, such as selective angiographic examination, in a critically ill patient may outweigh the possible benefits from such studies. A noninvasive, easily reproducible investigation would circumvent these problems and may prove beneficial in the postoperative management. In our experience, ultrasonography has fulfilled these criteria. Further support for this approach may be obtained by examining the role of ultrasonography in nontraumatic conditions of the portal vein.

Ultrasonography in the Evaluation of the Portal System

The normal portal vein has been recognized as an important landmark in upper abdominal ultrasonography. Merritt[16] studied the portal vein in 100 randomly selected examinations and identified it in 97% of the cases as it entered the porta hepatis, in 83% as it crossed the inferior vena cava, and in 83% at its origin. In addition, he documented the important ultrasonographic findings of portal vein thrombosis in three patients in whom angiographic examination subsequently confirmed this process. Raskin et al.[17] diagnosed portal and hepatic vein thrombosis by ultrasonographic examination. Webb et al.[18] documented the reliability of ultrasonography in assessing the patency of the portal vein in 20 patients with angiographic evidence of extrahepatic vein thrombosis. Employing real-time gray-scale ultrasonography, Weinreb et al.[19] presented a standard chart of normal portal vein measurements in 148 patients. Furthermore, they successfully used "sonographic portography" to screen patients with cystic fibrosis for the onset and progress of portal hypertension. In a more recent communication, Van Gansbeke et al.[20] demonstrated the reliability of real-time ultrasonography in the detection of portal thrombosis. They also pointed out that the detection of multiple serpiginous periportal collaterals with inability to image the normal portal vein is important evidence of portal vein obstruction. These observations may find an application in the sequential study of the patient treated by portal vein ligation. Finally, the more sophisticated Duplex ultrasonography is capable of measuring quantitative flow of the normal portal system and the system with portasystemic shunts. Using this technique, Ackroyd et al.[21] were able to measure portal flow in normal subjects and in patients with portasystemic shunts.

It is evident that ultrasonography provides a versatile, noninvasive, and reliable method for investigating the portal system. Our data suggest that this modality may have an important application for the assessment of patency after portal vein reconstruction. In our first patient it facilitated an early diagnosis of portal vein thrombosis and enabled a serial follow-up while the patient was treated by anticoagulation therapy. In the other two patients, the portal vein could be identified and the patency of the repair could be documented. In patients treated by ligation of the portal vein, sequential ultrasonography may be of value in monitoring the development of collateral channels as well as portal hypertension, should it occur. Wider application of this noninvasive modality will, perhaps, enhance our understanding of the sequelae of venorrhaphy and ligation of the injured portal vein.

Survival after Trauma in Geriatric Patients

ERIC J. DEMARIA, M.D., PARDON R. KENNEY, M.D., MICHAEL A. MERRIAM, M.D.,
LISA A. CASANOVA, M.D., and DONALD S. GANN, M.D.

In contrast to other studies, a recent report from the authors' institution has shown a good prognosis for functional recovery in geriatric patients that survive trauma. Because most survivors regained their pre-injury function, the authors examined factors related to nonsurvival in this population of 82 consecutive blunt trauma victims older than the age of 65. Seventeen patients died (21%). Compared with survivors, nonsurvivors were older, had more severe overall injury, and had more severe head and neck trauma but did not differ in severity of trauma that did not involve the head and neck, number of body regions injured, mechanism of injury, or incidence of surgery after injury. Nonsurvivors experienced more frequent complications (82% *vs.* 33%, $p < 0.05$), including a higher incidence of cardiac complications (53% *vs.* 15%, $p < 0.05$) and ventilator dependence for 5 or more days (41% *vs.* 14%, $p < 0.05$). Mortality rates were increased in patients who were 80 years of age or older compared with those ages 65–79 (46% *vs.* 10%, $p < 0.01$), despite injury of similar severity. More frequent complications may contribute to an increased mortality rate in the older group, including an increased incidence of prolonged mechanical ventilation (36% *vs.* 12%, $p < 0.025$), cardiac complications (54% *vs.* 10%, $p < 0.01$), and pneumonia (36% *vs.* 16%, $p < 0.06$). Severely injured patients (Injury Severity Score [ISS] ≥ 25) older than 80 years old had a mortality rate of 80%, and the survivors required permanent nursing home care. Discriminant analysis yielded a reliable method of differentiating survivors from nonsurvivors based on age, ISS, and the presence of cardiac and septic complications. To assess the accuracy of the discriminant function, 61 consecutive patients admitted during 1985 were reviewed prospectively. Discriminant scoring predicted outcome correctly in 92% of these patients. A Geriatric Trauma Survival Score (GTSS) based on the discriminant function was calculated for each of the 143 patients studied and was highly correlated with mortality rate ($r = 0.99$, $p < 0.001$). Thus, the GTSS may serve as a valuable tool for evaluating death in geriatric trauma victims. Furthermore, because complications are potentially avoidable and contribute to increased mortality rates, routine aggressive care for geriatric patients with moderate overall injury is indicated.

From the Department of Surgery, Brown University and Rhode Island Hospital, Providence, Rhode Island

ALTHOUGH the elderly population is growing, few studies have examined the outcome of seriously injured elderly patients. Oreskovich et al.[1] suggested that aggressive care of these patients is futile because of a high mortality rate and the finding that survivors rarely regained their pre-injury function. In contrast, we have recently reported a favorable prognosis for functional recovery in 63 consecutive geriatric patients with trauma.[2] Clearly, further studies to define factors related to mortality rate and outcome are required before aggressive care of any geriatric patient with trauma is withheld. Because most of our survivors were able to return home, we have now studied factors related to nonsurvival in this population. Our goals were as follows: (1) to determine any factors that predicted that resuscitation would be futile; and (2) to assess the impact of potentially avoidable complications on mortality rate.

Methods

We reviewed the records of 82 consecutive patients older than age 65 admitted to the Rhode Island Hospital Trauma Service from September 1982 to December 1984. All patients with thermal, penetrating, or isolated orthopedic injury were excluded. An Injury Severity Score (ISS)[3,4] based on the 1985 revision of the Abbreviated Injury Scale (AIS)[5] was calculated for each patient and confirmed by the analysis of a second, blinded observer. The AIS values for head and neck, thorax, abdo-

men, and extremity trauma were also recorded. The age, sex, mechanism of injury, number of body regions injured, presence of pre-injury cardiopulmonary disease, and length of hospital stay were noted for each patient. Those patients who required surgery after injury were grouped into emergent (less than 24 hours after admission) and delayed surgery groups. The type of surgery required was also recorded.

Cardiac, pulmonary, and septic complications and the number of complications during each patient's hospitalization were noted. Cardiac complications included myocardial infarction, arrhythmia with hypotension, and unstable or recent-onset angina. Pulmonary complications included pneumonia and ventilator dependence for 5 days or longer. The diagnosis of sepsis required blood cultures with positive results in the presence of a characteristic hemodynamic profile.

Data are presented as mean plus or minus standard error. Characteristics of survivors and nonsurvivors were compared by the chi square test and analysis of variance with comparison of individual means by use of Newman-Keuls testing.[6] A multivariate discriminant analysis using SPSS-X[7] (Brown University Computer, IBM VM/CMS 3081D) was used to identify variables that differentiated survivors from nonsurvivors. A stepwise model was used wherein variables were sequentially selected to enter the analysis. The order of selection was such that the residual variance in the population was minimized with the addition of each variable.[8]

In order to assess the predictive value of the discriminant analysis, we tested the ability of the function to predict outcome in a second population of geriatric trauma victims (test population). We prospectively reviewed 61 additional patients admitted from January through December 1985. The discriminant score calculated for each individual test case was used to assign it to the group (survivor or nonsurvivor) for which its probability of membership was greatest. The percentage of patients classified correctly (*i.e.*, predicted and actual outcome identical) was taken as an estimate of the predictive value of the discriminant function.

The characteristics of the population are provided in Table 1. The population had a mean age of 75.8 ± 0.8 years and a moderate overall level of injury with a mean ISS of 17.9 ± 1.2. All patients had blunt injury secondary to falls (48%), motor vehicle accidents (33%), pedestrian–motor vehicle accidents (16%), or assault (4%). Men outnumbered women nearly 2:1. Twenty-three patients (28%) had an ISS of 25 or more. The head and neck region was most frequently injured (64%), and 49 patients (60%) had multiple body regions injured. Most patients had pre-injury cardiac or pulmonary disease (72%). Half of the patients required surgery after trauma, and surgery was emergent in two-thirds of these cases. The types of operations performed are listed in Table 2.

Complications developed in 35 patients (43%), with a mean number of complications per patient of 0.8 ± 0.1. Cardiac complications (23%) and pneumonia (22%) were most frequent. Sixteen patients (20%) required assisted mechanical ventilation for 5 days or longer. Systemic sepsis occurred in only five patients (6%). More than one complication developed in 18 patients (22%) which included 11 with prolonged ventilatory assistance and pneumonia.

Seventeen patients died during hospitalization, yielding a mortality rate of 21%. Table 3 depicts the characteristics of survivors and nonsurvivors. Nonsurvivors were older (81.7 ± 2.1 *vs.* 74.3 ± 0.8 years, $p < 0.001$), had more severe overall injury (ISS: 26.7 ± 2.8 *vs.* 15.8 ± 1.1, $p < 0.001$), and had more severe head and neck

trauma (AIS: 3.5 ± 0.5 *vs.* 2.1 ± 0.2, $p < 0.025$). There was no difference in AIS values between survivors and nonsurvivors for trauma that did not involve the head and neck, number of body regions injured, mechanism of injury, incidence of surgery (emergent or delayed), or length of hospital stay.

TABLE 4. *Comparison of Patients Ages 65 to 79 with Patients 80 Years Old and Older*

	Ages 66–79 (N = 58)	Age ≥ 80 (N = 24)	
Sex	15 M/9 F	39 M/19 F	NS*
Mechanism of injury	30 falls/25 MVAs/3 assaults	9 falls/15 MVAs	NS*

Ventilator ≥ 5 days	7 (12%)	9 (36%)	†
Sepsis	3 (5%)	2 (8%)	†
Mortality rate	10%	46%	‡

* NS = not significant, $p > 0.05$.

† $p < 0.05$.

‡ $p < 0.01$.

BRI = body regions injured; M = male; F = female; MVA = motor vehicle accidents.

Complications were more frequent in nonsurvivors. Complications developed in 82% of nonsurvivors compared with 33% of the survivors ($p < 0.05$). Nonsurvivors had a higher incidence of cardiac complications (53% *vs.* 15%, $p < 0.05$) and ventilator dependence for 5 or more days (41% *vs.* 14%, $p < 0.05$). Four of 11 patients (36%) with the combination of pneumonia and assisted ventilation for 5 or more days died.

If mortality rate after trauma in geriatric patients is indeed primarily related to advanced age, patients older than 80 years may be at increased risk. Twenty-four patients (29%) were 80 years or older. The mortality rate in this age group was more than fourfold greater than for patients ages 65 to 79 (46% *vs.* 10%, $p < 0.01$, see Table 4). There was no difference in number of body regions injured, ISSs, AIS values for any body region, or length of hospital stay between these two age groups. However, there were more complications in patients who were 80 years and older (1.8 ± 0.3 *vs.* 0.6 ± 0.1, $p < 0.001$). In the older group prolonged mechanical ventilation (36% *vs.* 12%, $p < 0.025$) and cardiac complications (54% *vs.* 10%, $p < 0.01$) were more frequent and there was a trend toward a higher incidence of pneumonia (36% *vs.* 16%, $p < 0.06$). Thus, advanced age or more frequent complications may contribute to an increased mortality rate in patients older than 80 years old, although injury severity was not greater. However, severe overall injury in the older group appears to denote a particularly poor prognosis. Of 10 patients older than age 80 with ISSs greater than or equal to 25, eight died and the two survivors required permanent nursing home care.

Discriminant Analysis

Discriminant analysis revealed that outcome was related to four variables: ISS, age, and the presence of cardiac (CARDIAC) or septic (SEPSIS) complications (0 = no complication, 1 = complication) *via* the following discriminant function:

$$\text{Discriminant score} = (0.086)\text{AGE}$$

$$+ (0.064)\text{ISS} + (1.49)\text{SEPSIS} + (1.06)\text{CARDIAC} - 7.96$$

The canonic correlation coefficient was 0.63 ($p < 0.001$). Survivors had a mean discriminant score of −0.4, whereas nonsurvivors had a mean score of 1.55. Classification of each individual case based on its probability of group membership, as if survival were unknown, revealed that 85% of the cases were correctly classified by the discriminant function (Table 5). This percentage was not increased significantly if other variables were added to the discriminant analysis.

Test Population

To test the accuracy of the discriminant function, we prospectively reviewed the cases of 61 additional consecutive blunt trauma victims older than the age of 65

TABLE 5. *Analysis of the Predictive Value of the Discriminant Function: Predicted Outcome (Based on the Discriminant) was Compared with the Actual Outcome for the 82 Patients in the Original Population and for the 61 Patients in the Test Population**

	Predicted Survival	Predicted Death
Original patients (N = 82)		
Actual		
Survival	54	11
Death	1	16
Test population (N = 61)		
Actual		
Survival	50	1
Death	4	6

* Overall, 85% of the original patients were classified correctly by the discriminant function. In the test population, 92% were correctly classified.

admitted to our Trauma Service during the 1985 calender year. The characteristics of the test population are listed in Table 6. The mean age and incidence of cardiac complications and sepsis in the test population were similar to those of the original population. The mean ISS and mortality rate were somewhat lower, however. Despite these differences in the test population's characteristics, the discriminant function predicted outcome correctly in 92% of the test cases (Table 5).

Geriatric Trauma Survival Score and Mortality

Most errors in classification of individual cases as survivors or nonsurvivors occurred in patients with discriminant scores in the middle range (*i.e.*, discriminant score between 0 and 1.5). The mortality rate for patients scoring in this range is significantly less than 100% and greater than zero (Fig. 1). Because the mortality rate associated with each discriminant value in the test population was strikingly similar to the respective mortality rate in the original population (Fig. 1), we combined the two groups in an attempt to derive a clinically useful formula for assessing the mortality rate of geriatric patients with trauma admitted to our institution. First, we performed an algebraic transformation of the original discriminant function to obtain a Geriatric Trauma Survival Score (GTSS):

$$\text{GTSS} = 0.9(\text{AGE} - 65) + 0.6(\text{ISS}) + 14.9(\text{SEPSIS}) + 10.6(\text{CARDIAC})$$

As in the discriminant formula, SEPSIS and CARDIAC refer to the presence or absence (score = 1 or 0, respectively) of septic and cardiac complications. The GTSS differs from the original discriminant function in that all values are greater than zero. The range of possible GTSSs includes a minimum score near zero. Although the theoretic maximum GTSS is greater than 100, this would require extreme age and an ISS near the maximum possible score of 75. The calculated GTSSs in the 143 patients studied ranged from 3.9 to 58.4, with a mean GTSS of 21.7 ± 12.4 (standard deviation [SD]). The mean GTSS for survivors was 18 ± 9.5 (SD) and for nonsurvivors 37.8 ± 2 (SD).

TABLE 6. *Characteristics of the 61 Prospectively Reviewed Geriatric Patients with Trauma Constituting the Test Population*

Age (years)	76.3 ± 0.9
Injury Severity Score	10.0 ± 0.9
Complications	
Cardiac	15%
Sepsis	3.3%
Mortality rate	16%

Having derived a GTSS that is easier to calculate than the original discriminant function, we examined the mortality rate associated with values of the GTSS. The GTSS values for all patients were ranked in ascending order and arbitrarily divided into 15 roughly equal subgroups with consecutive scores. The mean GTSS and mortality rate for each subgroup were determined and plotted (Fig. 2). An iterative least-square logistic curve fitting model[9,10] was used to determine the best curve relating GTSS and mortality rate. In order to provide an accurate assessment of the curve, we assumed that patients with a near-maximum GTSS of 100 had a mortality rate of 100%. Thus, the asymptote of the curve converged on a 100% mortality rate for high GTSSs. This assumption appears reasonable, because a GTSS of 100 requires a near-maximum ISS and the mortality rate in younger patients with injury of this severity approaches 100%. The best fit relationship was:

$$\text{Mortality (\%)} = 100 - 100/(1 + [\text{GTSS}/32.8]^{5.2})$$

The correlation coefficient for the curve fit by the above formula was 0.99 ($p < 0.001$). The GTSS associated with

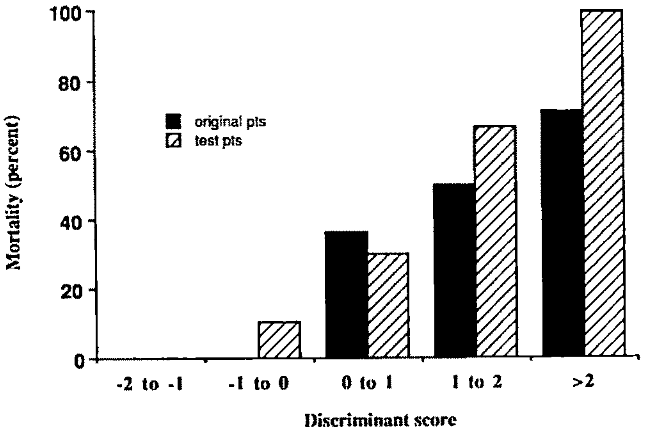

FIG. 1. Mortality rate associated with increasing values of the discriminant score. The mortality rates of patients in the original and test populations for a given discriminant score were similar. Most errors in classification of patients as survivors or nonsurvivors were in cases with discriminant scores in the middle range.

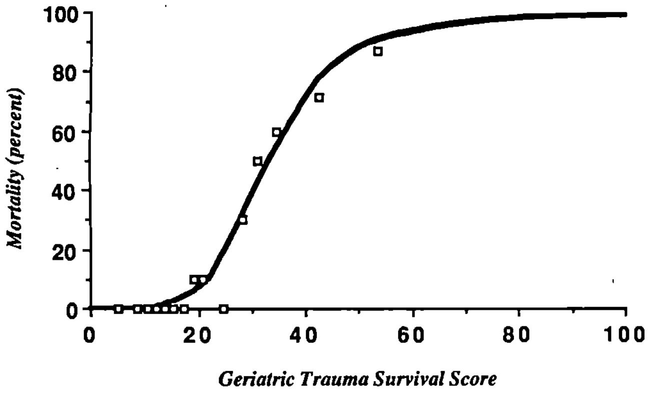

FIG. 2. Mortality rate associated with increasing values of the GTSS in the total population of 143 patients. There was a strong correlation between GTSS and mortality rate ($r = 0.99$, $p < 0.001$) with the use of the least-squares logistic analysis. A GTSS of 32.8 led to a predicted mortality rate of 50%, and the mortality rate of patients with GTSSs greater than or equal to 50 was 89%.

a 50% mortality rate was 32.8, with a 20% mortality rate was 25.5, and with an 80% mortality rate was 43.7. The curve predicts a 95% mortality rate for patients with a GTSS of 62.8.

Discussion

Elderly persons are seriously injured less frequently than any other segment of the population.[11] However, the mortality rate of elderly patients after trauma is higher than for any other age group.[11,12] Despite their lower injury rate, the elderly patients consume nearly one-third of all health care resources expended on trauma care.[13] Furthermore, the geriatric segment of the population is growing rapidly. The elderly population is projected to increase by 18% over the next 10 years[14] and by more than 50% within 50 years.[15] Clearly, trauma in elderly patients will become an increasingly important health care issue in the future.

Few studies have examined why the mortality rate is increased in geriatric patients after trauma.[1,16] Furthermore, comparison of such studies is potentially difficult. Many injured elderly persons have relatively minor trauma (*i.e.*, hip fractures resulting from falls), and high morbidity and mortality rates have been reported in this situation, presumably as a result of severe intrinsic disease.[17,18] Including these debilitated patients in a study of trauma would inevitably bias the outcome. Because we were primarily interested in previously healthy, independent patients with major trauma,[1,16] we defined our population carefully. We included only patients admitted to the trauma service and excluded those with isolated orthopedic injuries. Because nearly all of our patients were living independently before injury,[2] these criteria probably excluded most debilitated patients. Thus, we feel the study population is representative of previously independent elderly persons admitted to most trauma centers.

The mortality rate in our patients was high despite moderately severe injuries. In one of the few previous studies that has examined factors related to mortality rate in geriatric patients, Oreskovich et al.[1] in Seattle reported that nonsurvivors had an increased frequency of head trauma and thermal injury. However, they found no difference in age or injury severity as measured by ISS between patients that survived and those that died. In contrast, our data suggest that both of these factors contribute to mortality rate. The reasons underlying these conflicting results are unclear. A possible explanation may be found in the revisions of the ISS since its introduction in 1976. We used the 1985 revision of the ISS[5] that includes physiologic modifications added after the original version used by Oreskovich et al.[1] Thus, the updated ISS may be more useful than previous versions in predicting mortality rate.

In the Seattle study,[1] most nonsurvivors were characterized by hypotension upon arrival, prehospital intubation, prolonged mechanical ventilation, and pulmonary sepsis. However, this nonsurvivor profile is difficult to interpret, because the mortality rate associated with each factor was not reported. For example, although all nonsurvivors required prolonged ventilatory assistance, the overall mortality rate of patients in whom this complication developed was not reported. In our series, 44% of patients requiring prolonged ventilatory assistance died and six of nine that survived eventually returned home after hospital discharge.[2] Clearly, the need for prolonged ventilatory assistance is not an indication for withdrawing support.

Mortality rate in geriatric patients with trauma is difficult to predict based solely on the ISS.[12] Oreskovich et al.[1] found no difference in ISSs between survivors and nonsurvivors. Although our nonsurvivors had a higher ISS than survivors and ISS was correlated with outcome, the ISS alone was a poor predictor of survival rate. For this reason, we used a multivariate analysis to determine factors related to mortality rate. Discriminant analysis determined that survival rate was primarily related to age, ISS, and the presence of cardiac or septic complications in the original population, and the importance of these factors was confirmed in 61 additional prospectively reviewed patients. Algebraic transformation of the discriminant function yielded a Geriatric Trauma Survival Score, or GTSS, that was easier to calculate than the original equation.

Although the GTSS was strongly related to mortality rate, its clinical utility is difficult to determine. The GTSS appears to be a good predictor of mortality rate in geriatric patients at our institution, but its predictive value for other institutions has not been tested. Clearly, the GTSS should not be used to predict the mortality rate of geriatric trauma victims or the futility of resuscitation because the number of patients with high GTSS values in our study was small. Furthermore, the GTSS is unlikely to be helpful in determining whether or not resuscitation of an elderly patient in the emergency room should be continued, because complications, which are important contributors to the GTSS, are often not early events. In this study we have not examined prehospital variables (*i.e.*, prehospitalization endotracheal intubation, hypotension on arrival, *etc.*): doing so may have increased the predictive value of the GTSS.

The futility of geriatric trauma care is not supported by our data. Although the small group of patients with GTSSs over 50 had a high mortality rate, it is clear that further study is required before aggressive care of these patients is deemed hopeless. At the present time, the GTSS is likely to be most useful for trauma centers to evaluate their own experience with geriatric patients and for comparing the results of different institutions. The GTSS may also be useful for evaluating the effect of changes in treatment protocol at an individual institution. For example, routine invasive cardiac monitoring for patients with trauma who are older than 80 years old may decrease the mortality rate associated with cardiac complications and shift the curve relating GTSS to mortality rate to the right.

The data demonstrate the important role of complications in deaths of geriatric trauma victims. Cardiac complications in particular may reflect the severity of underlying disease, and many authors have suggested that the mortality rate is difficult to predict in this population because of intrinsic disease that may be clinically silent before injury.[1,12] Interestingly, the presence of previously diagnosed cardiopulmonary disease was not related to mortality rate. Thus, the lack of significant medical history should not be used as a criterion for intensive care unit admission and invasive monitoring in patients with moderate overall injury. Notably, of the factors related to survival determined by discriminant analysis, only the complications might be avoided with more aggressive care. Routine aggressive treatment of geriatric trauma victims, including intensive care unit admission, early invasive cardiac monitoring, and aggressive pulmonary therapy, might prevent complications in these patients and decrease mortality rates. Thus, our data indicate that routine aggressive care for elderly patients with moderate overall injury is appropriate, particularly because the survivors had a good prognosis for functional recovery.[2]

In summary, our data suggest that geriatric patients with trauma who are older than 80 years old, have severe overall injury (ISS $\geq$ 25), or have severe head and neck trauma have an increased mortality rate. Nearly half of the patients older than the age of 80 died after trauma, with no increase in injury severity in this group. The mortality rate is also increased in patients with complications, particularly cardiac complications and ventilator dependence. Cardiac and pulmonary complications were more frequent in patients who were older than 80 and this may contribute to the increased mortality rate in this group. Patients older than the age of 80 who had severe overall injury and patients with GTSSs greater than or equal to 50 had an extremely poor prognosis. Aggressive care of patients in this group may be futile, but further study is required to confirm this result. Because complications are potentially avoidable and contribute to increased mortality rates, routine aggressive care for geriatric patients with moderate overall injury is indicated.

Adrenergic Control of Adipocyte Lipolysis in Trauma and Sepsis

R. ARMOUR FORSE, M.D., PH.D.,* RUDOLPH LEIBEL, M.D.,† JEFFREY ASKANAZI, M.D.,‡ JULES HIRSCH, M.D.,§ and JOHN M. KINNEY, M.D.‖

Adipocyte lipolysis and its adrenergic control were studied *in vitro* from normal patients and those with trauma and sepsis. The adrenergic receptors were studied in terms of their responsiveness, a measure of the postreceptor mechanism, and their sensitivity, a measure of the receptor number or affinity. With early trauma, beta-adrenergic responsiveness and receptor number were significantly decreased. This is desensitization of the beta-receptors with down regulation and indicates increased *in vivo* lipolysis in early injury. After 4 days these changes had returned to normal. Early sepsis resulted in a significant increase in beta- and alpha-receptor responsiveness with beta-upregulation. This indicated hypersensitivity of the adipocyte adrenergic receptors and suggests the presence of an *in vivo* block of the adrenergic receptors in early sepsis. This would decrease adipocyte lipolysis. After 4 days there was a decrease in beta-receptor responsiveness in the patients with sepsis, indicating that the adrenergic receptor block was no longer present and adipocyte adrenergic stimulated lipolysis was increased.

From the Department of Surgery, College of Physicians and Surgeons of Columbia University, and The Laboratory of Human Behavior and Metabolism, The Rockefeller University, New York, New York

THE INJURED OR SEPTIC PATIENT has an elevated metabolic rate.[1-3] The fuel for this increased energy demand is a mixture of protein, fat, and carbohydrate; however, present data suggest that lipid calories provide the major calorie source.[4,5] These calories are stored as triglycerides in the adipocyte and are mobilized at the time of increased demand. Although this appears straightforward for the patient with trauma, alterations in lipid metabolism have previously been demonstrated in sepsis. Hepatic use of fat is impaired in sepsis and may contribute to the development of the fatty infiltration of the liver.[6] In patients with sepsis, lipid use and oxidation may be decreased, and this is possibly related to decreased clearance by the liver. There has been documentation of increased levels of plasma free fatty acids (FFAs) and plasma triglyceride levels in patients with severe sepsis.[7] Other studies have reported decreased plasma FFA levels in sepsis.[6,9] Previous studies from our laboratories using a ^{14}C-palmitate infusion and indirect calorimetry have documented an increase in total body lipid clearance with an increase in lipid oxidation in patients with both trauma and sepsis.[4,5] Subsequent studies on lipoprotein lipase (LPL) activity in the patient with trauma and sepsis showed a significant difference *in vitro.* The LPL activity was decreased in the patient with sepsis and increased in the injured patient. The decreased activity of both the adipose and muscle LPL in the patient with sepsis suggests a defect in clearance of the lipoproteins, particularly in those patients who were hypertriglyceridemic. In addition, the study showed that the direct relationship of insulin to LPL activity was lost in the patient with sepsis.[8] Thus, fat metabolism is still unclear in the injured patient, particularly in the patient with sepsis.

Lipolysis of the stored triglycerides and the control of adipocyte lipolysis is important in mobilization of lipid in the injured patient. Lipolysis in the adipocyte is carried out by the enzyme hormone sensitive lipase (HSL).[10] This enzyme complex is controlled by a number of circulating hormones, including the catechol-

amines. Presently it appears that HSL is stimulated by beta-1-adrenergic receptors and inhibited by alpha-2-receptors in the human adipocyte. The role of adipocyte lipolysis and its adrenergic control in trauma and sepsis has not been documented. It would appear that if endogenous substrate such as lipid is an important fuel during injury, then this system would play an important role. In this article we examine adipocyte lipolysis and its adrenergic control in patients with major trauma and sepsis.

Materials and Methods

Patients

Patients who were to have elective hip surgery were used as controls. Their adipose tissue biopsies were performed in the operating room after administration of general sodium pentathal anaesthesia but before the operation was started. Patients with trauma had multiple injuries requiring major surgery (Table 1). The adipose tissue biopsy specimens of these patients were taken in the surgical intensive care unit (SICU), within 24 hours after the patient had had surgery and with the patients not in shock. The patients with trauma had a second biopsy 4 days after their trauma. The patients with sepsis were those admitted to the SICU with a clinical diagnosis of sepsis (Table 1). Their adipose tissue biopsy specimens were taken 24 hours after the patients were admitted to the SICU, having had volume resuscitation and with the patients not in shock. The patients with sepsis also had biopsies performed after 4 days. None of these patients was receiving a major exogenous caloric source during the biopsies.

Biopsy

A biopsy was done of adipose tissue from the subcutaneous tissue of the anterior abdominal wall by a needle aspirate technique.[11] The tissue was transferred to a thermos containing 0.9 g/dL saline (37 C) and transported to the laboratory.

Preincubation

In the laboratory the tissue was dissected free from other fibrous tissue and cut into multiple small pieces. After rinsing with normal saline 0.9% at 37 C, the tissue was preincubated at 37 C for 30 minutes in 20 mL of preincubation media. The preincubation media contained a solution of 8 g/dL dialyzed bovine fatty acid–poor albumin mixed with an equal volume of double-strength Krebs-Henseleit original Ringer's bicarbonate buffer.[12] Glucose was added to give a final concentration of 4.16 mM. The adipose tissue was washed again over a nylon filter with warm 0.9 g/dL saline.

Incubation

Aliquots (20 mg) were placed in separate 15-mL polypropylene vials containing 2 mL of the isotopic incubation media and the various pharmacologic agents. To prepare the incubation media, labeled palmitic (9,10-^{3}H[N]) (NET-043, New England Nuclear, Boston, MA) of specific activity of 17 Ci/mmol was repurified in an aqueous ethanol heptane system. A thin film of approximately 6 Ci/mole was prepared by evaporation of twofold molar excess of ethanolic sodium hydroxide with labeled and unlabeled palmitic acid (Fischer Scientific). An 8 g/dL solution of dialyzed bovine fatty-poor albumin (Fraction V, Sigma Chemicals, St. Louis, MO) at pH 7.4 was added to the film to produce a final palmitate concentration of 1.0 mM. The molar ratio of fatty acid to albumin was approximately 1:1. The final incubation media (pH 7.4) was prepared by mixing equal volumes of the albumin–palmitate solution with double-strength Krebs-Henseleit original Ringer's bicarbonate buffer (gassed with 95% O_2 and 5% CO_2) and glucose to produce glucose, palmitate, and albumin concentrations of 4.16 mM, 0.5 mM, and 4 g/dL, respectively. Sufficient ^{14}C glucose D-(^{14}C[U])-glucose (NEC 042, New England Nuclear) in 0.9 g/dL saline was added to give a glucose-specific activity of approximately 2 Ci/mole. The addition of the labeled glucose increased the final glucose concentration in the media to 5–6 mM. The final media volume in each vial was 2.2 mL, and a gas phase was added to each vial containing 95% oxygen and 5% carbon dioxide. The tissue samples were incubated in triplicate in separate vials for each concentration of either isoproterenol, clonidine, or theophylline. After incubation for 2 hours at 37 C in a shaking bath, the tissue was separated from the incubation media over a nylon filter, washed with distilled water, and then placed in 5 mL of chloroform–methanol 2:1, v:v for extraction of lipids.

Pharmacologic Agents

To stimulate the beta-receptors, L-isoproterenol d-bitartrate salts (Sigma Chemicals) was used. To stimulate the alpha-2-receptors, clonidine hydrochloride (Sigma Chemicals) was used. These reagents were mixed on the day of the study with the use of 0.9 g/dL saline to produce concentrations from 1×10^{-4} to 1×10^{-8} M. Maximal stimulation of the hormone-sensitive lipase at a subreceptor level was achieved by use of theophylline (Sigma Chemicals) at a concentration of 3×10^{-4} M. The theophylline was mixed on the day of the study with the use of a solution of 0.45 g/dL fatty acid dialyzed bovine albumin. Theophylline (3×10^{-4} M) was also added to each concentration of clonidine in order to stimulate lipolysis, which allowed the alpha-2-inhibition of lipolysis to be more obvious.

Tissue Extraction and Chemical Analysis

After incubation, each sample was washed with saline and placed in 5 mL of chloroform–methanol 2:1 (v:v) solution layered with 10 mL of demineralized water at 5 C to extract the triglycerides. The solvent mixture was then layered with 10 mL of demineralized distilled water phase to generate a lower phase of chloroform containing the lipids. The water phase was changed in 24 hours and then removed after an additional 24 hours. The chloroform layer was transferred to small vials, where it was air dried to evaporate the chloroform, leaving the lipid. The samples were warmed on the final day of extraction and resuspended in 0.8 mL of chloroform. A 0.20-mL aliquot was then placed on a silica gel absorbent thin-layer chromatographic sheet (No. 13179 Eastman Kodak, Rochester, NY) and was run in a solvent of diethyl ether–hexane 1:9 (v:v) that clearly separates the triglycerides. The spot on the plate containing the triglycerides was cut out from the plate and placed in a scintillating vial with 10 mL of scintillating fluid (Aquasol, New England Nuclear, Boston, MA). The vials were then counted for ^{3}H and ^{14}C in a liquid scintillating beta counter (Beckman Instruments, Fullerton, CA) with quench correction.

Calculations

The media used for each experiment were counted in the scintillating counter to determine the exact specific activity of palmitate and glucose. The ratio of DPMs ^{14}C to DPMs ^{3}H was determined for the triglyceride spot of each tissue sample. When corrected for the specific activity of the ^{14}C-glucose and the ^{3}H-palmitic acid in the media, this ratio is designated the lipolysis factor. The lipolysis factor ratio is an index of lipolysis. When lipolysis is increased, the ratio is increased and *vise versa.*[12] The tissue stimulated with varying concentrations of isoproterenol (dissolved in 0.9 g/dL saline) provided a response curve for the beta-1-receptors. The tissue stimulated with the varying concentrations of clonidine (dissolved in 0.9 g/dL saline with theophylline) provided a response curve for the alpha-2-receptors. Each of the clonidine concentrations had theophylline added. This stimulated the adipocyte, allowing the inhibitory effect of the clonidine to be more obvious. The theophylline effect was then subtracted from the clonidine results to give a true clonidine effect, which results in a negative value because the clonidine is inhibitory.

The lipolysis factor at maximal beta-1 or alpha-2 stimulation is the responsiveness of the receptor, Vmax, a measure of the postreceptor response. The beta-1- and alpha-2-receptor data are then expressed as a percentage of the Vmax for each pharmacologic concentration to create a dose response curve for each receptor. These curves are then linearized by logit transformation.[13] The slope of the logit transformation of the dose response curve is related to receptor sensitivity. The receptor sensitivity is a reflection of both receptor number and agonist affinity.

Statistics

Triplicate determinations of the lipolysis factor for each pharmacologic effect of the individual tissue samples were averaged. This value was then used from each patient to calculate the mean response for the pharmocalogic effect of the group for normal patients and those with trauma and sepsis. The mean lipolysis factor for the basal, isoproterenol, and clonidine concentrations of the normal patients and those with trauma and sepsis were compared by an analysis of variance.[13] The theophylline values, and the Vmax, and slopes of the response curves of the samples were also compared by analysis of variance.

Results

The data for basal lipolysis are presented in Figure 1. The lipolysis factor for early trauma was 15.3 ± 1.3, which was significantly ($p < 0.05$) reduced 44.6% from the normal value of 27.6 ± 2.7. After 4 days the basal lipolysis factor for the patients with trauma was 19.3 ± 1.3, which was reduced from that of the normal patients but not significantly. In early sepsis the basal lipolysis factor was 55.0 ± 5.7, which was significantly increased ($p < 0.01$) over that of the normal patients by 99.3%. After 4 days the basal lipolysis factor for the patients with sepsis was 17.0 ± 2.9, which was decreased from the normal value of 27.6 ± 2.7 by 38.4%.

The data for the beta-adrenergic receptors for the three patient groups are presented in Table 2. In early trauma the beta-stimulated lipolysis factor is significantly ($p < 0.05$) decreased from the normal values (Fig. 2). After 4 days the curve has shifted toward normal and is not significantly different from the normal values. With early sepsis there was a significant ($p < 0.05$) increase in the beta-stimulated lipolysis factor as compared with normal values (Fig. 3). After 4 days the curve for the patients with sepsis had shifted below the normal curve. The lipolysis factors at isoproterenol concentrations of 1×10^{-5} M, 1×10^{-6} M, and 1×10^{-8} M were significantly ($p < 0.05$) less than those of the normal patients.

The beta-receptor Vmax (receptor responsiveness) for the patients with early trauma was 66.4 ± 3.8, which is statistically ($p < 0.05$) less 17.2% than the normal value of 80.2 ± 6.3 (Table 2) and significantly less 48.7% than the early sepsis value. After 4 days the beta Vmax for the group with trauma was 100.5 ± 9.7, which was not significantly different from the Vmax for the normal patients. With the patients with sepsis, the Vmax for the beta-receptors was 129.5 ± 12.8 in early sepsis, which is significantly ($p < 0.01$) elevated 61.5% above the Vmax of 80.2 ± 6.3 for normal patients (Table 2). After 4 days the beta-receptor Vmax for the patients with sepsis was 41.5 ± 5.2, which was significantly ($p < 0.01$) decreased 48.3% from the normal value.

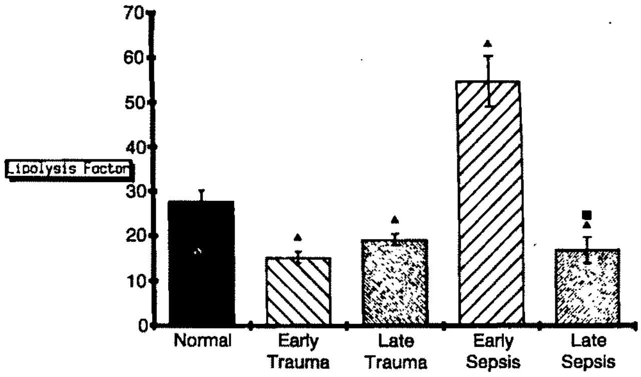

FIG. 1. Histogram of the basal lipolysis for all five groups, including the normal patients and those with early trauma, late trauma, early sepsis, and the late sepsis. The data presented are the lipolysis factors for each group. The ▲ indicates a significant difference ($p < 0.05$) from the normal values by an analysis of variance. The ■ indicates a significant ($p < 0.05$) difference of late from early by analysis of variance.

For the patients with early trauma, the slope of the response curve for the beta-receptors is 0.95 ± 0.03 (Table 2), which was significantly ($p < 0.05$) less than the normal slope of 1.09 ± 0.05. After 4 days the slope of the line was 1.02 ± 0.01, which was not statistically different from that for the normal patients. In early and late sepsis the slope was 1.23 ± 0.03 and 1.27 ± 0.06, respectively. Although both of these are decreased from the normal values, the differences were not significant.

The results for the alpha-receptors are presented in Table 3. In early trauma there was no difference in the decrease in the lipolysis factor with clonidine when compared with the decrease with the normal patients (Fig. 4). After 4 days the patients with late trauma had an increased alpha inhibitory effect as compared with normal patients. This was significant ($p < 0.05$) at a clonidine concentration of 1×10^{-5} M. With early sepsis there was an increase in the lipolysis factor with clonidine that was significant ($p < 0.05$) at concentrations of 1×10^{-7} and 1×10^{-5} (Fig. 5). These data support an inhibition of the alpha inhibitory effect in early sepsis. After 4 days the alpha inhibitory effect of the patients with sepsis was less than that of the normal patients, being significant ($p < 0.05$) at concentrations of 1×10^{-5}

TABLE 2. *Beta-adrenergic Receptor Data for Normal Patients and Both Groups of Patients with Sepsis and Trauma*

	Normal	Early Sepsis	Late Sepsis	Early Trauma	Late Trauma

* Significantly different ($p < 0.05$) from normal by analysis of variance.

† Late significantly different ($p < 0.05$) from early by analysis of variance.

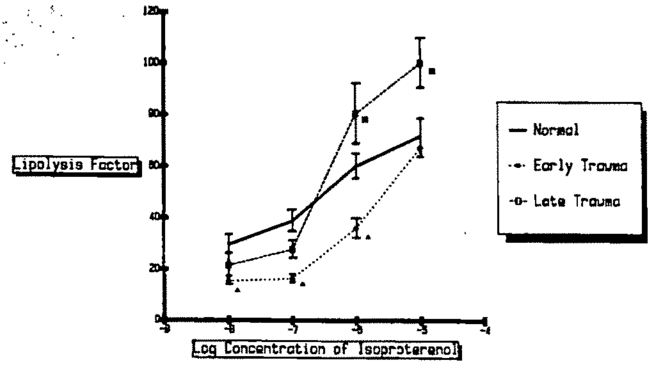

FIG. 2. Data for the beta-receptors. The lipolysis factor is plotted against the log concentration of the beta-agonist isoproterenol. The data are for the normal patients as well as for those with early and late trauma. The ▲ indicates a significant difference ($p < 0.05$) from the normal values by an analysis of variance. The ■ indicates a significant ($p < 0.05$) difference of late from early by analysis of variance.

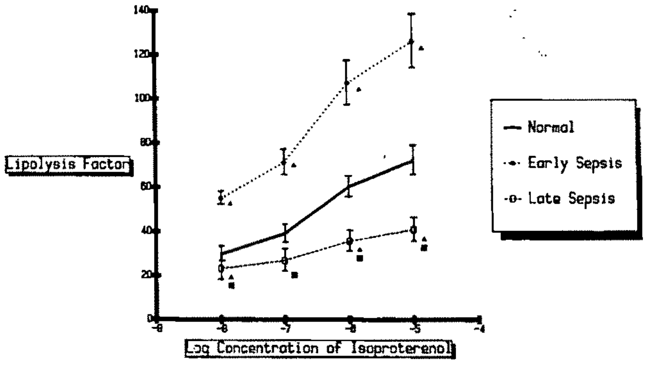

FIG. 3. Data for the beta-receptors. The lipolysis factor is plotted against the log concentration of the beta-agonist isoproterenol. The data are for the normal patients as well as for those with early and late sepsis. The ▲ indicates a significant difference ($p < 0.05$) from the normal values by an analysis of variance. The ■ indicates a significant ($p < 0.05$) difference of late from early by analysis of variance.

and 1×10^{-6} M. This indicates a increased alpha effect with late sepsis.

The maximal alpha effect or alpha responsiveness was achieved with a clonidine concentration of 1×10^{-5} M. In the patients with trauma the alpha Vmax for early trauma was −27.5 ± 7.4, which was similar to the −31.2 ± 3.2 for the normal patients (Table 3). In the group with late trauma the alpha Vmax had increased to −54.0 ± 7.2, which was significantly ($p < 0.05$) greater than the normal alpha Vmax. Patients with early sepsis had an alpha Vmax of −45.1 ± 7.2, which was significantly ($p < 0.05$) greater then the normal value. After 4 days their Vmax had decreased to a value of −19.9 ± 4.3, which was a significant ($p < 0.05$) decrease as compared with the normal Vmax and the Vmax of the group with early sepsis.

With both early and late trauma, the slopes of the response curve for the alpha-receptors were 0.82 + 0.02 and 0.80 + 0.11, respectively, and were not significantly different from the normal slope of 0.73 + 0.04 (Table 3). With early sepsis the slope of the alpha response curve was not significantly different from that of the normal patients. After 4 days the slope for the patients with sepsis was 0.78 + 0.11, similar to that of the normal patients.

The subreceptor stimulation was carried out by use of theophylline. These data are presented in Table 3. The theophylline-stimulated lipolysis factor for the patients with early and late trauma were not significantly different than the normal value. Those patients who had early sepsis had a theophylline-stimulated lipolysis factor of 110.4 + 10.7, which was significantly ($p < 0.01$) greater than the normal value. In late sepsis the theophylline stimulation resulted in a lipolysis factor of 35.4 + 5.8, which was less than that of the normal patients and significantly ($p < 0.05$) less than the early sepsis value.

Discussion

There are differences in fat metabolism between patients with normal trauma and those with sepsis. These data have principally come from studies on muscle metabolism, liver metabolism, and the alterations in the serum levels of FFAs, triglycerides, and lipoproteins.[4–6] The results of this study again indicate that there are major differences in fat metabolism between trauma

† Late significantly different ($p < 0.05$) from early by analysis of variance.

and sepsis. In early trauma there is a decrease in *in vitro* basal lipolysis, beta stimulation of lipolysis, and beta-receptor responsiveness. These findings are explained by an increased beta-adrenergic stimulation *in vivo* and stimulation of lipolysis. The decreased beta stimulation of the adipocytes of patients with trauma is the well-described phenomenon of desensitization. The term desensitization is used to describe a state of diminished hormonal response that follows after exposure to catecholamines.[15,16] This state has been previously reproduced with the adrenergic receptors of human adipocytes. The results of that study indicated that the desensitization from catecholamine exposure occurred with the beta-receptors but not with the alpha-receptors.[16] The results of our study are in complete agreement with these previous findings. A similar situation has been described in patients with pheochromocytoma where there is resistance of the adipose tissue to stimulation by catecholamines *in vitro*.[14,16] One of the most common mechanisms for desensitization is a decrease in receptor number, which is referred to as "down regulation."[14,15,17] Our data suggest that desensitization in early trauma results in part from down regulation of the beta-receptor as there was a significant decrease in the receptor sensitivity or number. Again, desensitization with down regulation is most commonly caused by prolonged exposure of the receptor to catecholamines. Another possible mechanism for beta-receptor desensitization with down regulation is alteration in the receptor affinity. This theory has received support from recent studies demonstrating that there is phosphorylation of the beta-receptor after prolonged catecholamine exposure, resulting in alteration of the receptor affinity.[14,19]

The receptor data from patients with trauma are consistent with down regulation as a result of the 24-hour catecholamine exposure before the biopsy. Our data further support the relationship of the beta-receptor desensitization and down regulation to catecholamine exposure in that after 4 days the adipocytes of the patients with trauma were similar to those of the normal patients. The plasma level of catecholamines has returned to normal by the 4th day after major surgery,[18] a stress similar in magnitude to that of our patients with trauma.

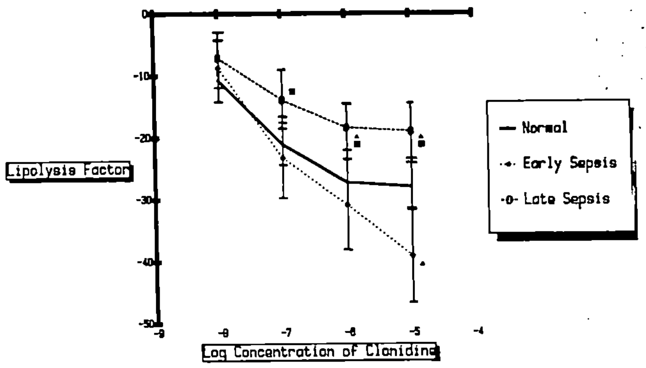

FIG. 4. Data for the alpha-receptors. The lipolysis factor is plotted against the log concentration of the alpha-agonist clonidine. The lipolysis factor is recorded in the negative as the alpha-receptor decreases lipolysis. The data are for the normal patients as well as for the patients with early and late trauma. The ▲ indicates a significant difference ($p < 0.05$) from the normal values by an analysis of variance. The ■ indicates a significant ($p < 0.05$) difference of late from early by analysis of variance.

The alpha-receptor data in the traumatized patient are interesting. With early trauma there is essentially no change from the normal alpha-receptors; however, after 4 days the alpha-receptors have an increased activity with increased responsiveness. These alpha-receptor findings in late trauma are similar to those of alpha-receptors that have not been stimulated, such as with denervation hypersensitivity. In these situations there is an greater response after time. This has been demonstrated in studies of the heart, where, when the catecholamine level has been decreased for a prolonged time, there was a greater response to subsequent catecholamine exposure.[20,21] These previous studies suggested that this hypersensitivity resulted from an increase in the number of receptors, or "up regulation" of the receptors. The alpha-receptor data in the patients with trauma had alpha-hypersensitization but without up regulation. It would appear that there was a period of time in which the alpha-receptors were not stimulated, which accounts for this receptor hypersensitivity. At present there are insufficient data on the alpha-receptors, and particularly with the human adipocyte, to completely explain this phenomenon.

In general, the adipocyte of the patient with trauma supports other data indicating increased adrenergic-stimulated lipolysis during early injury (Table 4). After 4

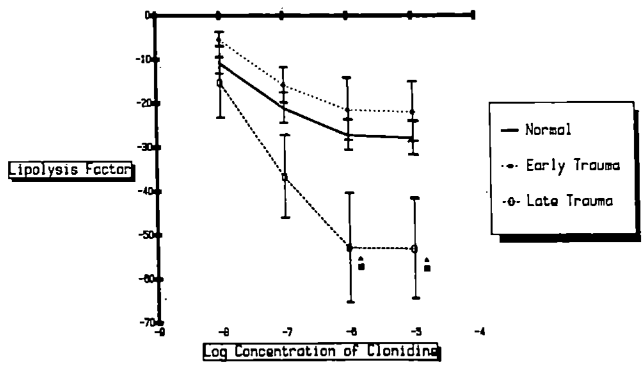

FIG. 5. Data for the alpha-receptors. The lipolysis factor is plotted against the log concentration of the alpha-agonist clonidine. The lipolysis factor is recorded in the negative as the alpha receptor decreases lipolysis. The data are for the normal patients as well as for the patients with early and late sepsis. The ▲ indicates a significant difference ($p < 0.05$) from the normal values by an analysis of variance. The ■ indicates a significant ($p < 0.05$) difference of late from early by analysis of variance.

TABLE 4. *Summary of Receptor Results*

Patients	Beta-receptor State *In Vitro*	Interpretation *In vivo*	Effect on Lipolysis	Alpha-receptor State *In Vitro*	Interpretation *In Vivo*	Effect on Lipolysis
Early trauma	Desensitization with down regulation	Increased stimulation	Increased lipolysis	No change	Normal situation	No change
Late trauma	Normal response	Normal situation	No change	Hypersensitization	Decreased stimulation	Increased lipolysis
Early sepsis	Hypersensitization with up regulation	Decreased stimulation (inhibited)	Decreased lipolysis	Hypersensitization	Decreased stimulation (inhibited)	Increased lipolysis
Late sepsis	Desensitization with up regulation	Increased stimulation	Increased lipolysis	Desensitization	Increased stimulation	Decreased lipolysis

days the adipocyte data indicate a reduction in the lipolysis that corresponds to the turning point of these patients toward the convalescence period.

In the patients with sepsis the adipocytes react very differently. With early sepsis there was an increase in basal lipolysis, beta stimulation, beta responsiveness, and beta sensitivity. These data indicate that the beta-receptors have developed hypersensitivity. This finding would suggest that the beta-adrenergic receptor was not stimulated *in vivo.* However, the catecholamine levels are very elevated with sepsis,[22] and remain elevated for a long time as a result of the prolonged stress state.[22,23] Thus, it would appear that the beta-receptors were not affected by the elevated catecholamine levels. The beta-receptor hypersensitivity in early sepsis is associated with up regulation of the receptors. This is similar to the denervation hypersensitivity in which there is an increase in receptor number because of the lack of stimulation. Beta-receptor hypersensitivity has been seen in other beta-receptor systems.[19,24,25] In these studies there was uncoupling of the receptor mechanism from the adenylate cyclase involved with the post–receptor stimulation and alterations in the protein structure.[19,20] The data from this study suggest that in early sepsis there is a block of the beta-adrenergic receptors of the adipocyte. This would most likely result from one of the circulating factors in sepsis. It is interesting to note that *Escherichia coli* endotoxin has been shown to block the effect of catecholamine stimulation of beta-receptors on animal adipocytes.[26]

In late sepsis, basal lipolysis and beta-receptor stimulations are decreased after 4 days, with a significant decrease in receptor responsiveness. This is similar to results of early trauma representing desensitization of the beta-receptors and adrenergic stimulation of lipolysis. As with trauma, this most likely results from the effect of the catecholamine levels that are still elevated in these patients. Unlike in the trauma situation, the beta-receptors of late sepsis do not have a decrease in the receptor sensitivity or receptor number. It is possible that, with the initial hypersensitivity of the beta-receptor, the subsequent stimulation does not result in the decrease or down-regulation of the receptor.

In the adipocytes from the patients with early sepsis there was an increase in the alpha-receptor response and the postreceptor mechanism with no change in the alpha receptor number. This again represents receptor hypersensitivity without up regulation of the receptors. Thus, as with the beta-receptors in early sepsis, there appears to be an *in vivo* block or inhibition of the alpha-receptor complex. The block prevents the alpha-receptors from being affected by the high circulating levels of catecholamines in early sepsis. It is possible that this alteration of the alpha-receptors is similar or coupled to that of the beta-receptors. These alterations of the alpha-receptors in early sepsis will need further study, and there is no current evidence that endotoxin alters these receptors. It is possible that other circulating factors are involved with these adrenergic alterations in early sepsis.

The alpha-receptor response was decreased in late sepsis with a decreased alpha responsiveness. This pattern is similar to one described with adipose tissue from patients with hyperthyroidism and increased catecholamine stimulation of the alpha-receptors. In that situation the alpha-receptors were desensitized with both down regulation and altered responsiveness.[18] Our data demonstrate the altered responsiveness but do not show the decrease in receptor number. At present, because of the limited research done on the alpha-receptors, we are unable to explain the significant alteration in the alpha-receptor number or affinity.

The alterations in the adrenergic receptors and basal lipolysis reported here would suggest that there was a decrease in adipocyte adrenergic-stimulated lipolysis in early sepsis. The data suggest that it results from a reversible block of the adrenergic system (Table 4). After 4 days both the beta- and alpha-receptors are altered again but this time indicate an increased adrenergic effect and increased lipolysis. The object to understanding these early receptor alterations in sepsis would be to determine if these alterations result in a significant decrease in lipolysis and thus the availability of endogenous lipid for fuel. If this were the case it could explain in part the increased protein catabolism in patients with sepsis.

Aminoterminal Propeptide of Type III Procollagen in Healing Wound in Humans

KARI HAUKIPURO, M.D., LEILA RISTELI, M.D., PH.D., MATTI I. KAIRALUOMA, M.D., PH.D., and JUHA RISTELI, M.D., PH.D.

From the Department of Surgery and Collagen Research Unit, Biocenter and Department of Medical Biochemistry, University of Oulu, Oulu, Finland

For quantitative analysis of wound healing in surgical patients, samples of wound fluid were collected through a silicone rubber tube and their concentration of the aminoterminal propeptide of type III procollagen was measured with a specific radioimmunoassay. Peritoneal fluid, collected through an abdominal drain, and serum were also analyzed. At day 1 after operation, the mean concentration of the propeptide was 30 times higher than the mean preoperative serum level (2.5 μg/L). A significant increase ($p < 0.001$) occurred at day 3 in the wound and at day 2 in peritoneal fluid. At day 5 the mean wound concentration (2670 μg/L) was 1000 times higher than the serum level. In serum a small but significant increase ($p < 0.05$) was found at days 5 and 30. The increase in wound fluid resulted from the intact, liberated propeptide, indicating that the results reflect the synthesis of type III collagen deposited in the wound. This procedure offers a quantitative tool for wound healing studies. Other extracellular matrix components can also be measured, the sequential pattern of their appearance can thus be assessed, and disturbances and treatment effects in wound healing can be detected.

EARLY STRENGTH of a healing wound is mainly based on a load-resistant myofibroblast–reticulin network that connects the wound margins. The exact biochemical nature of this reticulin is not known, but it is thought to consist of fibronectin, type III collagen, and other compounds.[1] Later this network is replaced by more dense connective tissue, which contains increasing amounts of type I collagen. Immunohistochemical studies have shown that type III procollagen and collagen appear in granulation tissue 1 day after wounding, but the first signs of type I collagen are seen 2 days later.[2,3]

The fiber-forming collagens (types I–III) are synthesized as procollagens, which contain additional propeptide extensions at both ends. These are cleaved off *en bloc* when collagen molecules are deposited into the tissue. The complete removal of the carboxyterminal propeptides is necessary for fiber formation, whereas not all the aminoterminal propeptides, especially those of type III collagen, are cleaved. Such pN type III collagen molecules are found on the surface of the fibers, where they most likely prevent further growth of the fibril.[4] The liberated propeptides can be found and their concentration measured in the extracellular fluid and in circulation. The assay for the aminoterminal propeptide of type III procollagen in serum has been used in a number of clinical studies.[5,6] However, the antigens detected in serum are heterogenous, because the degradation of tissue pN type III collagen and further degradation of the propeptide itself form larger and smaller antigens than the propeptide, respectively.[7]

We have recently developed a modification of the assay for the aminoterminal propeptide of type III procollagen based on the purified human peptide.[8] The assay is not sensitive for the smaller degradation products. Here, for the first time, we demonstrate the quantitative analysis of this propeptide in wound and peritoneal fluid after abdominal surgery and compare the observed changes with those found in serum. In addition, the antigen heterogeneity is studied in wound fluid during the first 5 days of healing.

Materials and Methods

Patients

The cases of 18 consecutive, otherwise healthy, nonobese patients, 13 men and five women, were investigated (mean age: 45 years; range: 30–69 years). They

were electively operated on at Oulu University Central Hospital for duodenal ulcer (proximal gastric vagotomy, seven patients); reflux esophagitis (Nissen fundoplication, six); gallstones (cholecystectomy, two); or for two of these reasons (three). For wound infection prophylaxis, a single dose of cefuroxime (1.5 g) was given intravenously at induction of anesthesia. Informed consent was obtained from each patient for participation in the study. The study was approved of by the Ethical Committee of the Medical Faculty of the University of Oulu.

Collection of Samples

For collecting wound fluid, two 15 cm Silastic silicone rubber tubings (Dow Corning medical grade tubing no. 602-235, external diameter 2 mm) were left subcutaneously for 120 hours at the end of the operation. The outer ends, closed with a clip, were conducted through separate stab skin incisions and secured with adhesive strips. After the tubings and the adjacent skin were cleansed with chlorhexidin solution (5 mg/mL), the daily samples of wound fluid were drawn into a 1.0-mL syringe by puncture of the tubing with a 18-G needle. A new clip was then applied proximal to the puncture site. The volume of the fluid was measured and the appearance determined visually as bloody, semiserous, or serous. As reported previously by Viljanto et al.,[9] no wound healing complications were associated with the presence of the tubings. The wound fluid samples of a female patient in whom a wound hematoma developed were excluded from the final results because the propeptide concentrations were low, approaching the serum levels. A few other samples are missing for technical reasons or were unintentionally not taken. Thus, the total numbers of wound fluid samples studied were 12, 12, 16, 13, and 13 for days 1–5, respectively.

Peritoneal fluid was obtained by puncturing the abdominal drain (Exudrain no. 18, Astra Meditec, Mölndal, Sweden) near the skin level and the appearance determined as above. The numbers of peritoneal fluid samples analyzed were 12, 11, and 8 for days 1–3, respectively. At day 3 the drains were removed, and at that time four of them were already dry. Serum samples were taken after overnight fasting from the patients before operation and 5 and 30 days after operation.

All the samples were stored at −20 C until analyzed. The wound and peritoneal fluid samples were initially diluted 1:10 with phosphate-buffered saline containing 0.04% of Tween 20 (ICI Americas, Wilmington, DE). All further dilutions were also made in this buffer.

Radioimmunoassays

A modification[8] of the assay for the aminoterminal propeptide of human type III procollagen was used that detects only the serum antigens that are similar in size to the intact propeptide or larger.[7,8] The antiserum and the assay conditions have been selected in order to diminish the interference caused by the small molecular weight degradation products of the propeptide (see Fig. 1). Thus, the standard antigen and samples of biologic fluids give parallel inhibition curves. Briefly, 0.1 mL of an antiserum dilution (rabbit no. 70) capable of binding 50% of the labeled antigen was incubated for 2 hours at +37 C with 0.2 mL of nonlabeled standard antigen or unknown sample before addition of the I^{125}-labeled human aminopropeptide. After 1 hour of incubation at +37 C, the free and bound antigens were separated by precipitation (overnight at +4 C) with goat antiserum against rabbit IgG. The precipitate was isolated by centrifugation for 30 minutes at +4 C and washed once, and the radioactivity was counted with a Multigamma gamma counter (LKB–Wolloc, Turku, Finland). An assay was also used to analyze the antigenic profile of wound fluid that detects both the propeptide and its degradation products (see below).

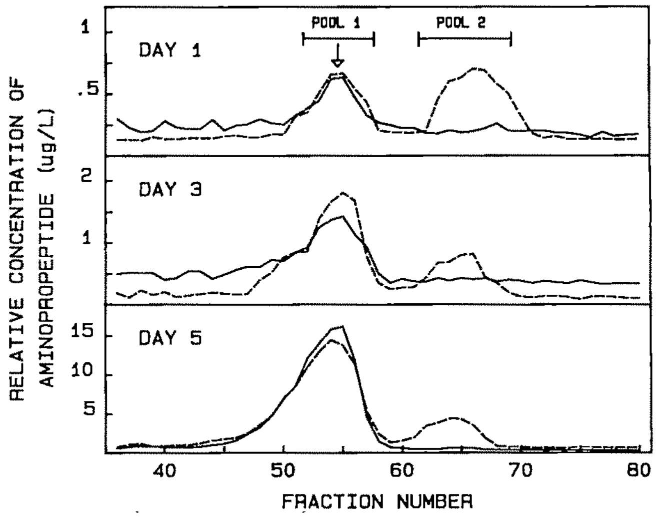

FIG. 1. Sephacryl S-300 gel filtration analysis of the profile of antigens related to the aminoterminal propeptide of type III procollagen in wound fluid. Two different radioimmunoassays were used (for details see "Materials and Methods"): one that measures only the intact propeptide (solid line) and another that detects both the propeptide and its degradation products (dashed line). Two pools were thereafter collected: pool 1 contained the propeptide, and pool 2 contained its degradation products. The exact amounts of the antigens in the pools (see Table 1) were then analyzed as described in "Materials and Methods." The arrow indicates an elution position of the isolated aminoterminal propeptide of human type III procollagen.[15] Note the different scales of the propeptide concentrations at days 1, 3, and 5.

For each wound or peritoneal fluid sample, a dilution curve containing three to five points was made. The results were calculated with the 50% intercept method.[6] This was obtained with a Kaypro 16 microcomputer (IBM compatible) (Kaypro Co., Solana Beach, CA) using a program[10] in which logit and log transformations

* Propeptide concentration in wound fluid as measured with the standard radioimmunoassay (antiserum no. 70) before gel filtration.

† The pools are indicated in the gel filtration profile (Fig. 1). The amounts of the intact propeptide (pool 1) and its degradation products (pool 2) were analyzed as described in "Materials and Methods."

are used to obtain a linear dose–response curve, followed by iterated weighted-least-squares regression analysis. In addition to the 50% intercept, the program calculates the slope of the inhibition curve for each sample: these were similar to that of the standard. The intra-assay variation was 7%.

Antigenic Profile of Wound Fluid

Wound fluid samples of 0.1 mL from days 1, 3, and 5, obtained from the same patient, were chromatographed on a column (1.5 × 110 cm) of Sephacryl S-300 (Pharmacia, Uppsala, Sweden) equilibrated in phosphate-buffered saline, pH 7.2, containing 0.04% Tween 20. Fractions of 2.5 mL were collected. Each fraction was then directly analyzed both with the radioimmunoassay described above and with an assay (using the antiserum from the rabbit no. 47) that detects both the propeptide and its degradation products, the latter with a less steep slope of the inhibition curve, however.[6] In molar terms, the same amounts of a major degradation product (the so-called Col1 domain), obtained after bacterial collagenase digestion, and of the intact propeptide were needed to obtain a 50% inhibition. After localizing the propeptide and its degradation products with the latter assay, two pools based on the inhibition profile were made (Fig. 1), pool 1 containing the propeptide and pool 2 its degradation products. The concentrations of the respective antigens were then estimated in the pools with the radioimmunoassay with antiserum no. 47, with the use of the intact propeptide or its Col1 domain as a standard antigen to eliminate the effect of different slopes of the inhibition curves (Table 1).

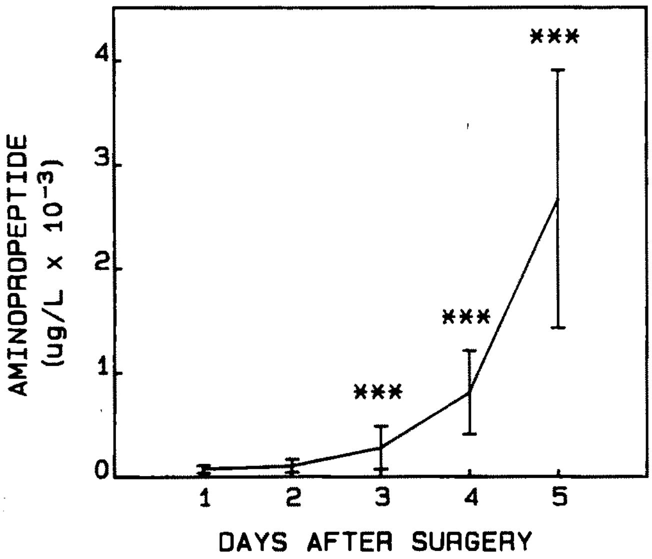

FIG. 2. Effect of time on the concentration of the aminoterminal propeptide of type III procollagen in wound fluid (mean ± SD). ***$p < 0.001$ compared with the concentration at day 1.

Statistical Analysis

Before comparing the propeptide concentrations in wound and peritoneal fluid at different time points, a logarithmic transformation was necessary because the variances differed (Bartlett's test), being dependent on the mean of the group. A one-way analysis of variance for repeated measurements was then performed and the significance of the differences in the concentration of propeptide, compared with the first day level, was tested using a modified t-test and calculating the critical t-value by the Bonferroni method.[11] The correlations between the wound fluid propeptide concentration and the other parameters were analyzed by use of the Pearson correlation coefficient or, for discrete measurements, the Spearman rank correlation coefficient.

Results

Aminopropeptide in Wound Fluid, Peritoneal Fluid, and Serum

The concentration of the aminoterminal propeptide of type III procollagen in wound fluid at day 1 was 75 ± 37 μg/L. It remained almost unchanged during the first 2 days after operation and increased rapidly thereafter (Fig. 2). On day 5 the mean concentration was 35-fold that of day 1. Compared with the mean preoperative serum level (see below), this indicates a 1000-fold concentration. A significant increase in propeptide concentration already occurred in peritoneal fluid (Fig. 3) between days 1 and 2 ($p < 0.001$). However, in the wound (Fig. 1) a significant change was evident only 3 days after surgery ($p < 0.001$).

In serum the propeptide concentration was significantly increased at day 5 ($p < 0.05$) and at day 30 ($p < 0.05$), compared with the preoperative values (Fig. 4). However, these concentrations were all within the reference interval, determined for healthy adults (1.7–4.2 μg/L).

Antigenic Profile of Wound Fluid

The radioimmunoassay applied for the fluid concentration analyses only detected one propeptide antigen species in wound fluid; this was of similar size as the propeptide, when cleaved off *en bloc* during the extracellular processing of type III procollagen (Fig. 1, solid line). The gel filtration profile indicates that no procollagen or other high-molecular-weight propeptide antigens are present in wound fluid. Thus, the cleavage of the aminoterminal propeptide, which often is not complete, has occurred efficiently during wound healing. Degradation products of the propeptide were detected by another radioimmunoassay (Fig. 1, dashed line). Because this assay also recognized the intact propeptide, the two antigen forms could be pooled separately (Fig. 1). The analysis of both pools with the use of proper standard antigens indicated that the concentration of intact propeptide had increased 22-fold by day 5, compared with day 1, and that of the degradation products only fivefold (Table 1).

Correlation Analysis

About one-third of the wound fluid samples were bloody at days 1 and 2. Later, at days 3–5, less than 10% contained visible blood. No correlation was found between the appearance of wound fluid and the aminopropeptide concentration. The mean volumes of fluid obtained on the five postoperative days were 215 μL (range: 70–600 μL); 200 μL (range: 90–500 μL); 180 μL (range: 70–430 μL); 145 μL (range: 70–240 μL); and 175 μL (range: 40–400 μL). There was no correlation between the volume and the propeptide concentration. The thickness of subcutaneous tissue also had no effect on the propeptide concentration in wound fluid.

Discussion

A lot of experimental data are available concerning wound healing, but human studies are hampered by technical and ethical difficulties in collecting samples of granulation tissue. However, two acceptable methods have been developed: the Cellstic[12] and a method using a miniature PTFE tube.[13] The former has been used for studying the appearance of cells,[14] collagen types,[3] and fibronectin[9] during early wound healing. The latter was used for histologic and hydroxyproline analyses.[13] In this study the silicone rubber tubing of the Cellstic device without viscose cellulose sponge was left subcutaneously in the wound, offering a gate for repeated wound fluid collection for at least 5 days after operation, and then a new method for analyzing the aminoterminal propeptide of type III procollagen was applied.[8] If such a quantitative analysis reflects the tissue events, then the problems encountered with tissue sampling are avoided.

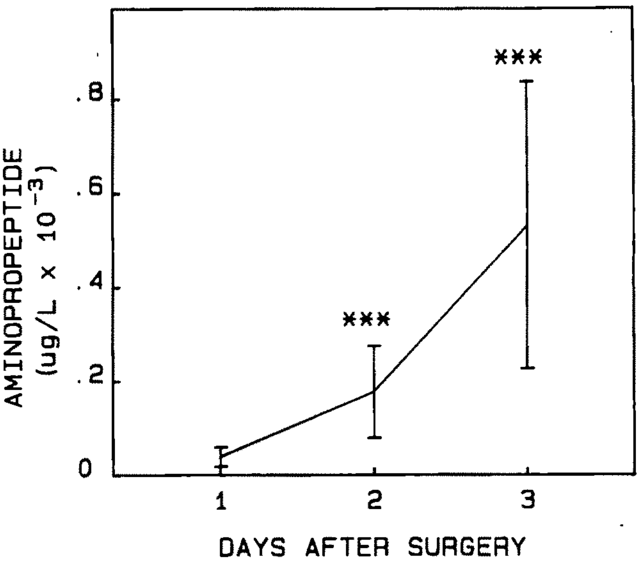

FIG. 3. Effect of time on the concentration of the aminoterminal propeptide of type III procollagen in peritoneal fluid (mean ± SD). ***p < 0.001 compared with the concentration at day 1.

The content of free aminoterminal propeptide of type III procollagen in wound fluid increased significantly 3 days after operation and continued to do so until day 5, which was the last day studied. This finding is in agreement with the previous immunofluorescence studies that demonstrated the first signs of type III procollagen and collagen 1–2 days after wounding and increasing amounts thereafter.[3] The concentration of the propeptide at day 5 was 1000-fold, compared with the normal serum level. At the same time there was a significant

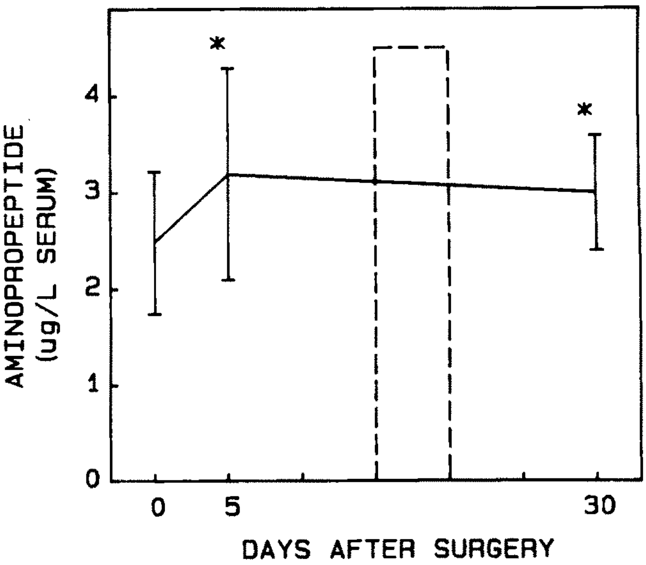

FIG. 4. Effect of abdominal surgery on the concentration of the aminoterminal propeptide of type III procollagen in serum (mean ± SD). The column indicates the reference range for nonoperated controls. *p < 0.05 compared with the preoperative level.

increase in the serum concentration, although the values remained within the reference range. Thus, the increase in the synthesis of type III collagen in the granulation tissue after moderate surgical trauma was large enough to be reflected in the serum.

The analysis of the antigenic profile in wound fluid indicated that the processing of type III procollagen was complete; only the liberated aminoterminal propeptide and no higher molecular weight forms were present in this extracellular fluid. The further degradation of the propeptide in the wound was also studied (Fig. 1). The increase in the concentration of the degradation products was smaller than that in the concentration of the intact propeptide (Table 1). Because most of the serum antigenicity results from the smaller fragments, however, the findings suggest that the evident further degradation does not take place *in situ,* but during the later stages of the propeptide elimination. The analysis of the gel filtration fractions with the new assay modification verified the fact that the degradation products of the propeptide are not interfering in this assay. The increased concentrations found in the wound result from increased amounts of the intact propeptide cleaved *en bloc* and not from the other antigen forms that predominate in serum.[7] Thus, the results seem to reflect the synthesis of type III collagen, which is also deposited in the wound granulation tissue.

The procedure described offers a new method of quantitative study of early events in human wound healing. Applying new immunoassays for different collagen types and other extracellular matrix components[5,6] will provide accurate information on the sequential pattern of their appearance and provide the possibility for detecting disturbances in the healing process itself. Also, the effects of different treatment regimens could be compared easily.

BC/BE General Surgeon to join expanding department in multispecialty group practice serving FFS and prepaid patients in Central Massachusetts. Practice in university-affiliated hospitals with opportunities for clinical research. Send CV to **Medical Director, Fallon Clinic, 630 Plantation Street, Worcester, Massachusetts 01605.**

BC/BE General Surgeon to join surgical service performing a full range of general, vascular and non cardiac thoracic surgical procedures. Endoscopy experience preferred. Research opportunities available. Send C.V. to **Chief of Surgery, Boise VAMC, 500 W. Fort St., Boise, ID, 83702-4598.**

BC/BE General Surgeon to associate with two active internists in NE Wisconsin. New clinic and modern hospital with state of the art ICU. **Box ANN12B, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

BOARD CERTIFIED OR ELIGIBLE GENERAL SURGEON—The VA Medical Center in Jackson, Mississippi, a 455 bed facility, affiliated with the University of Mississippi School of Medicine is recruiting for a General Surgeon with peripheral vascular capabilities. As a major teaching affiliate, the position will necessitate an active interest in teaching medical students and residents. The candidate will be eligible for an academic appointment at the University. To apply, send your CV to: **Dr. T. K. Williams, Acting Chief, Surgical Service (112), VA Medical Center, 1500 E. Woodrow Wilson Drive, Jackson, MS 39216.**

Chief, Surgical Service— Veterans Administration Medical Center, Albuquerque, NM and University of New Mexico School of Medicine are seeking an individual to lead active clinical, teaching and research programs for undergraduates and residents in General, Thoracic, Plastic, Urologic and Orthopaedic Surgery. Individual will have major clinical and academic responsibilities and must have experience and accomplishments to qualify for senior academic appointment in the Department of Surgery, University of New Mexico, School of Medicine. Inquiries should be accompanied by resume and addressed to **Donald E. Fry, M.D., Chairman, Dept. of Surgery, c/o Chief of Staff, VA Medical Center, 2100 Ridgecrest Drive S.E., Albuquerque, New Mexico 87108.** VA Medical Center, Albuquerque is an equal opportunity employer.

COSMETIC SURGERY FELLOWSHIP, Department Of Cosmetic Surgery, Graduate Hospital, Philadelphia, PA. Available July 1988. Twelve month program. Yearly case load of over 3,000 facial, breast, and body cosmetic procedures. Candidates must have had an otolaryngology/head and neck, plastic and reconstructive surgery, general surgery, or gynecologic residency to qualify. Upon completion you will be eligible to take the board examination in cosmetic surgery. Call or Write: **Julius Newman, M.D., Chairman, 1455 City Line Avenue, Philadelphia, PA 19151, 215-896-6677.**

FELLOWSHIP/CRITICAL CARE MEDICINE— One year fellowship in Critical Care Medicine, beginning July 1, 1988, are available at the Maryland Institute for Emergency Medical Services Systems. The Institute specializes in the care of adult trauma victims, and is the center of a state-wide trauma network. Approximately 45 beds (of a total of 96) are devoted to intensive care. Admission numbers are about 2800/year. Opportunities for elective experience in Pediatric ICU, trauma anaesthesia, open heart recovery, and hyperbaric medicine are available. Respond to: **John S. Britten, M.D., Department of Critical Care Medicine c/o MIEMSS 22 S. Greene Street, Baltimore, Maryland 21201.**

FOR SALE— General Surgery Practice in Central Massachusetts. Solo practitioner retiring immediately. BC/BE required. Reply with CV. Reply **Box ANN12A, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

GENERAL SURGEON— BC/BE to join another and well-established HMO practice in south suburban Boston. Competitive salary and benefits. Send curriculum vitae to: Director of Physician Recruitment **Medical East Community Health Plan, 325 Wood Road, Braintree, MA 02184, (617) 849-3061.** We are an equal opportunity/affirmative action employer.

GENERAL SURGEONS— Newly established prepaid group practice desires to begin offering general surgery services. Looking for general surgeons interested in establishing and building a department. Physicians must be from high quality residency programs. Positions available immediately. C.V.s to: **Larry A. Oates, M.D., Regional Medical Director, Carolina Permanente Medical Group, P.A. 2900 Highwoods Blvd., Raleigh, N.C. 27604 (919) 878-9870.**

GENERAL SURGEON—To join busy private practice in Capital District/Upstate New York. Excellent benefits and salary leading to partnership. **Box ANN12D, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

Made of # Fr. biocompatable silicone for minimum trauma without sacrificing efficiency of performance.

* Send for reprints documenting results from independent clinical centers.

CASE # 24 **AGE:** 55 **SEX:** FEMALE

DIAGNOSIS: CECAL CARCINOMA

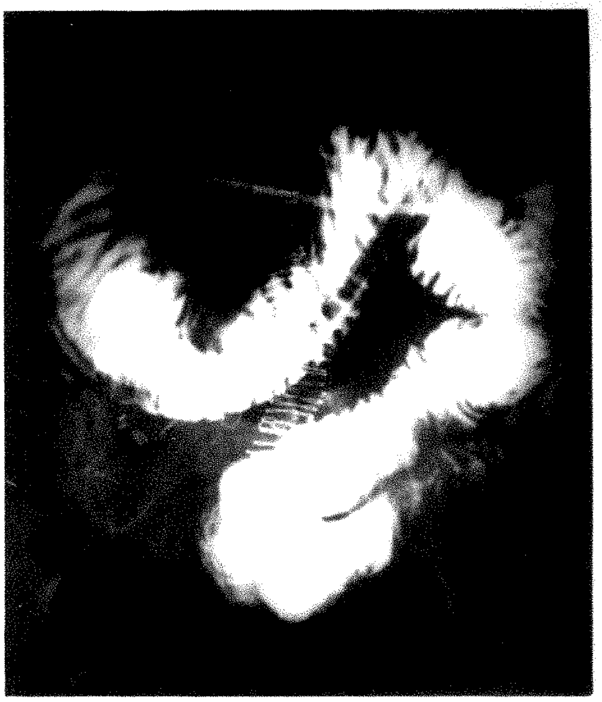
SYMPTOMS: ANEMIA (Hg 6 gm/dl)

OPERATION: RIGHT HEMICOLECTOMY & GASTROSTOMY

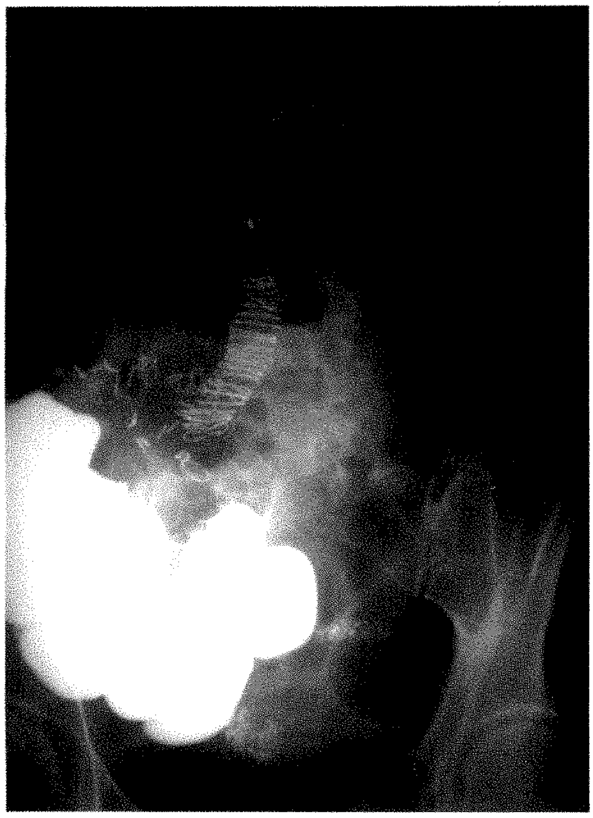
The patient had a right hemicolectomy with stapled (U.S. Surgical Corp) anastomosis and fascia closure and a MOSS® gastrostomy tube. The stomach and proximal duodenum were aspirated, with immediate simultaneous feeding into the distal duodenum.

Barium feeding 5 hours postop documented adequate motility. The deliberate excess was totally removed. No contrast (i.e.: excess feeding) escaped efficient aspiration within the proximal duodenum, to reflux into the stomach. (Figure A) Serial motility study showed barium had traversed the anastomosis and colon, and already was exiting in a spontaneous bowel movement by 21 hours postop. (Figure C)

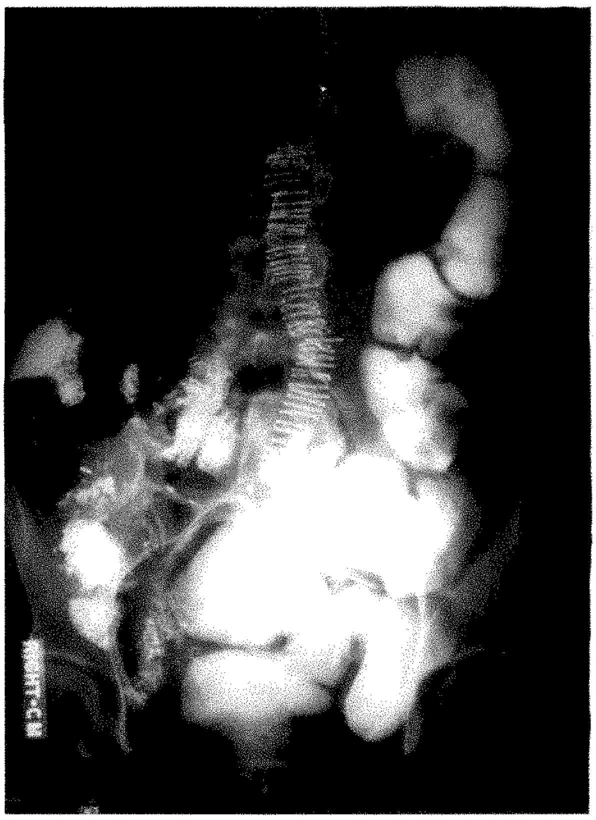
She received 300 ml/hr of Vivonex TEN (Norwich Eaton Pharm), absorbed 5,000 kcal the initial 20 hours, and then tolerated a general diet. She was the 4th patient discharged uneventfully 24 hours after bowel resection and reanastomosis.



A. Study @ 5 minutes (5 hours postop).
Note efficient removal of all excess barium, with none reaching the stomach.



B. Motility @ 4 hours (9 hours postop).
All barium is within the ileum.



C. Motility @ 16 hours (21 hours postop).
Barium is exiting in a spontaneous bowel movement.

Call MOSS TUBES, INC (518) 674-3109 for introductory sample and literature.

Large physician owned multi-speciality medical group seeks General Surgeon to join department of four. We offer an excellent salary/incentive bonus and benefit package as well as opportunity for partnership. Easy access to beach, mountains or desert. Please send C.V. to **Patti J. Hines, Friendly Hills Medical Group, 951 S. Beach Blvd., La Habra, CA 90631.**

Long-established 47 physician multispecialty clinic in the Puget Sound area seeking BE/BC General, Vascular and Non-Cardiac Thoracic Surgeon. Guaranteed salary leading to stockholdership. Excellent fringe benefits. Send CV and letter to: **Box ANN12C, J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105.**

MAINE—Opportunity for BC/BE general surgeon to join established two-man surgical group in northern Maine. Subspecialty training helpful but not required. Progressive family-oriented university community. Affiliation with well-qualified, 40-member primary care and subspecialty medical staff and modern multi-facility hospital. Competitive salary plus benefits leading to future partnership. For further information, please forward curriculum vitae to **John Ginty, Associate Director, The Aroostook Medical Center, P.O. Box 151, Academy Street, Presque Isle, ME 04769.**

SOUTHEASTERN NEW MEXICO—We are seeking a board certified/board eligible general surgeon interested in a lucrative career move with a first year guaranteed salary of $90,000+. This up-to-date private practice has a service area population of approximately 30,000. For additional information, please send current CV to **Linda Smith, Central Business Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri, 64111; or call 1-800-821-5147 or 816-561-1025.**

KANSAS—We are seeking a general surgeon interested in a full-time private practice opportunity in the greater Kansas City area. For further information, please send current CV to **Linda Smith, Central Business Services, Inc., 3101 Broadway, Suite 1000, Kansas City, Missouri, 64111; or call 1-800-821-5147 or 816-561-1025.**

The community of **ARTESIA, NEW MEXICO** is seeking a Board Certified or Eligible GENERAL SURGEON to establish a private practice. Fully-equipped office with established referral patterns available for purchase. Community-based financial assistance may be available to the right individual. Artesia is a community of 14,000 located in Southeast New Mexico. A great place to raise a family—peaceful community with year-round recreation and excellent weather. Fully equipped, 38-bed new hospital. Please submit CV to: **Bill Norris, Southwest Community Health Services, P.O. Box 26666, Albuquerque, NM 87125-6666; or, call 1-800-545-4030, Ext. 8300.**

The Department of Surgery of the University of South Dakota is seeking full time academic surgeons. An excellent research facility and opportunities for private practice are available. Salary and benefits are highly competitive. Closing date for receipt of applications is March 1, 1988 or until position is filled. Please forward curriculum vitae to **Frank E. Jones, M.D., Chairman, Search Committee, 2501 West 22nd Street, Sioux Falls, SD 57105.** The University of South Dakota is an equal employment opportunity/affirmative action employer.

TRANSPLANT SURGEON— Position available for an individual to join an established renal transplant team at the Assistant or Associate Professor level in the Department of Surgery at Southern Illinois University School of Medicine. The qualified candidate will have completed an ASTS approved transplant fellowship; board certification is preferred. Experience and interest in pancreatic transplantation desirable. The applicant should have additional commitment to surgical intensive care and surgical education, and transplantation related research. Academic rank and salary negotiable depending on applicant's experience. Send current curriculum vitae to **Alan G. Birtch, M.D., Chief, Section of Transplantation, Chairman, Division of General Surgery, Southern Illinois University, School of Medicine, P.O. Box 3926, Springfield, Illinois 62708.** Southern Illinois University is an equal opportunity/affirmative action employer.

TRAUMA SURGEON—PENNSYLVANIA— Join 3 MD's in 569+ bed tertiary care center now seeing 500 category I pts., 900+ total. Hosp. is designated PA Level I Trauma Center. Full, advanced equip., includes own copters, 3 CT's & angiography in ER, NMR, MRI, hyperbaric chamber, all monitors. Top surgical specialty support including 18 surg. residents. Research & publ. encouraged. Beautiful, non-urban PA locale ideal for family/recreation. Enjoy excel. salary; benefits incl. 4 wks vac. & 4 wks. CME. Call 215/363/5600 or send CV: **Walt Downing, c/o John Downing Associates, 50 Welsh Pool Rd., Lionville, PA 19353.**

VASCULAR SURGEON—Full time academic position. Excellent opportunity with large clinical volume and funds for research. Candidate should be eligible for appointment as Assistant Professor of Surgery, SUNY Stony Brook. Attractive area on North Shore of Long Island. Must be board certified or eligible for vascular certificate. Excellent salary/benefits. Send curriculum vitae to: **Leslie Wise, MD, Chairman-Department of Surgery. Long Island Jewish Medical Center, 270-05 76th Avenue, New Hyde Park, NY 11042.** An Equal Opportunity Employer.

Inhibition of Vessel Allograft Rejection by Endothelial Removal

Morphologic and Ultrastructural Changes

MATTHEW A. GALUMBECK, M.D.,* FRED P. SANFILIPPO, M.D., PH.D.,†‡ PER-OTTO HAGEN, PH.D.,‡
ANTHONY V. SEABER,* and JAMES R. URBANIAK, M.D.*

From the Orthopaedic Research Laboratories, Department of Pathology,† and Department of General and Thoracic Surgery,‡ Duke University Medical Center, Durham, North Carolina*

The vascular endothelium plays an important and complex role in vascular allograft rejection. Antigens expressed by the endothelium can act to promote and be the target of rejection reactions, which often lead to thrombosis and ischemic necrosis of the allograft. In this study, segments of femoral artery and femoral vein with or without endothelium were grafted between allogenic or autologous control rats. Immunocompetent Lewis ($RT1^{l}$) recipient rats were randomly selected for groups (N = 14 for each) receiving the following: ACI^{-} ($RT1^{a}$) allografts with intact endothelium, allografts with endothelium removed before operation, autografts with endothelium, and autografts with endothelium removed. Rejection was assessed by graft patency as well as morphologic and ultrastructural changes. At 5 days, the allografts with intact endothelium were totally occluded, whereas allografts without endothelium remained patent, as did autologous control grafts with or without endothelium. Two additional groups (N = 14 each) receiving the de-endothelialized allografts or autografts were examined at 120 days after operation, revealing that grafts in both groups were still patent and had been re-endothelialized. These findings indicate that physical removal of vascular endothelium may depress vessel allograft rejection without immunosuppressive therapy.

DESPITE SIGNIFICANT ADVANCES in the field of transplantation, the rejection phenomenon remains the major cause of graft failure. Previous investigations assessing rejection in renal allografts,[1] cardiac allografts,[2] and cutaneous allografts[3] have reported that graft failure may often occur as a result of vascular rejection, especially after presensitization to antigens expressed on the vascular endothelium. This rejection manifests itself as endothelial destruction, with subsequent luminal thrombus formation and graft occlusion. Allograft endothelial destruction is initiated by surface antigens encoded by the major histocompatability complex (MHC), as well as blood groups and other antigen systems.[4,5] In addition to expressing these antigens, which can stimulate and act as targets for immune responses, vascular endothelium may directly express inflammatory mediators that can promote the activation of T cells,[6] which are the major immune effectors in acute rejection.[6,7]

In an attempt to arrest acute rejection, immunosuppressive agents have been employed in allograft transplantation. However, many of these agents lead to serious complications and death in the host.[8] Newer agents, such as cyclosporin A, effectively diminish the host immune response to allograft transplantation, yet current investigations reveal that once the immunosuppressive agents are discontinued, the host immune response often becomes reactivated, leading to allograft rejection.[9]

In this investigation attempts were made to alter vascular allograft rejection in immunocompetent animals without the use of immunosuppressive agents. Removal of the vascular allograft endothelium before graft insertion resulted in long-term patency, and de-endothelialized allografts were found to be resurfaced with cells structurally and phenotypically similar to endothelium.

Materials and Methods

Vascular Transplantation

MHC-disparate rats, ACI ($RT1^{a}$), and Lewis ($RT1^{l}$) were used. All animals were males weighing between 195 and 200 g and were obtained from Harlan Sprague

Dawley. Grafts used were 1-cm portions of femoral artery and vein harvested between the inguinal ligament and the profunda femora vessel of the donor rat. Before operation, all rats received 200 U/kg of porcine heparin intraperitoneally (I.P.). The rats were anesthetized with pentobarbital (Nembutol®, Abbott Laboratories, North Chicago, IL) (60 mg/kg I.P.). All operative procedures were conducted under sterile conditions. The donor site was exposed, as was the host vascular bed. The graft was then excised by use of the operating microscope and standard microsurgical instrumentation. The graft was immediately transplanted into the host femoral vessel (artery to artery, vein to vein) by use of the Microsurgical Triple Clamp, previously described.[10] The wound was closed with 3-0 dexamethasone sodium phosphate (Dexon, Kay, Tulsa, OK), and the animal was returned to the housing facility and cared for according to National Institutes of Health guidelines.

Endothelial Removal

Endothelium was removed by placing a 1-mm metal dilator inside the arterial and venous lumina. The vessel was then rotated around the dilator, and the dilator was removed. Scanning electron micrographs revealed complete endothelial removal without damage to the media (Fig. 1). Comparable mechanical procedures to de-endothelialize arteries and veins have revealed similar results.[11,12]

Experimental Groupings

Eighty-four Lewis rats were randomized equally into six groups. Group 1 consisted of ACI donor femoral artery and vein segments transplanted into Lewis rats, referred to as allograft—endothelium intact. Group 2 consisted of Lewis artery and vein autografts, referred to as autograft—endothelium intact. Group 3 consisted of ACI donor femoral artery and vein segments, with the endothelium mechanically removed before being transplanted into Lewis rats, referred to as allograft—endothelium removed. Group 4 consisted of Lewis artery and vein autografts in which the endothelium was mechanically removed, referred to as autograft—endothelium removed. Group 5 consisted of ACI donor femoral artery segments that had the endothelium mechanically removed, transplanted into Lewis rats, and held for 120 days, referred to as long-term allograft—endothelium removed. Group 6 consisted of Lewis artery autografts held for 120 days, in which the endothelium was mechanically removed and referred to as long-term autograft—endothelium removed.

Postoperative Graft Harvesting, Colloid Carbon Tracer Injection, and Fixation Procedures

Five days after operation, the host rats in groups 1–4 were anesthetized with pentobarbital I.P. The operative

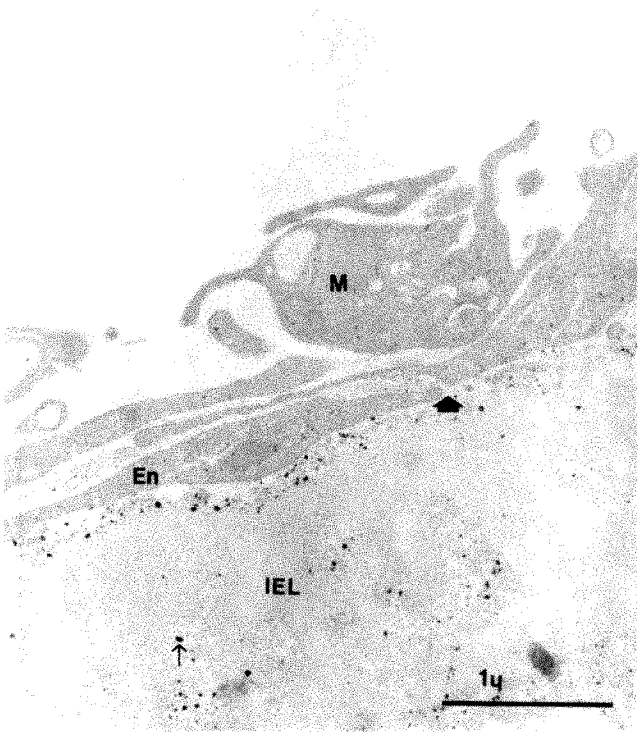

FIG. 3. Transmission electron micrograph of an arterial allograft 5 days after transplantation. Macrophage (M) is juxtaposed to hypertrophic endothelial cells (En), which are separated by endothelial gaps (arrowhead). Carbon particles (arrow) are present throughout the internal elastic membrane (IEL). (Original magnification ×30,000.)

site was re-exposed, and the graft was tested for patency by use of the two-forceps test. The rat was then injected with 2.5 mL of a 10% colloid carbon solution into the femoral vein, contralateral to the operated side.[13,14] Thirty minutes after tracer injection, a cannula was introduced into the abdominal aorta, and the rats were perfused with a 10 mM Hepes buffer solution at 10 cm H_2O for 5 minutes. This was followed by perfusion of a 0.1 sodium cacodylate buffer with 5% sucrose for 5 minutes, followed by a 3% gluteraldehyde in 0.1 M sodium cacodylate perfusion for 5 minutes. The grafts were then removed, placed in vials, coded, and processed for the scanning and transmission electron microscopes by use of previously described techniques for vascular fixation.[15,16] The vessels were then assessed by Jeol JSM-35E (Jeol, Peabody, MA) scanning and Philips 301 (Phillips Electronic Inc., Mahwah, NJ) transmission electron microscopes. The tissues were assessed in a masked fashion for changes in the vessel lumen, as well as endothelial ultrastructural morphologic characteristics and patterns of colloid carbon vascular distribution. Rats in groups 5 and 6 were harvested at 120 days and processed in a similar manner.

Immunoperoxidase Labeling

Frozen sections of fresh graft specimens were labeled with monoclonal antibodies to rat leukocyte common antigen (OX-1), rat T cells (OX-19), rat T helper cells (W3/25), and rat T cytotoxic/suppressor cells (OX-8) and polyclonal antibodies to factor VIII–related antigen

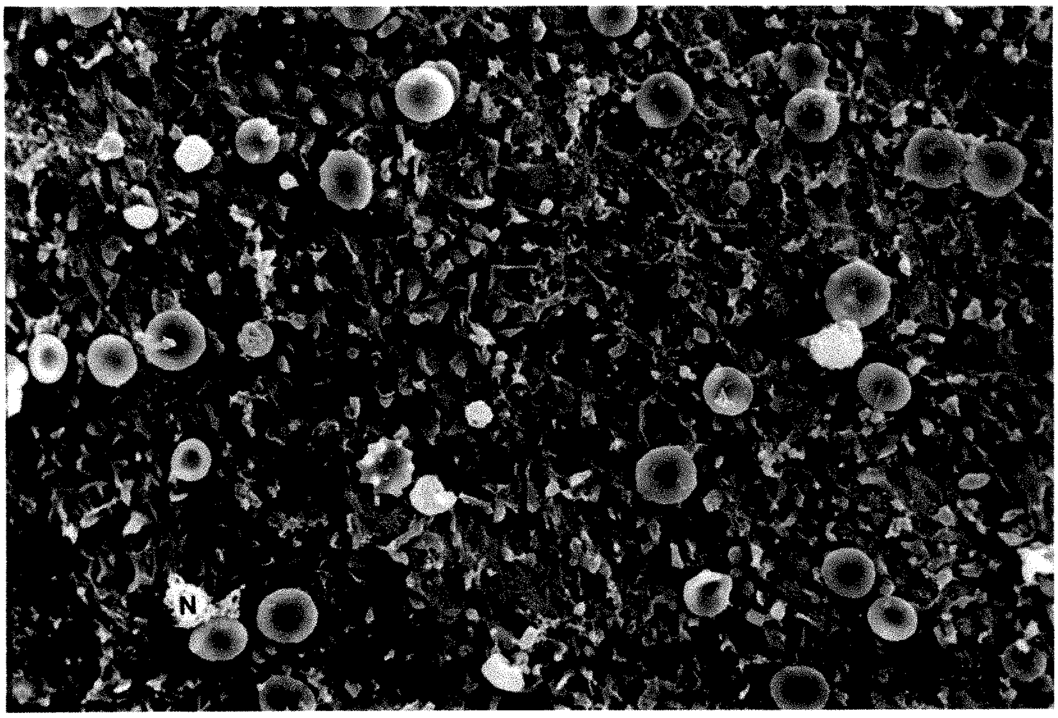

FIG. 5. Scanning electron micrograph of de-endothelialized arterial allograft 5 days after transplantation. Present on the vessel surface are erythrocytes (E), neutrophils (N), platelets (P), and fibrin (arrow). (Original magnification ×1400.)

and vascular smooth muscle myosin, as previously described.[17,18]

Statistical Analysis

Student's t-test was used to determine significance.

Results

Graft Function (Table 1)

Group 1 (allograft—endothelium intact). No arteries or veins were patent at 5 days. All vessels had areas of clot within the vessel lumina. These clots ranged from partial to total transmural obstruction of the graft.

Group 2 (autograft—endothelium intact). All arteries were patent, and 13 of the 14 veins were patent. One vein was occluded because of poor anastomotic technique.

Group 3 (allograft—endothelium removed). Thirteen of 14 arteries were patent, and all 14 veins were patent. The arterial occlusion resulted from poor anastomotic technique.

Group 4 (autograft—endothelium removed). All vessels were patent.

Group 5 (long-term allograft—endothelium removed). All vessels were patent.

Group 6 (long-term autograft—endothelium removed). All vessels were patent.

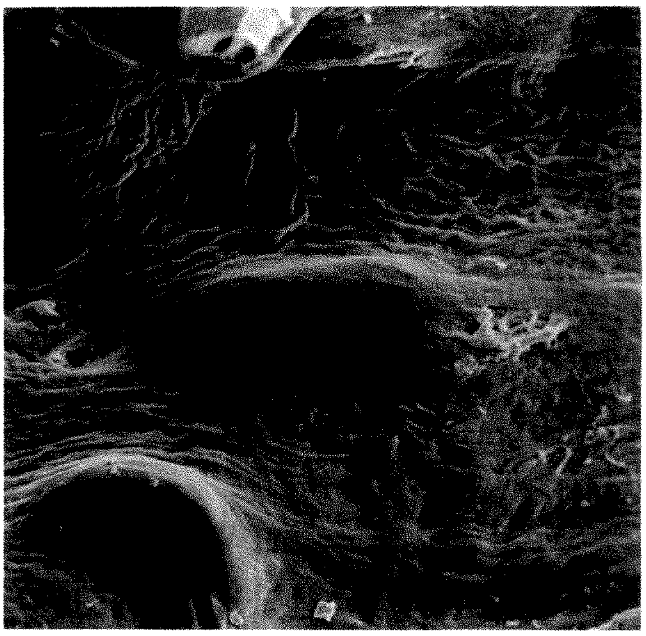

FIG. 6. Scanning electron micrograph of a 120-day arterial allograft. The luminal surface is covered by a monomorphic layer of cells resembling endothelial cells. (Original magnification ×750.)

Ultrastructural Changes

Group 1 (allograft—endothelium intact). Luminal contents included erythrocytes, platelets, and lympho-

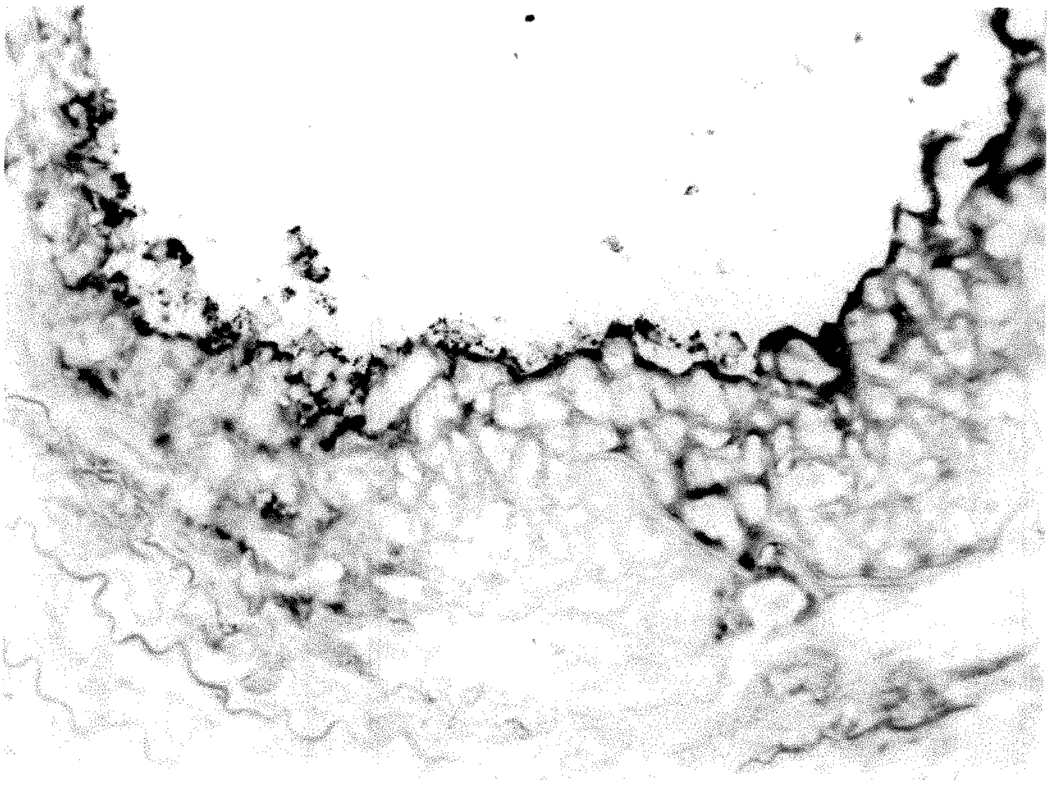

FIG. 7. Immunoperoxidase labeling of a 120-day arterial allograft using anti-factor VIII-related antigen. The luminal surface monolayer of cells is positively stained. (Original magnification ×450.)

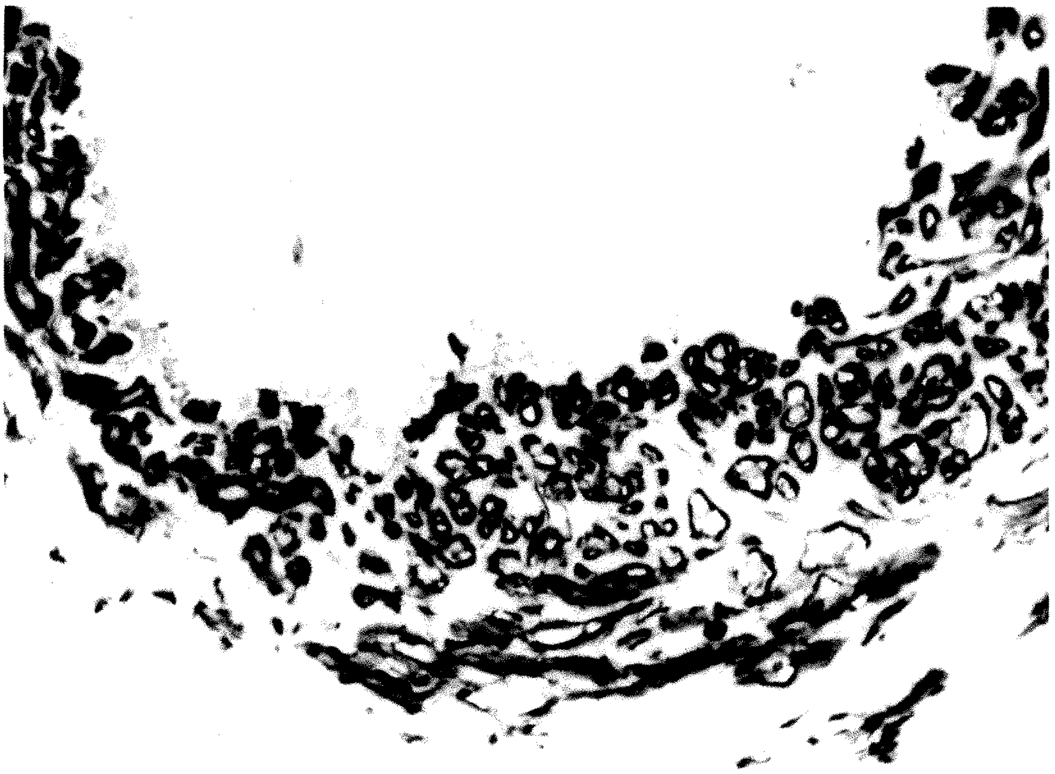

FIG. 8. Immunoperoxidase labeling of a 120-day arterial allograft with the use of anti-smooth muscle myosin. The muscularis had positive results, whereas the luminal monolayer had negative results. (Original magnification ×450.)

cytes enmeshed in fibrin and cellular debris (Fig. 2). Macrophages appeared to marginate from the lumen and invade the vessel wall (Fig. 3). Extensive segments of denuded endothelium were present. Where endothelial cells did exist, they were separated by interendothelial gaps. The endothelium appeared to be hypertrophic and contained multiple vesicular bodies. Colloid carbon tracer was present subintimally, suggesting destruction of the basement membrane.

Group 2 (autograft—endothelium intact). In this group arteries and veins showed no vascular alterations when compared with the host's own unoperated vessels. Normal endothelia with competent interendothelial junctions were present (Fig. 4). Carbon tracer was not subintimal, suggesting an intact basement membrane.

Group 3 (allograft—endothelium removed). As the endothelium was removed before operation, the subintimal surface was covered with a meshwork of fibrin strands, in which platelets, erythrocytes, and neutrophils were observed (Fig. 5). There was no evidence of intraluminal clot. Carbon tracer was present subintimally.

Group 4 (autograft—endothelium removed). Ultrastructurally the surfaces of these arteries and veins appeared similar to those of group 3. A fibrin meshwork covered the subintimal surface, in which platelets, erythrocytes, and neutrophils were observed. Intraluminal clot was not present, and carbon tracer was seen subintimally.

Group 5 (long-term allograft—endothelium removed). The luminal surface was covered with a monomorphic layer of cells, resembling endothelium (Fig. 6). Intraluminal clot was not present, and carbon tracer was not present subintimally.

Group 6 (long-term autograft—endothelium removed). Ultrastructurally, the luminal surfaces of these arteries appeared indistinguishable from those of group 5. A monomorphic layer of cells covered the luminal surface. Intraluminal clot was not present, and carbon tracer was not seen subintimally.

Lymphocyte Infiltrates

Representative specimens of arterial and venous grafts from each of the four groups were examined for the presence of leukocyte infiltrates and T cell subsets by immunoperoxidase labeling with monoclonal antibody. No significant infiltrates were seen in autografts with an intact endothelium, whereas a mild intravascular infiltrate was seen in autografts with the endothelium removed. Occluded arterial and venous allografts with an intact endothelium both showed a mild–moderate infiltrate that was greater in the muscularis than the adventitia and had equivalent infiltrates of OX-8 and W3/25-positive T cell subsets. Patent arterial and venous allografts with removed endothelium also showed moderate T cell infiltrates of the same pattern and distribution as allografts with an intact endothelium. Sampling of grafts from Groups 5 and 6 (long-term allografts and autografts with removed endothelium) revealed the presence of a monomorphic layer of cells that showed positive labeling with anti-factor VIII-related antigen (Fig. 7) and negative staining with anti-vascular smooth muscle myosin (Fig. 8). Staining results for rat MHC antigens of donor ACI (R2/10P) and recipient Lewis (OX3) strains were negative for the former and equivocal for the latter.

Discussion

Current theory of vascular rejection suggests that allograft endothelial surface antigens serve as a stimulus to initiate host immune responses.[19] These surface antigens include MHC gene products such as class I and class II antigens, as well as non-MHC antigens, such as blood group and endothelial-monocyte antigens.[20,21] These alloantigens attract various mediators of the host immune response, especially cytotoxic T-cells, helper/suppressor T cells, and macrophages.[22,23] Our results show that vascular allografts with an intact endothelium become occluded, whereas vascular allografts without endothelium remain patent.

Evidence for endothelial rejection, thrombus formation, and graft occlusion has been based on observations in organ transplantation. However, rejection of a vascular allograft has not been described. This study shows that vascular allografts undergo changes similar to those seen with organ transplants. These ultrastructural changes include destruction of the endothelium and basement membrane, resulting in thrombus formation and graft occlusion. Similarly, the cellular infiltrates observed in preliminary immunopathologic analysis are consistent with infiltrates seen during rejection of organ transplants.

Previous studies have shown that in subjects given heparin before operation, de-endothelialized vessels become covered with a thin layer of platelets, erythrocytes, and other blood elements.[24] Within several days this surface becomes nonthrombogenic. Inflammatory cells, macrophages, and neutrophils, but apparently not lymphocytes, infiltrate the media of these vessels.[25] Simultaneously, endothelium adjacent to the area of injury begins to multiply and migrate, eventually covering the de-endothelialized portion of the vessel.[26]

Our study suggests that a similar process occurs with endothelial removal in allografts. Within 1 week after endothelial removal, allografts appeared to be covered with platelets, erythrocytes, neutrophils, and fibrin. Immunopathologic observations suggest that the de-endothelialized allografts are associated with an inflammatory response but, unlike autografts, are infiltrated with T cells. Moreover, unlike the allografts with endothelium, the vessels remained patent. Patent allografts harvested at 120 days after operation revealed that the luminal surface is covered by a monomorphic layer of cells ultrastructurally similar to endothelium. Further, these cells stained positively for factor VIII and had negative results for vascular smooth muscle myosin, also suggesting that they were endothelial in origin and probably host derived.

Although vascular allografts with and without endothelium have similar cellular infiltrates, endothelial removal precludes endothelial rejection and resultant thrombus formation. This alteration of acute rejection maintains vascular patency, ultimately resulting in resurfacing of the allograft vessel with host endothelium. These findings suggest that endothelial manipulation and appropriate anticoagulation in the absence of immunosuppressive therapy may provide a means of using nonautologous vessels for vascular replacement surgery.

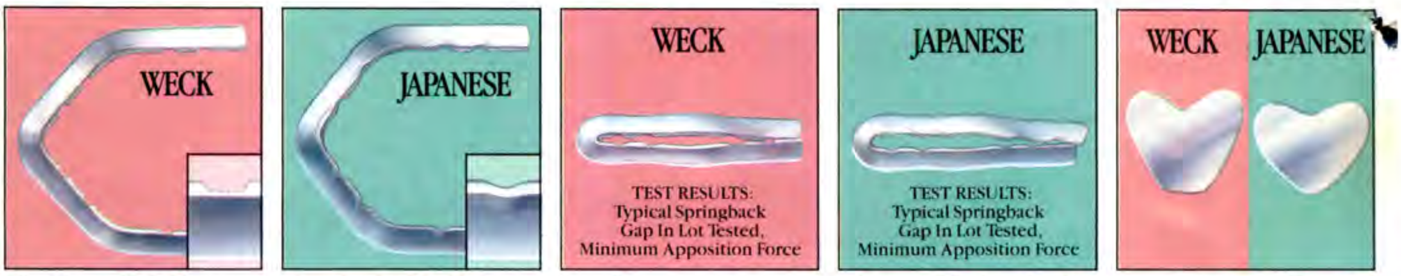
Hemoclip® ligating clips are made for blood vessels.

That sounds obvious, but it's not to everyone.

It's not easy to make ligating clips that are finely balanced between strength and malleability–two desirable ligating clip properties.

But in a quarter-century of manufacture, Weck has learned to do the job on this key implant device as no one else has.



The Hemoclip® ligating clip is coined with distinct rectangular transverse grooves, designed for longitudinal gripping power. Clip wire is processed metallurgially for malleability in closure. The Japanese imitation clips have shallow-drawn wire, and smaller, rounded transverse grooves. Deeper Hemoclip® wire shape aids retention in Weck appliers. (Typical closure illustrated from independent study.)

But now there's a problem you should be aware of. Some U.S.-based companies have begun distributing–not manufacturing–Japanese imitations of the Hemoclip® ligating clip. These clips are not the product of Weck manufacturing expertise and the technical performance of these clips is simply not the same as that of Hemoclip® ligating clips, an exclusive Weck product.

They may look the same, but they're not.

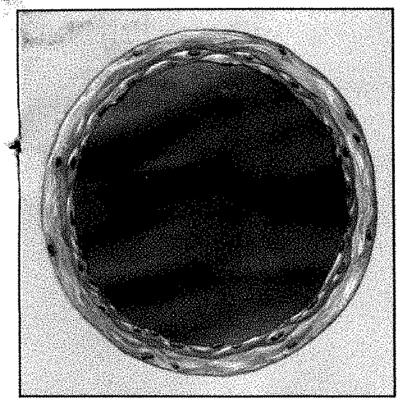
The recently-introduced Japanese clips look the same as Hemoclip® ligating clips to the naked eye. But a recently completed independent lab study of sample quantities of clips confirms Weck's own observation of substantial differences in closure properties between the Japanese clips and Weck clips.

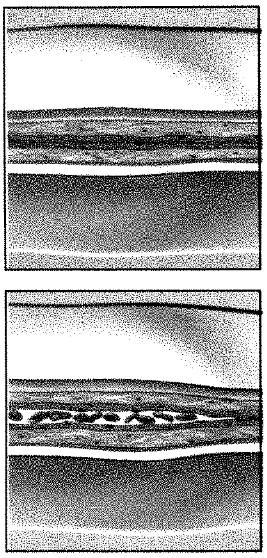
Vessel walls may be as thin as one-twelfth of vessel diameter.

Veins, in contrast to arteries, have very thin walls. When you consider that the vein tributaries ligated in surgery are sometimes one millimeter in diameter or smaller, with combined vessel walls as small as seven-thousandths of an inch (178 microns), according to animal studies on comparable vessels, you can appreciate the functional importance of differences in closure gap.

Arterial tributaries can be tiny, too, and although their walls are generally thicker than vein walls, arterial pressure is higher than venous pressure.

It seems prudent to employ ligating clips which offer the response and clip-closure performance Weck usage has established in your surgery.





ABOVE. A vein tributary of 1mm can have a combined wall thickness of just seven-thousandths of an inch (178 microns), according to animal studies. RIGHT. A ligating clip that demonstrates greater springback than the clip you have regularly used for such vessels may be more likely to leave a closure gap larger than the vessel-wall thickness of a tiny vessel.

Weck's titanium clip vs. their titanium clip. A 23-27% difference.

Examine the chart for a visual representation of the difference in closure springback an independent research firm discovered between a set of Weck titanium medium-size clips and a set of Japanese titanium medium-size clips obtained directly from U.S. distributors of those clips. Both sets of clips were closed in Weck appliers through use of force-control devices.

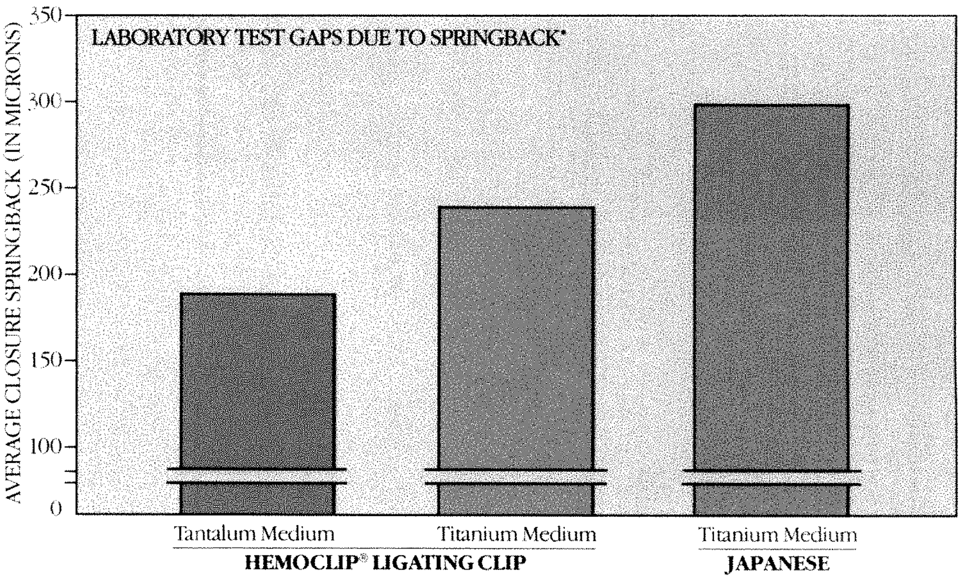
Closure of two sample sets of 25 Japanese titanium medium clips at forces adequate to achieve initial complete touching along clip legs resulted in closures of about 12 thousandths of an inch (305 microns) for the Japanese clips, 23-27% larger than the Weck titanium clip closure gap.

Weck's tantalum clips vs. their titanium clips. A 56% springback difference.

The comparison of Japanese titanium with Weck tantalum clips is even more important.

The Japanese companies make only titanium clips, and so they have sold hard on the benefits of titanium.

Tantalum is a softer material known for excellent clip closure. And the study revealed 56% and 61% larger mean closure gaps after springback for two sets of Japanese titanium clips, a ringing endorsement of the closure advantages of the Weck tantalum clips tested.



An independent lab study on two sample sets of 25 Japanese imitation clips vs. Weck clips found that the Japanese medium-size clips, closed to initial complete touching of clip legs, evidenced mean closure gaps, due to springback, 23-27% larger than Weck medium-size titanium clips, and 56-61% larger than Hemoclip® tantalum clips from Weck. Other sizes produced similar results. (Closure gap in microns-one micron = one thousandth of one millimeter).

**Stronger closure forces would likely be employed during actual surgery cases.*

The comparison was similar for Weck stainless vs. Japanese titanium, with the stainless scoring substantially smaller gaps after springback.

Odds are, if you are using Weck clips you are accustomed to tantalum or stainless steel clip closure, because the vast majority of Weck accounts use these two metals.

And a new Weck-funded NMR major-university study indicates that magnetic deflection of tantalum clips is negligible, just as it is for titanium clips. So if your local competitive salesman distributing Japanese clips tries to convince you that titanium clips are exclusively acceptable for NMR magnetic deflection in preference to tantalum, we suggest you cite the new Weck-sponsored university study.

Look for the Weck name on the cartridge.

To visually and quickly confirm that you really are using Weck clips, look at the end of the clip cartridge. If you are using Weck clips, you should see there the Weck name molded into the plastic. The Weck name is your assurance of genuine Hemoclip® clip processing experience and knowledge.

Repair of Large Abdominal Wall Defects with Expanded Polytetrafluoroethylene (PTFE)

JOEL J. BAUER, M.D., BARRY A. SALKY, M.D., IRWIN M. GELERNT, M.D., and ISADORE KREEL, M.D.

From the Department of Surgery, Mount Sinai School of Medicine, Mount Sinai Hospital, New York, New York

Most abdominal wall incisional hernias can be repaired by primary closure. However, where the defect is large or there is tension on the closure, the use of a prosthetic material is indicated. Expanded polytetrafluoroethylene (PTFE) patches were used to repair incisional hernias in 28 patients between November 1983 and December 1986. Twelve of these patients (43%) had a prior failure of a primary repair. Reherniation occurred in three patients (10.7%). Wound infections developed in two patients (7.1%), both of whom had existing intestinal stomas, one with an intercurrent pelvic abscess. The prosthetic patch was removed in the patient with the abscess, but the infection was resolved in the other without sequelae. Septic complications did not occur after any operations performed in uncontaminated fields. None of the patients exhibited any undue discomfort, wound pain, erythema, or induration. Complications related to adhesions, erosion of the patch material into the viscera, bowel obstruction, or fistula formation did not occur. Based on this clinical experience, the authors believe that the PTFE patch appears to represent an advance in synthetic abdominal wall substitutes.

THE MANAGEMENT of major abdominal wall defects or incisional hernias continues to be a fundamental problem for surgeons. Primary musculofascial repair is sufficient for most patients. There are, however, refractory cases where the use of a prosthetic material is indicated. During the course of this century, many materials have been tried with such variable results that skepticism exists among surgeons regarding the role of *any* prosthetic material in abdominal wall repair.

In an extensive review of the literature, Poole[1] found the incidence of abdominal incisional hernia to from 1 to 3%. A recent British study that followed patients up to 10 years after abdominal surgery reported an 11% incidence of incisional hernia, with most occurring within 3 years after operation.[2] The rate of incisional hernia after primary closure undoubtedly varies widely among surgical centers because of differences in surgical technique and patient population. Once herniation through the abdominal wall has occurred, studies indicate that 30% of patients who have repair without the use of a prosthetic patch will have a recurrence.[3,4]

A variety of prosthetic materials have been used for abdominal wall replacement with equivocal results. Complications of synthetic materials have been largely related to the intrinsic tendency of the materials to promote inflammation or serve as a nidus for infection. Theoretically, the ideal synthetic fascial substitute would be strong, biologically inert, noncarcinogenic, and stable in the presence of infection. Expanded polytetrafluoroethylene (PTFE) material appeared to meet these criteria. We report our experience with the recently developed expanded PTFE patch (GORE-TEX Soft Tissue Patch, W. L. Gore and Associates, Inc., Flagstaff, AZ) in a group of patients who had incisional hernias or abdominal wall defects of such magnitude as to preclude primary repair without prosthetic materials.

Clinical Material

Ninety-one incisional hernia repairs were performed by the authors at the Mount Sinai Hospital, New York, between November 1983 and December 1986. Repairs requiring the use of a prosthetic patch were performed in 28 patients (30.8%). There were 13 men and 15 women in this group, with an average age of 56 years (range: 27–79 years). Twelve patients (42.9%) had at least one previous repair of the incisional hernia. Of the hernias requiring a prosthetic patch, nine were associated with failed midline incisions, eight were present at prior os-

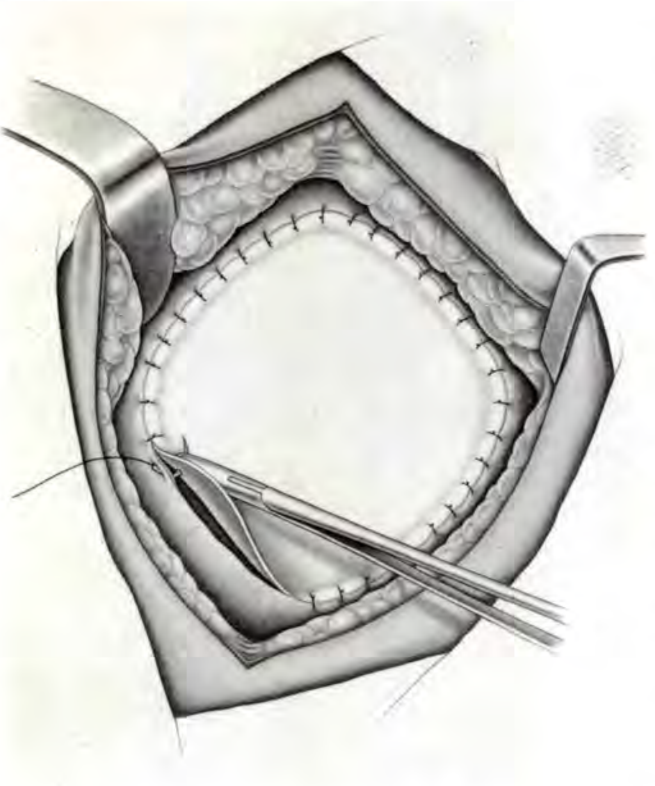

FIG. 1. Full-thickness implant of expanded PTFE patch in the tension-free repair of abdominal incisional hernia.

tomy sites, three involved failed flank incisions, and two were associated with incisions made for spinal fusion, with the balance at various other points in the abdominal wall. Only one defect was associated with a tumor (ovarian) that had infiltrated the substance of the abdominal wall. The dimensions of the hernias repaired with patch material varied between 5 × 8 cm and 12 × 20 cm.

Methods

A broad-spectrum antibiotic was administered to patients 6 hours before operation. Two patients had existing intestinal stomas, and one of these had an intercurrent pelvic abscess. The remaining 26 operations were performed in a clean, uncontaminated field.

After skin preparation with a povidone–iodine solution, the fascial margins of the incisional hernia were identified. The peritoneal cavity was entered, and any loops of intestine adherent to the parietal peritoneum near the fascial margin were dissected free to avoid injury to the bowel during the reconstruction. At this point, tension on the wound was assessed and, if a tension-free repair could be performed, the wound was closed with interrupted sutures. If not, an appropriately sized expanded PTFE patch of 2 mm thickness was implanted.

The prosthetic patches were trimmed to bridge the tissue defect. No attempt was made to re-establish the peritoneum between the prosthetic patch and the underlying viscera. The patch was sutured to the fascial margins with the use of interrupted number 0 polypropylene sutures. All sutures were placed 2–3 mm from the edge of the prosthetic patch. The patch was tailored so that normal abdominal contours were reconstituted while minimal tension was placed on the repair (Fig. 1). No drains of any kind were used.

Antibiotic administration was terminated 5 days after operation unless there was evidence of wound infection. The surgical wounds were inspected daily for general state of healing and any evidence of infection, erythema, induration, tenderness, seroma, hematoma, or abscess formation. Patients were walking on the first day after operation, fed when intestinal function resumed, and normally discharged from the hospital within 7 days. Patients were seen at 3- to 4-month intervals during the first postoperative year and at yearly intervals thereafter. No patients were lost to follow-up.

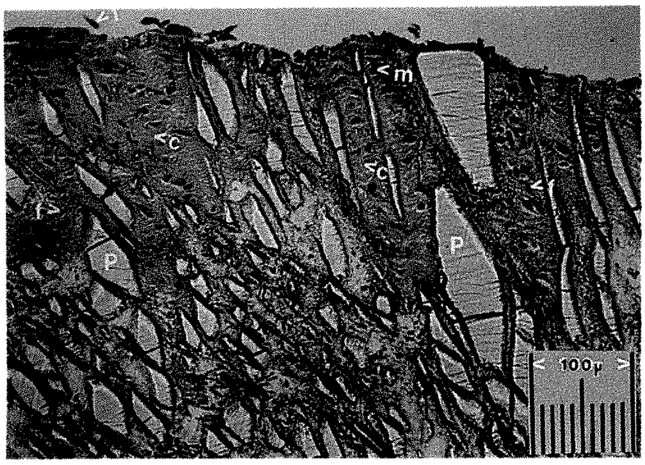
Results

Mean follow-up of patients receiving expanded PTFE patches was 22.5 months (range: 3.5–38 months). Twenty-three of the 28 patients (82%) had an uneventful postoperative course. None of these 23 patients demonstrated any adverse tissue reaction to the PTFE material. Erythema, edema, induration, and excessive pain at the operative site were not seen.

Reherniation occurred in three patients. These recurrences were noted at 3, 4, and 9 months after operation. The patient in whom a recurrence developed at 3 months was the only one who elected to return for reoperation. When this wound was explored 5 months after the original operation, a single polypropylene suture at the recurrence site was found lying free and untied in the subcutaneous scar tissue. This had allowed the fascia/patch interface to separate at its lateral inferior margin. A biopsy revealed firmly adherent fibrous tissue on the anterior surface of the patch. Fibroblasts were found within the interstices of the material, and collagen had penetrated into the anterior surface of the patch for a mean distance of 200 μm, demonstrating good healing within the 5-month period of implant. A minimal inflammatory response was noted (Fig. 2).

The remaining two recurrences were in patients who had previous repairs for incisional hernia. One of these also had undiagnosed liver disease and drained ascitic fluid through the wound for 5 days after operation.

Postoperative wound infections developed in two pa-



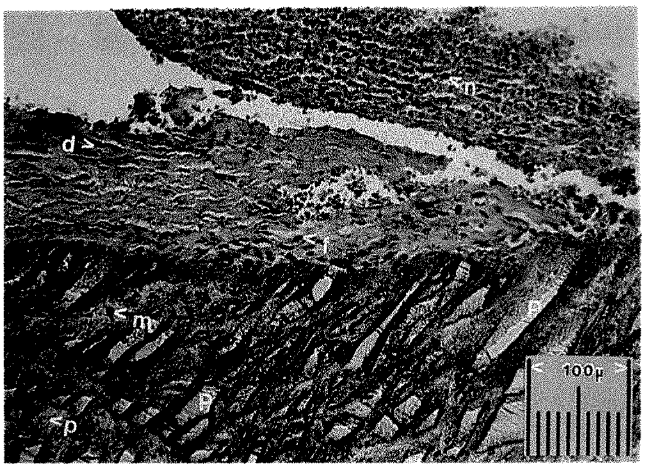


FIG. 2 (*left*). Biopsy specimen of expanded PTFE patch material obtained during reoperation for recurrent hernia. Good fibroblastic and collagen penetration is noted beneath healthy fibrous tissue on surface. f = fibroblast, c = collagen, m = macrophage, P = PTFE (node). (Hematoxylin and eosin stain, original magnification ×50.) FIG. 3 (*right*). Expanded PTFE patch removed from infection site. The patch material was covered (top) by a small fragment of fibrous tissue and a granular protein-neutrophil-erythrocyte matrix. Beneath the healthy tissue (center), slight infiltration of fibroblasts into the patch wall was evident. The remainder of the interstices was filled with thin granular protein. f = fibroblast, m = macrophage, n = neutrophil, p = protein, P = PTFE (node), d = degenerated cell mass. (Hematoxylin and eosin stain, original magnification ×50.)

tients. One patient, operated on for a massive parastomal hernia, had a low-grade wound infection that resolved with local and systemic antibiotic treatment. The sinus in this patient drained intermittently for 4 months but has now been closed for 3 months. In the other patient, the expanded PTFE patch, placed in the presence of multiple abdominal stomas and a pelvic abscess, became grossly infected. Attempts were made to salvage the patch, but after 10 days of local antibiotic, topical povidone–iodine treatment, and tissue debridement the patch was removed. There was a large amount of purulent exudate beneath it. Cultures revealed a variety of enteric organisms. After explantation, the wound healed well and eventually closed, leaving the patient with a large ventral hernia.

Histologic analysis of the explanted patch revealed slight healing at the suture line associated with a minimal inflammatory response. The remainder of the expanded PTFE material showed a degenerated cellular protein matrix usually associated with infection (Fig. 3).

Discussion

The lack of suitable musculofascial tissue in the proximity of the abdominal wall that can be used to repair defects has led to the use of synthetic prostheses when tension-free approximation of abdominal musculofascial tissues cannot be achieved. Abdominal wall reconstruction is, in fact, one of the few areas of surgical practice where the use of synthetic prostheses antedated the use of autologous tissue. Silver mesh was employed in Germany at the end of the last century[5,6] and was adopted in the United States by 1903.[7] Unfortunately, silver was found to corrode when in contact with tissue fluids and was replaced by mesh fabricated from the inert metal tantalum in 1940.[8]

The tendency of tantalum to fragment after repeated flexion in the tissues[9–11] was recognized before the 1950s, but the serious complications of small bowel fistula, ulceration, and erosion of metal fragments through the skin and peritoneum were not reported until the 1960s.[12–14] A variety of synthetic polymers discovered in the late 1950s and early 1960s soon became available for use in abdominal wall replacement. Two prosthetic mesh materials used in ventral hernia repair at the present time, polypropylene[15] (Marlex [C. R. Bard, Inc., Murray Hill, NJ], Prolene [Ethicon Inc., Summerville, NY]) and Dacron[16] (Mersilene [Ethicon Inc.]), date from this period. A third material, PTFE (Teflon, DuPont, Wilmington, DE), appeared promising in animal studies,[17] but clinical experience with mesh woven from solid Teflon fiber was so unfavorable[18] that its use was all but abandoned. With the discovery in the 1970s of a process to expand Teflon polymers into a porous form[19] (expanded PTFE), it once again became useful as a prosthetic material.[20]

Polypropylene has been the most widely used prosthetic patch material used in the repair of hernias[21] since its formulation and testing by Usher in 1963.[15] However, the clinical experience with polypropylene mesh has been replete with a variety of complications, such as wound sepsis,[22] erosion into intra-abdominal organs,[23] bowel fistula,[22,24,25] and mesh extrusion.[25] After review of the clinical and experimental data on expanded PTFE prostheses, it became apparent that the expanded PTFE material possessed several advantages, namely (1) it elicits a low foreign body reaction[26]; (2) it has low infectability[27,28]; (3) it exhibits a low rate of adhesion formation[29]; and (4) supports fibrous tissue incorporation.[30] In addition, expanded PTFE sheet material is soft and flexible and has been reported to produce a more aesthetic result with less patient discomfort when reconstituting abdominal contour.[31] These physical characteristics also reduce any tendency by the material to provoke sinus formation or erode into the abdominal viscera, leading to fistulae.

Prosthetic materials are employed during the repair of abdominal wall defects to avoid closure of the wound under excess tension, which might result in recurrent incisional hernia. In this series of patients, we have experienced three recurrent hernias, for an overall recurrence rate of 10.7%. One of the three was related to failure of a suture. The other two occurred in patients who had at least one prior recurrence, but the reason for the failure of their present repair is unknown. These results compare favorably with a recent study, using full-thickness placement of polypropylene mesh, that reported a 12% recurrence rate within 3 years of operation.[4]

There have been several studies that have compared prosthetic patch materials in terms of inertness, host tissue response, and adhesion formation. Elliot and Juler[32] studied the inflammatory reaction and fibroblastic ingrowth into polypropylene and expanded PTFE implanted into the abdominal walls of rabbits. They reported only a minimal inflammatory reaction engendered by the expanded PTFE. In contrast, the polypropylene mesh elicited a marked inflammatory reaction and was encased in a mass of dense scar tissue whose contracture had caused distortion of the graft. This same phenomenon was noted in a clinical study in which the outcome was extrusion of the polypropylene mesh.[25] Brown et al.[29] compared the two materials in full-thickness implants in the mid-abdominal wall of guinea pigs. Expanded PTFE produced significantly fewer adhesions than did polypropylene.

The minimal inflammatory reactions elicited by expanded PTFE in these experimental studies were confirmed in our clinical study. No patient exhibited any overt signs of inflammation at the site of the incision, such as erythema, induration, edema, or excessive pain. Moreover, histologic examination of the explants revealed a low foreign body response.

Both the PTFE material and its expanded configuration are critical to its long-term stability and function as a fascial replacement. The physicochemical properties of the polymer have long been known to elicit a negligible tissue reaction within the abdominal cavity.[33] The advent of the technique to expand the material into a microporous sheet of solid nodes connected by fine fibrils rendered it clinically useful. Fibroblasts are able to infiltrate the void spaces of the material and synthesize collagen within the interstices. The PTFE patch is incorporated with minimal inflammation, resulting in a strong, stable repair that exhibits few adhesions.

The clinical course of the wound infections noted in this study underscores the resistance to infection of expanded PTFE. A persistent draining sinus occurred in a patient who had repair of a very large paraileostomy hernia. After several months of antibiotic therapy, this sinus closed and the reconstruction is intact. The other septic complication occurred in a patient where there was massive intra-abdominal contamination from multiple existing intestinal stomas and an intercurrent pelvic abscess. Even though aggressive treatment failed to salvage the reconstruction, the patch material was not extruded from the wound and had to be surgically retrieved. In an animal study comparing bacterial adherence to polypropylene mesh and expanded PTFE, bacterial colonization per square centimeter of polypropylene was 100 times that of expanded PTFE.[29]

The two methods used to repair abdominal wall defects with synthetic prostheses are full-thickness implant or onlay reinforcement. Although both methods are considered safe, the risk of adhesion formation between the bowel and the prosthetic material and the risk of the material eroding into the bowel exists only with full-thickness implants. In this study, full-thickness implants were used in all cases, and no effort was made to reperitonealize beneath the prosthetic patch. During the follow-up period, no complications related to adhesions, erosion, or fistula formation have occurred. There have been several reports where erosion of polypropylene mesh into the esophagus and stomach,[23] the splenic flexure of the colon,[24] and the small bowel[22] have occurred, resulting in obstruction or fistula formation.

The lack of any fistula formation in this study may be fortuitous or may be related to the softness and conformability of expanded PTFE combined with the minimal inflammatory response it elicits. Further study and greater clinical experience should answer this question.

Effects of Indomethacin on Endocrine Responses and Nitrogen Loss after Surgery

TSUKASA ASOH, M.D., CHIAKI SHIRASAKA, M.D., ICHIRO UCHIDA, M.D., and HIDEO TSUJI, M.D.

In 14 patients who had elective gastrectomy, 50 mg of indomethacin was administered intrarectally every 6–8 hours after operation until postoperative day 3. Body temperature, plasma cortisol and glucagon concentrations, blood glucose level, urinary catecholamine level, and urinary nitrogen excretion level were compared with those of 16 patients who did not receive indomethacin. Postoperative fever was significantly reduced by indomethacin. Plasma cortisol levels in the indomethacin-treated group were significantly lower on postoperative days 2 and 3. Postoperative increases in plasma glucagon and blood glucose levels were not influenced by indomethacin administration. Urinary epinephrine excretion tended to be inhibited, and urinary norepinephrine excretion was significantly inhibited in the indomethacin-treated group after operation. Urinary nitrogen excretion levels during the observation period were significantly less in the indomethacin-treated group. The cumulative urinary nitrogen level from postoperative days 1–3 in the indomethacin-treated group was 82% of that in the control group. These results indicated that fever reduction by indomethacin after surgery resulted in reduced protein loss, associated with attenuated cortisol and catecholamine responses.

LOSS OF BODY PROTEIN, which is indicated by negative nitrogen balance, is a prominent characteristic of the metabolic changes in patients with infection, trauma, and other stress states. Mechanisms of the protein loss are not well understood, although the involvement of endocrine mediators[1,2] and of neural stimulation[2,3] have been demonstrated. We have previously reported that epidural local anesthetics or epidural morphine reduced nitrogen loss after upper abdominal surgery.[2]

During infection, fever and inflammatory mediators such as prostaglandins are thought to be additional triggering factors of catabolism,[4,5] and it has been suggested that indomethacin, an inhibitor of prostaglandin synthetase, may prevent proteolysis in patients with sepsis.[4]

From the Department of Surgery, Medical Institute of Bioregulation, Kyushu University, Beppu, Japan

In elective clean surgery in which patients have postoperative fever but have no infection, the role of the inflammatory mediators in protein catabolism is not known. It is also not known whether fever *per se* affects the endocrine system and catabolic processes. Therefore, this study was planned to evaluate the effect of fever reduction by indomethacin on endocrine responses and nitrogen balance after elective uncomplicated surgery.

Patients and Methods

Thirty patients who had elective gastrectomy for cancer or ulcers were studied. There were no patients who had hepatic and renal diseases, nor had they any hormonal or metabolic disorders. None had inflammatory diseases or fever, and no patient had any medications before operation. Patients with poor nutritional status, estimated by body weight and plasma albumin level, and patients who received noncurative operation because of advanced cancer were excluded from the study. Patients in whom operative blood loss exceeded 1000 mL were also excluded. Informed consent was obtained for participation in the study.

All of the patients were operated on while under epidural analgesia with the use of 0.5% plain bupivacaine extending to the Th_{3-4} segment. The detailed technique of the epidural analgesia employed was the same as has been previously described.[6] For postoperative pain relief, morphine hydrochloride 3 mg/10 mL saline was administered through the epidural catheter every 8 hours, starting at 1 hour after operation until 6:00 A.M. on postoperative day 4. By this regimen, patients were all pain-free after operation and did not require supplementary analgesics.

Submitted for publication: April 24, 1987.

TABLE 1. *Patient Characteristics*

	Control Group (N = 16)	Indomethacin-treated Group (N = 14)
Sex: male/female	13/3	10/4
Disease: cancer/ulcer	15/1	12/2
Gastrectomy: total/ partial	7/9	1/13
Age (years)	61 ± 3	60 ± 3
Height (cm)	157.1 ± 1.4	158.4 ± 2.2
Weight (kg)	50.7 ± 1.5	53.7 ± 2.2
Albumin (g/dL)	4.2 ± 0.1	3.8 ± 0.1
Operation time (min)	212 ± 12	199 ± 11
Blood loss (mL)	426 ± 62	383 ± 58

Intravenous infusion during operation was restricted to lactated Ringer's solution only. However, when blood loss during operation exceeded 500 mL, the same amount of citrated whole blood was transfused. After operation, 1000 mL of 10% glucose solution was administered. On the first 3 postoperative days, 3 g/kg body weight of glucose was infused, together with appropriate amounts of electrolyte solutions, the total amount of water being adjusted to 2000–2500 mL. No amino acid solution was infused throughout the study. Food intake did not start before postoperative day 4. All of the operations started between 9:00 A.M. and 10:00 A.M., after overnight fasting.

The patients were randomly allocated into two groups: the indomethacin-treated group (N = 14) and the control group (N = 16). In the indomethacin-treated group, the suppository containing indomethacin 50 mg was administered starting at 1 hour after operation, every 6 hours on the day of operation, and every 8 hours on the first 3 postoperative days. No indomethacin was administered to the control group.

Peripheral arterial and venous blood samples were drawn five times from each patient: before preanesthetic medication, 30 minutes after skin closure, and at 8:00 A.M. on postoperative days 1, 2, and 3. A part of each venous blood sample was transferred to a chilled tube, and the plasma for cortisol analysis was immediately separated. Another part of the sample was transferred to a chilled tube containing EDTA-2K2Na/Trasylol® (Aprotinin, Bayer AG, Leverkusen, West Germany) and the plasma for the measurement of glucagon was immediately separated. Each plasma sample was stored frozen until analysis. Glucose levels were measured in the arterial blood samples. Twenty-four–hour urine samples were collected in glass bottles containing 15 mL of 6 N HCl from the day before operation until postoperative day 3. Plasma cortisol levels were measured by radioimmunoassay with the use of the GammaCort cortisol kit (Baxter Travenol Diagnostics, Inc., Cambridge, MA), glucagon levels by radioimmunoassay with the use of pancreatic glucagon-specific antibody,[7] and glucose levels by a routine glucose oxidase method. Measurement of urinary epinephrine and norepinephrine levels was performed by use of a high-speed ion-exchange column chromatography and the automated trihydroxyindol method.[8] Urinary nitrogen was measured by the micro-Kjeldahl method.

Values were expressed as mean ± standard error of the mean. Statistical analysis was performed with the use of Wilcoxon's rank sum test; $p < 0.05$ was considered significant.

Results

The characteristics of the patients studied are summarized in Table 1. The ratio of total gastrectomy in the control group tended to be greater than in the indomethacin-treated group. However, the other characteristics were all comparable between the groups.

Body Temperature

Axillary temperature was recorded at 6:00 A.M., 10:00 A.M., 3:00 P.M., 6:00 P.M., and 9:00 P.M. in each patient. Individual maximum values in the morning and/or those in the afternoon were averaged and listed in Table 2. In the control group, highest body temperature was observed in the afternoon on the day of operation, after which body temperature gradually returned toward normal. In the indomethacin-treated group, body temperature also showed a peak value in the afternoon on the day of operation, although the value tended to be lower than in the control group. On the first 3 postoperative days, mean values of body temperature in the indomethacin-treated group were consistently lower than in the control group and showed statistically significant differences ($p < 0.05$ or $p < 0.01$, Table 2).

Cortisol

The preoperative cortisol level in the control group was higher than in the indomethacin-treated group, but the difference was not statistically significant. In the control group, plasma cortisol concentration increased at 30 minutes after operation and lowered thereafter. In the indomethacin-treated group, plasma cortisol concentrations were almost the same as in the control group at 30 minutes after operation and on postoperative day 1. However, plasma cortisol concentrations on postoperative days 2 and 3 were significantly lower ($p < 0.01$) in the indomethacin-treated group than in the control group (Table 3).

Glucagon

The preoperative plasma glucagon concentration in the control group was slightly lower than in the indomethacin-treated group, although there was no significant difference between the groups. In the control group, plasma glucagon concentration did not change from the baseline value at 30 minutes after operation. On postoperative day 1, glucagon concentration in the control group increased to 160% of the baseline value and then gradually decreased. Plasma glucagon levels in

the indomethacin-treated group showed a similar pattern as in the control group. However, values in the indomethacin-treated group were consistently higher than in the control group. There was a significant difference ($p < 0.05$) between the groups at 30 minutes after operation (Table 4). When percentage changes from the baseline values were compared, there were no significant differences between the groups at any points in time after operation.

Glucose

In the control group, blood glucose levels increased at 30 minutes after operation and returned toward the preoperative level thereafter. Blood glucose levels in the indomethacin-treated group showed an almost similar pattern as in the control group. There were no significant differences in blood glucose values between the groups (Table 5).

Urinary Epinephrine Excretion

In the control group, the urinary epinephrine level showed an approximately threefold increase on the day of operation, then gradually returned toward the preoperative value. Urinary epinephrine excretion on postoperative day 3 was still greater than the preoperative value. In the indomethacin-treated group, urinary epinephrine increased on the day of operation, remained high on postoperative day 1, and returned toward the preoperative value thereafter. Urinary epinephrine excretion on the day of operation and on postoperative days was consistently less than that of the control group, although the differences were not significant (Table 6).

Urinary Norepinephrine Excretion

In the control group, urinary norepinephrine increased only slightly on the day of operation but then increased to higher levels on the postoperative days, showing a maximum value on postoperative day 1. In the indomethacin-treated group, the time course of urinary norepinephrine excretion was the same as in the control group. However, norepinephrine excretion in the indomethacin-treated group was significantly less ($p < 0.01$) than in the control group on postoperative days 2 and 3 (Table 7).

Urinary Nitrogen Excretion

In the control group, sustained nitrogen excretion levels of more than 140 mg/kg/day were observed on postoperative days. In the indomethacin-treated group, the urinary nitrogen excretion level on the day of operation was significantly less ($p < 0.05$) than in the control group. Nitrogen excretion levels on postoperative days were consistently less in the indomethacin-treated group than in the control group. There were significant differences ($p < 0.05$) in nitrogen excretion levels on postop-

erative days 1 and 3 between the groups. Cumulative nitrogen excretion of the 3 postoperative days was 82% of that of the control group, the difference being statistically significant ($p < 0.05$, Table 8).

Postoperative Course

No side effects related to the administration of indomethacin were noted. All patients recovered uneventfully.

Discussion

In this study, indomethacin administered for 4 days after elective gastrectomy reduced postoperative fever associated with decreased cortisol and catecholamine responses and reduced nitrogen loss. Aspirin-like drugs are known to reduce fever resulting from infection or pyrogen mediated by the inhibition of synthesis of prostaglandins in the central nervous system.[9] Although the mechanism of postoperative fever is not clear, our present results indicate that febrile response to clean elective surgery can also be effectively reduced by indomethacin.

On postoperative days 2 and 3, when fever was significantly reduced by indomethacin, both cortisol and norepinephrine responses were inhibited. Indomethacin has an analgesic effect, and postoperative pain is considered to stimulate adrenocortical and sympathetic responses.[2,10] It is unlikely, however, that the lowered hormonal responses in the indomethacin-treated group resulted from the analgesic effect of the drug because postoperative pain was almost completely relieved by epidural morphine, irrespective of the indomethacin treatment.

The mechanism of the reduced cortisol and catecholamine responses by indomethacin is unclear. There are many studies as to whether prostaglandins mediate adrenal steroidogenesis, but the results are controversial.[11-14] Although prostaglandins have been reported to modulate sympathetic nerve transmission, the suppressive or

facilitating effect depends on the types of prostaglandins.[15] Reports on the effects of prostaglandins on the release of catecholamines from the adrenal gland are conflicting, probably because of the difference in species studied and the types of prostaglandins.[16–18] It is thus difficult to explain the hormonal suppression by the inhibition of prostaglandin synthesis in the peripheral organs. Weeke and Gundersen[19] and Kim et al.[20] reported that artificial hyperthermia induced by heating elicited an increase in plasma norepinephrine. This fact is in accordance with our result in which norepinephrine response was decreased by fever reduction. Change in body temperature may also have an influence on activity in the pituitary adrenocortical axis, although no reported evidence is available.

Glucagon, together with cortisol and catecholamines, is an important catabolic hormone.[21,22] We have suggested that glucagon may contribute to postoperative nitrogen loss.[2] In contrast to the suppressive effect of indomethacin on cortisol and catecholamine responses, this drug did not affect postoperative glucagon response. Glucagon is thus not responsible for the decreased nitrogen loss in this study.

We have reported the inhibitory effect of epidural blockade and splanchnic nerve blockade on hyperglycemic response as well as endocrine responses.[23] However, hyperglycemic response to gastrectomy was mainly observed during and immediately after operation, and neither type of neural blockade affected the slightly elevated blood glucose levels in the later postoperative period.[23] In this study, indomethacin administered after surgery also had no influence on blood glucose levels, although it suppressed febrile and hormonal responses, as mentioned above.

Postoperative administration of indomethacin not only suppressed the endocrine responses but also reduced nitrogen loss. Rowe et al.[24] reported that indomethacin given after fracture stress in rats suppressed the increase in fibrinogen, an acute phase reactant, which may suggest a reduced catabolic response to trauma. They also studied the effects of indomethacin combined with prostaglandin E_2 on the urinary excretion of nitrogen, urea, and creatinine and found that the production of the nitrogenous compounds was reduced by indomethacin.[25] Goldberg et al.[26] reported that administration of indomethacin *in vivo* to endotoxin-treated rats prevented the increase in proteolysis in isolated muscle tissue. These results suggest that inhibition of prostaglandins by indomethacin results in a reduced protein degradation. However, the involvement of the prostaglandin system in protein loss after surgery is not proven.

Because catabolic hormones are important mediators in protein catabolism,[1,2] the attenuated hormonal responses caused by indomethacin possibly contributed to the decreased nitrogen loss in this study. On the other hand, Baracos et al.[4] reported that rat muscle incubated in a medium at 39 C showed a greater increase in proteolysis than at normal body temperature. This result suggests that an increase in body temperature directly promotes protein breakdown in the muscle, and therefore fever reduction by indomethacin may have resulted in the reduced negative nitrogen balance.

In this study, fever reduction after surgery did not cause any detrimental effect. A benefit in using prostaglandin synthetase inhibitors in endotoxin or septic shock has been demonstrated,[27] although caution in its use has been suggested.[28] Whether the reduction of postoperative fever benefits patients should further be investigated.

In conclusion, the administration of indomethacin after elective gastrectomy resulted in reduced negative nitrogen balance after surgery. This reduced catabolic response may have been caused by associated inhibition of cortisol and catecholamines and by the direct effect of fever reduction.

One hundred forty-one dilatations of stenotic lesions in dialysis access fistulas were performed. The initial success rate was 82%. The one-year patency rate was 45%, with a 2-year patency rate of 24%. Best results were obtained with a discrete stenosis at a graft-to-vein anastomosis. The procedure can be done on an outpatient basis and, although long-term results are poor, in appropriate patients multiple dilatations can be performed to keep a fistula functioning for many years.

THE INCREASING NUMBER of patients with end-stage renal disease in the United States has created the need for reliable vascular access. The initial and favored procedure for the creation of an access fistula is the direct arteriovenous (A-V) fistula of the Brescia-Cimino type.[1,2] If this fistula fails or is not feasible, a graft made of polytetrafluoroethylene (PTFE) or bovine carotid artery can be placed subcutaneously between an artery and vein to provide access.[3–6]

The most common problems encountered with A-V fistulas and grafts are inadequate dialysis and graft thrombosis.[2,7] These usually result from a venous outflow stenosis or, less frequently, from inadequate inflow from an arterial lesion. Treatment has consisted of surgical revision of the stenosis or graft replacement at a different site. An alternative to surgical revision is treatment *via* percutaneous angioplasty. In this article we present our experience with dilatation of 141 stenotic lesions in dialysis access fistulas over a 7-year period.

Materials and Methods

Over the past 7 years we have performed 141 dilatations in 95 patients. Indications for angiography included repeated graft thrombosis (31 patients), inadequate dialysis with high recirculation (65 patients), high venous pressure during dialysis (75 patients), arm edema (15 patients), and enlarging venous aneurysms or graft pseudoaneurysms (13 patients).

One hundred twelve dilatations were performed in patients with grafts. Of these, three stenoses were at the arterial anastomosis, and 93 at the venous anastomosis. Sixteen venous stenoses were proximal to the anastomosis in the axillary or subclavian vein. Twenty-nine lesions were dilated in patients with direct A-V fistulas. Of these, 15 were in the outflow vein within 5–6 cm of the A-V connection and 14 in a vein distant from the A-V connections (five at the elbow, five in the axillary vein, and four in the subclavian vein).

Direct A-V fistulas were studied either by direct brachial artery puncture or by a venous puncture with inflation of a pressure cuff proximally to allow reflux of contrast into the arterial system.[8,9] Grafts were studied *via* a 5-F catheter placed directly in the venous end of the graft. If the arterial anastomosis needed to be visualized, a pressure cuff was inflated proximally to allow reflux of contrast into the arterial system. No study results were considered negative until the entire venous system to the level of the subclavian vein was visualized. Spurious narrowing of the axillary vein may be created by compression of chest wall muscles when the arm is in an adducted position, so this area is always studied with the arm abducted.

After delineation of the lesion, the stenosis was crossed with a 5-F catheter and a pressure pullback obtained. An appropriate size dilatation catheter was then chosen, depending on the size of the graft and normal vein on either side of the stenosis. Lesions longer than 4 cm were referred for surgery because these were univer-

sally unsuccessful in our early experience. The dilatation catheter was introduced through the graft. There have been no problems introducing large balloon catheters through grafts that are older than 1 month old, and no pseudoaneurysms have developed at the puncture site after dilatation. Before dilatation the patient is given 3000 units of heparin intravenously (I.V.). Dilatation of veins may be painful. Infiltration of lidocaine around the stenotic lesion before balloon inflation may alleviate some of the pain. The first 50 cases were dilated with standard balloons that generated pressure of 3–4 atmospheres. The last 91 dilatations were done with high-pressure balloons that generate 10 atmospheres pressure. The dilatation pressure is monitored and the balloon left inflated for 1–2 minutes. Most patients received treatment on an outpatient basis and were observed for 30 minutes in the angiography suite after the procedure before being sent home.

Immediate results after the procedure were evaluated by angiography and pressure pullback. Long-term results were evaluated *via* clinical symptoms and efficacy of dialysis.

Results

Three patients died within 2 months of the procedure (causes of death unrelated to the dilatation), and 18 patients were lost to follow-up. Initial and long-term results are summarized in Table 1.

There were nine complications (6%): six graft thromboses within 48 hours of the procedure and three venous ruptures. All three ruptured veins were controlled by manual occlusion of the fistula and pressure dressings. None required transfusion or emergency surgery. All three were operated on electively within 1–7 days after procedure.

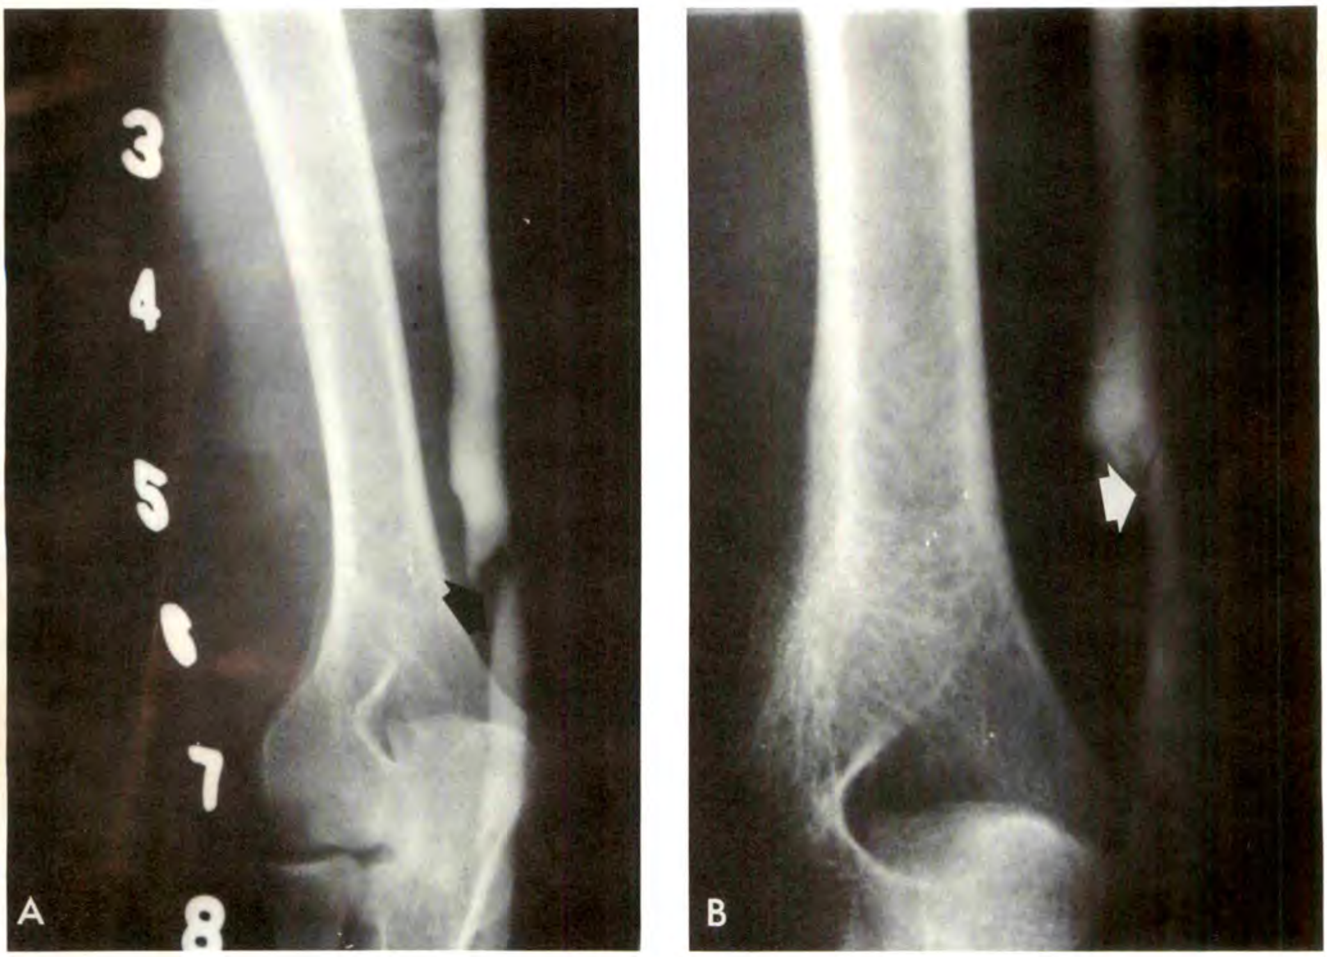
Discussion

Clinical problems necessitating fistula study include repeated thrombosis and inadequate dialysis as manifested by arterial sucking, high venous pressure, and recirculation of dialyzed blood.[2,9] These problems usually indicate poor arterial inflow or inadequate venous outflow. Other problems include arm edema, enlarging venous or graft aneurysms and pseudoaneurysms, and venous varicosities. These usually result from venous outflow obstruction.

Over the past 2 years, 800 graft and direct A-V fistulas have been surgically revised at Downstate Medical Center. Causes of fistula failure included a venous outflow stenosis in 70%, an arterial stenosis in 10%, and a combination of the two in 15%. Both the venous and arterial lesions invariably resulted from intimal hyperplasia, even in those fistulas corrected as early as 2 months after creation.

The most common operation performed was a thrombectomy and venous patch angioplasty. Only 20% of patients with a vascular access problem have diagnostic angiography. The remainder generally have complete fistula thrombosis and have surgical correction. Of those patients studied angiographically, approximately 90% have a venous outflow problem, either a total occlusion or significant stenosis. Approximately 40% of all patients studied have a lesion amenable to angioplasty.

Venous stenoses in direct A-V fistulas generally occur within 5–6 cm of the A-V communication. Graft venous stenoses usually occur at the graft-to-vein anastomosis or within 2–3 cm of the anastomosis.[9–13] Anastomotic venous lesions result from the combination of intimal hyperplasia and perivenous fibrosis. These stenoses are often resistant to dilatation and necessitate the use of high-pressure balloons.[14] Our last 91 angioplasties have been performed with high-pressure catheters (10 atmospheres), resulting in improved initial results (88% *vs.* 67% with standard balloons generating 3–5 atmospheres). Long-term results have been the same with both types of balloons. The turbulence and abnormal shear stresses thought to play a role in the deposition of platelets and thrombi that eventually lead to endovenous fibrosis and stricture are still present after dilatation and inevitably lead to restricture.

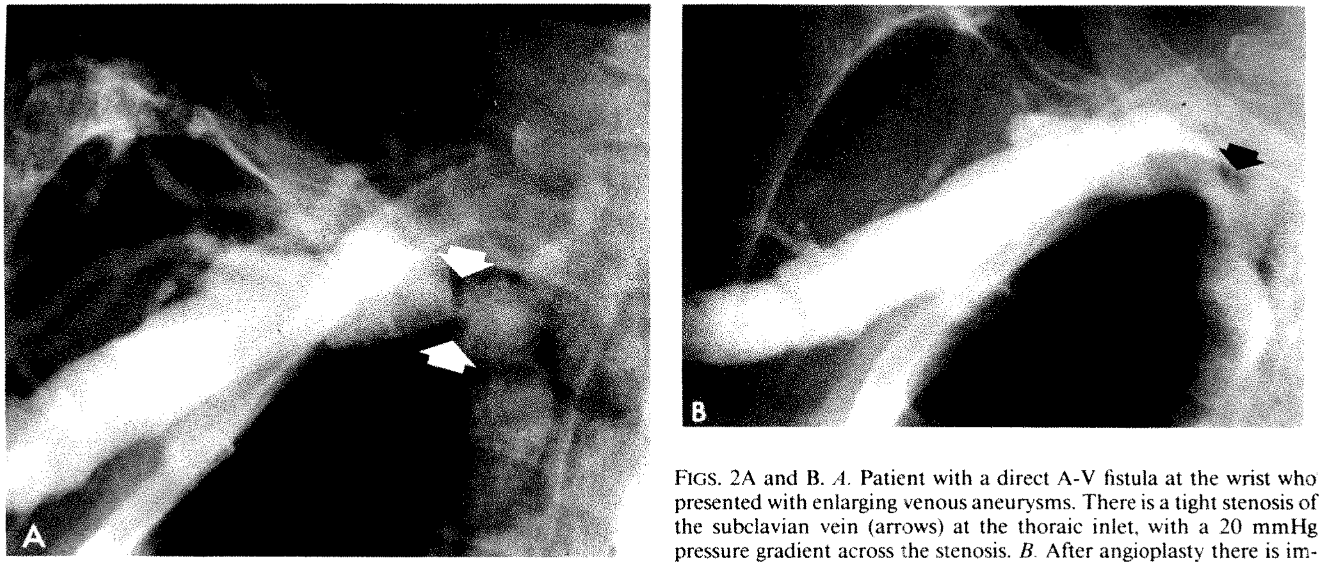


FIGS. 1A and B. *A*. There is a tight stenosis (arrow) at the anastomosis of a GORE-TEX (W. L. Gore and Associates, Inc.) graft to the basilic vein. *B*. After angioplasty there is significant widening of the stenosis (arrow), and the pressure gradient has been reduced from 60 mmHg to 0 mmHg.

Venous stenoses near the anastomosis of a direct A-V fistula are generally longer than the more discrete graft anastomotic venous lesions. This probably accounted for the better results obtained with graft dilatations (Fig. 1). Our results with long stenoses were so poor that we no longer perform dilatation in patients with lesions longer than 4 cm. Two total occlusions were treated. One was a short segment occlusion at the anastomosis of a graft to the basillic vein and the other was at the anastomosis of a graft to the axillary vein. A straight wire passed through the occluded segment easily. One dilatation was unsuccessful, and the other was patent for only 2 weeks. We now refer patients with total occlusions for surgical correction. New anastomotic sites are not dilated for a minimum of 4 weeks after operation, to preclude dehiscence of the anastomosis.

Stenosis may also occur within a graft because of progressive pseudointimal hyperplasia or trauma from repeated puncture. We have not dilated intragraft lesions because of the lack of muscular structure and elasticity in a graft and the subsequent risk of graft rupture. Intragraft lesions are usually long because of the widespread nature of pseudointimal hyperplasia.

Thirty proximal venous strictures were dilated. These tend to occur at sites of physiologic narrowing, the most common being in the cephalic vein at the elbow; the axillary vein, which is compressed by chest wall muscles when the arm is adducted; and the subclavian vein as it crosses between the clavicle and first rib (Fig. 2). Hypertrophied valves may also cause venous obstruction. Large valves most commonly occur in the axillary vein at the lower border of the subscapularis muscle and in the subclavian vein 2–3 cm proximal to its junction with the internal jugular vein (Fig. 3). Sites of previous central venous lines may also stricture when subjected to abnormal flow patterns. Three of the subclavian vein stenoses were at sites of a previous Shiley catheter. The turbulence created by high flow in a venous system with a physiologic or iatrogenic narrowing leads to eventual intimal hyperplasia and stenosis. Because of the fre-



FIGS. 2A and B. *A*. Patient with a direct A-V fistula at the wrist who presented with enlarging venous aneurysms. There is a tight stenosis of the subclavian vein (arrows) at the thoracic inlet, with a 20 mmHg pressure gradient across the stenosis. *B*. After angioplasty there is improvement of the lesion (arrow), with a decrease in the pressure gradient to 3 mmHg. There is still a residual narrowing caused by compression of the vein as it passes between the clavicle and first rib.

quency of proximal venous lesions (21%), all patients should be evaluated to the level of the subclavian vein before study results are considered negative. If angiograms are equivocal, pressure pullback from the superior vena cava to the anastomosis should be performed. Although there is normally a gradual venous pressure increase as one pulls back from the superior vena cava to the axillary vein, a discrete gradient of more than 5–10 mmHg should be considered significant. Because the anatomic problem that precipitated these stenoses is still present after dilatation, proximal venous lesions tend to recur more quickly than anastomotic stenoses.

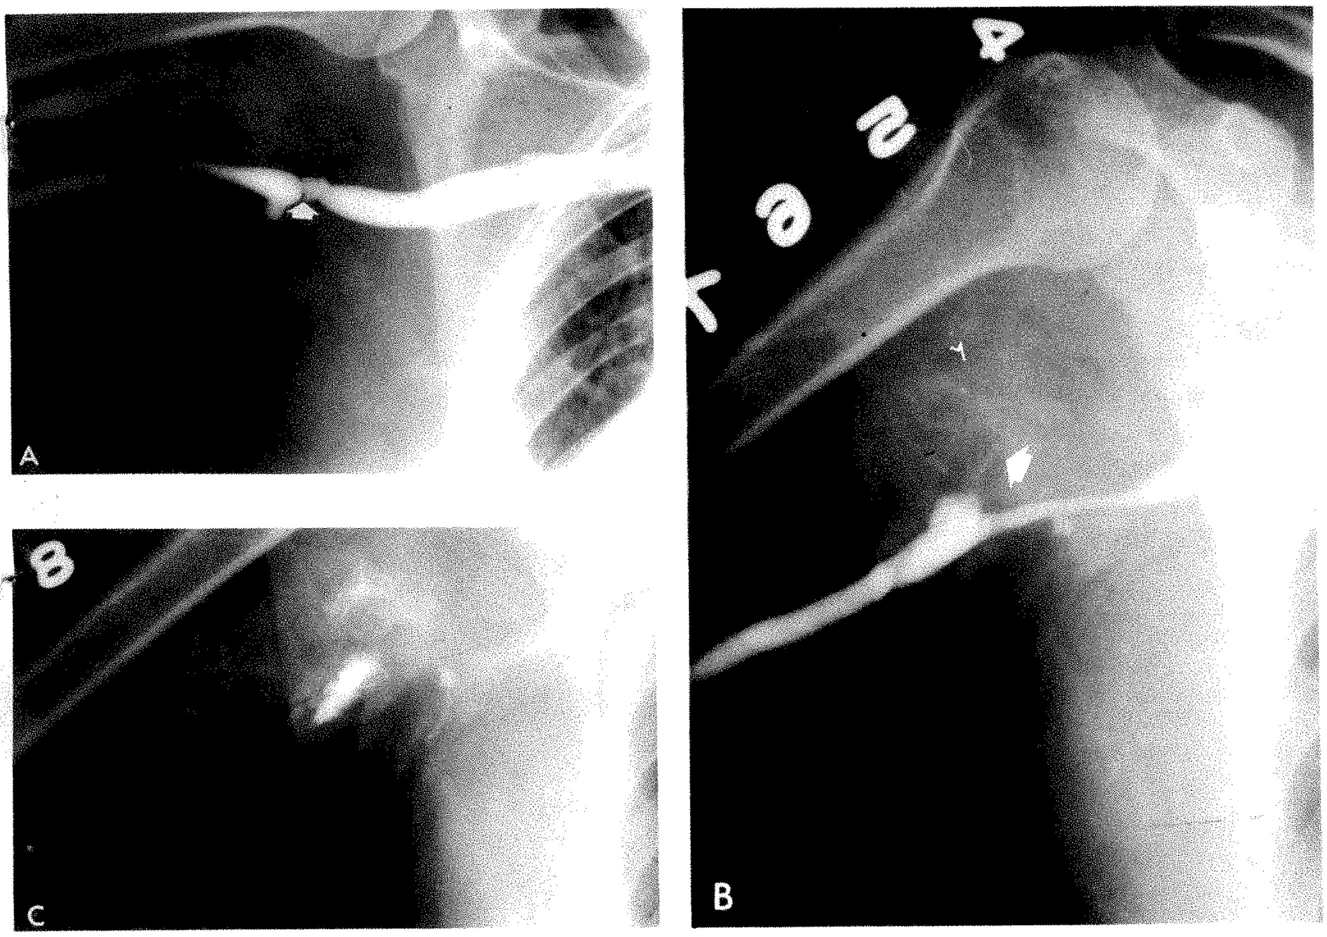
Venous stenosis and hypertension may cause other problems such as arm edema, enlarging venous aneurysms and varicosities, and enlarging graft pseudoaneurysm.[9,15] These clinical problems should alert the physician to a possible venous outflow obstruction and study should include the entire venous system to the subclavian vein. These problems can often be alleviated by angioplasty (Fig. 2).

Most angioplasties were technically not difficult and were performed on an outpatient basis. Once a graft has been incorporated into the subcutaneous tissues, puncture of the graft and introduction of a balloon catheter can be performed without difficulty. No significant problems have been encountered in removal of the catheter from the graft, and no pseudoaneurysms have occurred at the puncture site.

Complications included graft thrombosis (4%) and extravasation at the dilatation site (2%) (Fig. 3). Extravasation was controlled by compression of the fistula and a pressure dressing at the site of venous rupture. No patients required emergency surgery or blood transfusion.

It is clear that angioplasty, although initially effective, does not solve the long-term problem of recurrent venous outflow obstruction. However, angioplasty is safe and relatively simple and can be performed on an outpatient basis. A failed angioplasty or fistula thrombosis means the patient can still have the surgical correction that would have been done before angioplasty. Dilatation can be repeated numerous times to keep a fistula functioning for many years, often for the rest of the patient's life. Several patients have had multiple dilatations to keep a fistula patent for 4–5 years. We feel that any patient with a stenotic lesion less than 4 cm in length at or near a graft-to-vein anastomosis should have angioplasty before surgical repair. Expected patency rates at this location are 50% at 1 year and 32% at 2 years. Patients with proximal lesions in the axillary or subclavian vein, areas difficult to approach surgically, should also be treated primarily with angioplasty. Patients with a Brescia-Cimino type direct A-V fistula at the wrist who have a good radial artery and cephalic vein proximal to the stenosis may do better with a more proximal side-to-side direct fistula because of the high long-term patency of this type of vascular access.

Patients on chronic hemodialysis for more than several years are likely to have multiple surgical corrections of their vascular access. More aggressive angiography at the earliest sign of any problem coupled with angioplasty can help preserve many of these fistulas and decrease the hospitalization time and the number of corrections in this group of patients who have already had



FIGS. 3A–C. *A*. Patient with a GORE-TEX graft to basilic vein anastomosis who presented with high venous pressure during dialysis. There is a stenosis in the axillary vein caused by a hypertrophied valve (arrow). *B*. After angioplasty there is still narrowing of the axillary vein and the beginning of extravasation (arrow). *C*. A late film demonstrates contrast extravasation. The patient was treated by compression of the graft and a pressure dressing. The fistula was electively corrected.

and are still likely to have numerous surgical procedures during their lives.

Total Thyroidectomy

The Preferred Option for Multinodular Goiter

T. S. REEVE, M.B.B.S., F.R.A.C.S., F.A.C.S., L. DELBRIDGE, M.D., F.R.A.C.S., A. COHEN, M.B.B.S., F.R.A.C.S., and P. CRUMMER

Total thyroidectomy is an operation that has generally been reserved for the management of differentiated thyroid carcinoma. Over the last decade total thyroidectomy has become used increasingly and is now the preferred option in the authors' unit for the management of multinodular goiter affecting the entire gland. Over the period from 1975 to 1985, 853 thyroidectomies have been performed for multinodular goiter; of these, 115 have been total thyroidectomies. During that time, the incidence of total thyroidectomy for multinodular goiter has increased in percentage terms from 9% in 1975 to 50% in 1985. There have been two cases of permanent hypoparathyroidism and one case of permanent recurrent laryngeal nerve injury, and these occurred in patients who had less than total thyroidectomy. Total thyroidectomy is an appropriate operation for the management of diffuse multinodular goiter where the entire gland is involved because it precludes patients from requiring further surgery for recurrent disease, with its high associated risks. It must be emphasized, however, that protection of the recurrent laryngeal nerve and parathyroid glands must still be paramount in dealing with benign thyroid disease.

From the Department of Surgery, The University of Sydney at Royal North Shore Hospital, Sydney, Australia

IN MANY AREAS OF SURGERY there is a balance between the benefits from extensive resection in terms of palliation and cure and the increased potential for complications associated with more radical procedures. Total thyroidectomy is such a procedure, where considerable controversy still exists with respect to its use for conditions such as differentiated thyroid carcinoma.[1,2] Even more controversial is its use for benign thyroid disease such as multinodular goiter or thyrotoxicosis.[3] On the other hand, re-operation for recurrent disease carries a very significant risk of damage to both the recurrent laryngeal nerves and the parathyroid glands.

Although total thyroidectomy has always been an option for the management of multinodular goiter, this approach was pursued in 1983, after the introduction of a revised technique for total thyroid lobectomy in which dissection is performed, hugging the true capsule of the gland.[4] By 1985, the policy of the Department of Surgery, the University of Sydney at Royal North Shore Hospital, had been established such that total thyroidectomy had become the preferred option for multinodular goiter when the whole gland was involved, with no visible or palpable normal thyroid tissue, and where it was considered that the operation could be performed without risk of complications. The aim of this article is to review the experience of our department with total thyroidectomy for multinodular goiter and to make an assessment on the justification of the approach taken toward total thyroidectomy for multinodular goiter.

Patients and Methods

During the period from 1975 to 1985, 2052 thyroidectomies were performed in the University of Sydney Department of Surgery at Royal North Shore Hospital. There were 853 procedures carried out for multinodular goiter during this period and, of these, 115 were total thyroidectomies. During this same period, 104 secondary thyroidectomies were carried out for recurrent multinodular goiter causing compression or for intrathoracic goiter. Many of these patients had had their original surgery (usually a bilateral subtotal thyroidectomy) performed in our department 15–20 years previously. All information relating to these operative procedures,

and to their pathologic conditions and complications, was recorded prospectively and stored in the Department of Surgery Thyroid Data Base. This data base, stored on a DEC PDP-11/73 computer, now contains detailed information on 6024 thyroidectomies performed over the last 25 years.

Preoperative investigations, including thyroid function tests and routine biochemistry, were performed on all patients. Other tests, such as nuclear and ultrasonographic scanning and fine-needle aspiration biopsy, were performed selectively. Vocal cord function was assessed routinely before and after operation by an independent otolaryngologist, as well as by the anesthetist at the time of extubation.[5] Stasis-free serum calcium levels were also measured both before operation and on day 1 and day 5 after operation.

Operative Technique

Within our department thyroidectomy is performed by use of a standard operative technique[6,7] while patients are under general anesthesia, with muscle relaxation and intubation. With the neck extended, the skin is marked and infiltrated with POR-8, flaps are raised, and the strap muscles are divided transversely. Attention is first turned to one lobe where the upper pole is mobilized through the avascular space with individual ligation of the vessels to protect the external laryngeal nerve, according to our long-standing technique. The lower pole is then mobilized by ligating individual tertiary branches of the veins and arteries on the thyroid capsule, with gradual dissection of the vasculature from the gland by ligation and division of the perforating vessels at the capsule and preservation the blood supply of the parathyroid glands (Fig. 1). These glands may often be preserved on a slender pedicle of artery and vein. Any parathyroid gland that cannot be salvaged because of its anatomic location is minced and placed in the sternomastoid muscle.

Before 1983, the recurrent laryngeal nerve was routinely identified during dissection,[5,7] but, since that time, the nerve is protected by the technique of capsular dissection. As emphasized by Harness et al.,[8] the nerve is not sought laterally early in the procedure, but as dissection proceeds to the area of the ligament of Berry the nerve will often be encountered as it courses through or close to the ligament itself.

The remaining lobe is removed by the same technique. Where there is considered to be significant risk to the nerve, especially as it enters the cricothyroid muscle, a small remnant of thyroid tissue may be retained if necessary to preserve the integrity of the nerve. Hemostasis is secured, the strap muscles and platysma layer sutured, and the skin closed with subcuticular sutures without drainage. It is important to emphasize, as does Perzik,[3] that the parathyroid glands and recurrent laryngeal nerve are not routinely sought. Rather, the main object is to avoid them by the capsular technique but to be ready and able to recognize and preserve them if they appear in the operative field during dissection.

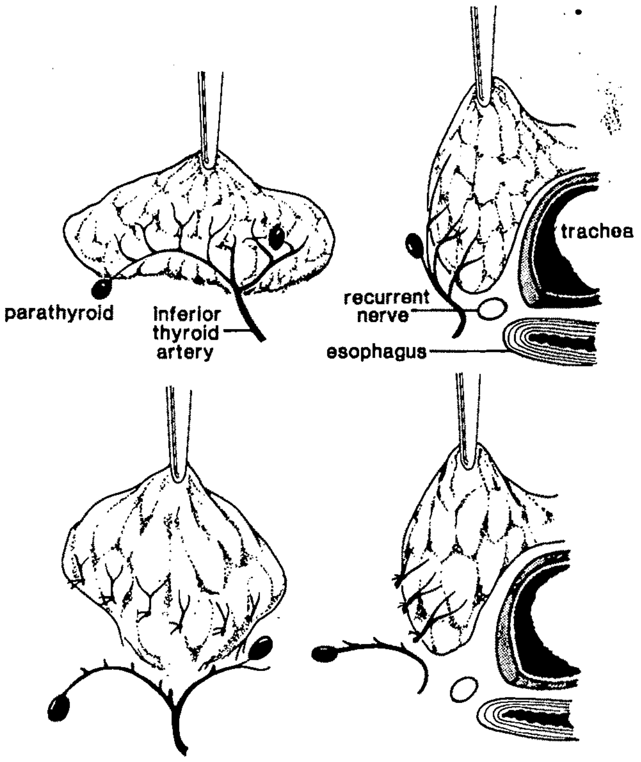

FIG. 1. Dissection used during the capsular technique for thyroidectomy, with ligation and division of the small tertiary vessels on the gland, preserving the blood supply to the parathyroid glands (adapted from Kurihara H, Takashi M. Safety of operation and indications for total thyroidectomy. Operation 1981; 35:1077–1086).

Results

Over the period from 1975 to 1985, 115 total thyroidectomies were performed for multinodular goiter. The progressive increase in the frequency with which total thyroidectomy has been performed for multinodular goiter is shown in Figure 2. It can be seen that, in 1975, there were 16 total thyroidectomies performed, and of these seven were for multinodular goiter. Over the subsequent 10 years, the number of total thyroidectomies for malignancy has remained virtually constant, whereas the overall number of thyroidectomies performed in our department has decreased.[9] On the other hand, there has been a progressive increase over the last 2 years in the number of total thyroidectomies (44 in 1985), and this has been entirely confined to operations for multinodular goiter.

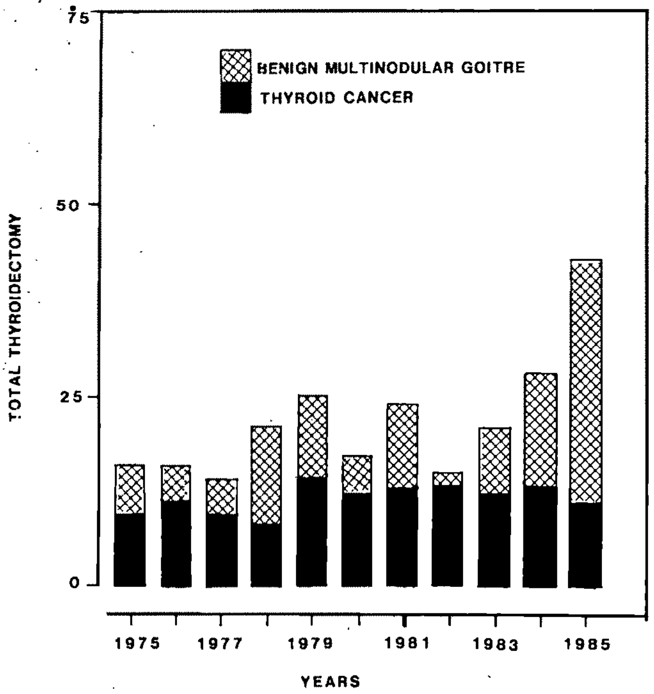

FIG. 2. Total thyroidectomies performed for both thyroid cancer and multinodular goiter during the period from 1975 to 1985.

Another way of looking at this changing practice is to examine operations performed specifically for multinodular goiter. These data are summarized in Figure 3, which shows the ratio of thyroidectomies (total *vs.* other procedures) performed for that condition over the last 10 years. Although the number of procedures overall for multinodular goiter has been relatively constant, the proportion of cases where a total thyroidectomy was performed has increased from 9% in 1975 to 50% in 1985.

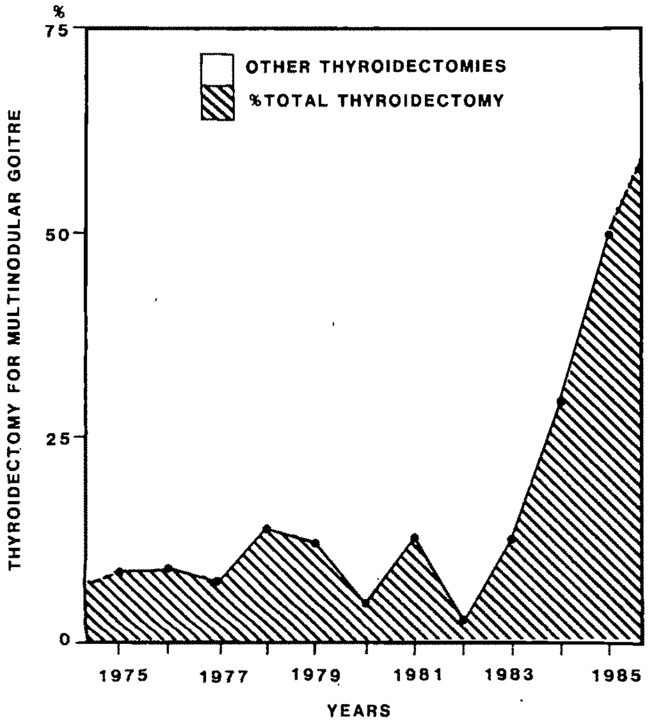

FIG. 3. Operations for multinodular goiter (1975–1985), showing the increasing percentage being performed as total thyroidectomies.

The complications of thyroidectomy for multinodular goiter are summarized in Table 1. These have been divided into two consecutive groups so that changing trends can be examined: 1975–1984 (789 thyroidectomies); and 1985 (64 thyroidectomies), by which time total thyroidectomy had become the established routine. There were two postoperative deaths overall, both resulting from cardiac causes. Before 1985, there were two cases of permanent hypoparathyroidism and one permanent recurrent laryngeal nerve palsy. All of these complications occurred in the group having a lesser procedure. There were no permanent complications when a total thyroidectomy was performed. There was no significant difference between the two groups with respect to temporary vocal cord dysfunction (normal cord function at extubation but subsequent impaired movement), temporary hypocalcemia, or postoperative hemorrhage/bruising. In 1985 there were no permanent complications in any group.

These figures compare more than favorably with the incidence of these complications in cases requiring reoperation for multinodular goiter. Within our own department (unpublished data) there has been a permanent recurrent laryngeal palsy rate of 3.1% and an incidence of permanent hypoparathyroidism of 3.7% after secondary thyroidectomy for multinodular goiter in 258 cases.

Discussion

Total thyroidectomy is an operation that continues to evoke considerable controversy, even in the management of conditions such as differentiated thyroid carcinoma,[1] in spite of the significant advantages in terms of this therapeutic option that can be demonstrated. When it comes to benign thyroid disease, total thyroidectomy has not been generally advocated, although some authors have recommended its use for Graves' disease (especially in patients with severe ophthalmopathy), thyroiditis, and nodular goiter. Indeed, in one review of 909 total thyroidectomies, less than one-quarter of the procedures were performed for thyroid cancer, the remainder being for benign thyroid disease.[3] The argument put forward by these authors was that, if total thyroidectomy can be performed as safely as lesser procedures for benign disease, then the indications for its use may be justifiably expanded to those situations where recurrent disease is a significant problem.

When dealing with multinodular goiter in particular, the surgeon commonly finds that there is no apparently normal thyroid tissue remaining. He or she must then choose between leaving abnormal thyroid tissue behind or performing a total thyroidectomy. The former approach carries with it the risk of recurrent disease, which may require subsequent re-operation, whereas the latter approach theoretically has the potential hazards of an increased risk of either permanent hypoparathyroidism or recurrent laryngeal nerve injury.

The incidence of permanent complications after thyroidectomy, total thyroidectomy in particular, varies considerably from center to center. In experienced hands, however, the incidence is acceptably low; for example, Clark[1] reports an incidence of 1% permanent hypoparathyroidism and no permanent recurrent laryngeal nerve damage in 82 consecutive total thyroidectomies. More than one-third of these were performed for benign thyroid disease. In 250 total thyroidectomies for nodular goiter, Perzik[3] reported an incidence of only 0.4% nerve injury and no hypoparathyroidism. This contrasted with 5% nerve injury and 3% hypoparathyroidism when the total thyroidectomy was performed for thyroid cancer. These latter complications were attributable to the more extensive surgery done because of the degree of spread of the malignancy rather than to operative technique. Other authors have reported that the incidence of complications increases as the complexity of the procedure increases; for example, Martensson and Terins[10] showed a progressive increase in the incidence of nerve injury from 5% for unilateral lobectomy up to 18% for total and subtotal lobectomy or 14% for total thyroidectomy.

In this study we have shown that total thyroidectomy for multinodular goiter can be performed with minimal complications. We believe that this results from the use of the technique of thyroidectomy as described, whereby dissection and ligation of the multiple vessels on the thyroid capsule preserve the blood supply of the parathyroids and minimize inadvertent injury to the recurrent laryngeal nerve.

On the other hand, the risks involved in re-operation for recurrent multinodular goiter are significantly greater than at the first operation. In our department this risk increases significantly, the rate of permanent nerve injury increasing to 3.1%, whereas that of permanent hypoparathyroidism is 3.7%. In other reports,[11] the risk of permanent nerve damage after secondary thyroidectomy for benign disease was 9.5%, whereas the risk of permanent hypoparathyroidism was 3.4%.

Total	83 (11%)	706	32 (50%)	32

When the entire gland is diseased in patients with multinodular goiter, a bilateral subtotal thyroidectomy, although reducing the bulk of the diseased tissue, is less than optimal treatment. Leaving a small portion of diseased gland is unlikely to prevent the need for long-term thyroxine replacement therapy, whereas attempts to suppress regrowth of that remaining gland by thyroxine do not guarantee success.[12] In performing a subtotal thyroidectomy it is also possible to leave behind the small posterior–lateral lobule of thyroid tissue that was first described by Zuckerkandl.[13] This tissue often extends into the retrotracheal retro-esophageal area, causing significant pressure symptoms. The presence of this lobule is frequently only recognized when the full mobilization necessary for a total thyroidectomy has been performed (Fig. 4).

We recommend, therefore, that total thyroidectomy is the procedure of choice for multinodular goiter where the entire gland is involved. It must be emphasized, however, that protection of the recurrent laryngeal nerve and parathyroid glands must still be paramount in

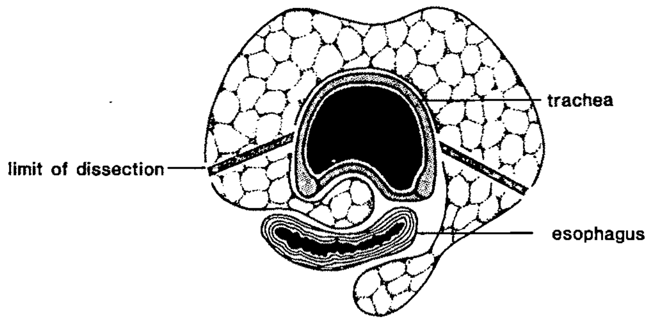

FIG. 4. Transverse section of the thyroid, showing the normal posterior limit of dissection during a bilateral subtotal thyroidectomy and its relationship to the posterior–lateral lobule.

dealing with benign thyroid disease. Ensuring such protection will, on occasion, require that minimal remnant thyroid tissue be left when anatomic vagaries render total excision of the gland less than totally safe. Of course, this policy requires that the operation be performed by an experienced surgeon who can guarantee that the procedure will be performed with minimal risk of complication.

Motor Function in the Excluded Esophagus and Its Implications in the Management of Patients with Unresectable Carcinoma of the Esophagus

ANDRÉ C. H. DURANCEAU, M.D.,* EDWIN R. LAFONTAINE, M.D.,† SUZANNE C. ARCHAMBAULT,‡
and GLYN G. JAMIESON, M.D.§

From the Department of Surgery, Université de Montréal, Hôtel-Dieu de Montréal, Montreal, Quebec, Canada

Palliative exclusion of the esophagus by use of transposed stomach was performed in a 63-year-old woman with unresectable cervical esophageal cancer. Twelve weeks after this operation, motor function of the excluded esophagus was assessed. All voluntary swallows produced a motor response in the esophageal body. Eighty-five per cent of the contractions were peristaltic and generated mean pressures of 28 mmHg. Fiften per cent of the deglutitions were followed by nonpropulsive waves with mean pressures of 24 mmHg. Spontaneous tertiary activity occurred at a rate of 2.5 contractions per minute with an amplitude of 16 mmHg. Motor function in the excluded esophagus persists after bypass of the organ. This suggests that the excluded esophagus should be decompressed after surgery to prevent "blowout" of its closed ends.

WHEN THERE is a contraindication to esophageal resection for esophageal carcinoma, many patients are treated palliatively with a substernal or subcutaneous route to bring the stomach into the neck in order to totally exclude the esophagus.[1-5]

The fate of an excluded esophagus remains unclear. Both Johnson et al.[6] and Orringer[3] reported that the esophagus becomes an asymptomatic mucocele after exclusion. Similarly, Mannell reported on 51 patients who had total esophageal exclusion: in 20 of the 38 patients who had the esophagus closed at both ends, a mucocele was formed. Ninety-five per cent of the patients were asymptomatic, and the mucocele did not continue to increase in volume.[2] Experimentally, Deaton and Bradshaw[7] also described an isolated segment of the esophagus in which the cystic structure resulting from exclusion did not continue to increase in size.

Division of the esophageal musculature in the experimental animal does not interrupt peristalsis.[8,9] Similarly, transection of the esophagus with re-anastomosis or transection followed by a short jejunal or prosthesis interposition does not stop progression of a normal propulsive wave after voluntary swallowing.[5,8,10,11] Longhi and Jordan[12] and Janssens et al.[10,11,13] noted, however, that in dogs no primary peristalsis occurred in the excluded esophagus if the bolus was diverted away in the neck or even at the midesophageal level.

The purpose of this report is to document the motor function of an excluded esophagus that was bypassed for palliative reasons.

Case Report

History

A 63-year-old white woman with a significant history of alcohol consumption and tobacco smoking was investigated for cervical dysphagia, and she was found to have an esophageal epidermoid carcinoma. She was treated with curative radiotherapy (5500 rads in 22 sessions). However, her dysphagia did not improve, and she was referred when she had total esophageal obstruction. Endoscopic evaluation revealed neoplastic closure of the esophageal lumen 6 cm below the pharyngo-esophageal junction. Bronchoscopic examination showed posterior tracheal wall deformation without evidence of malignant cells from the tracheal mucosal brushings.

Surgical Procedure

Clinical staging suggested that the disease was confined locally. However, simultaneous exploratory laparotomy and neck exploration

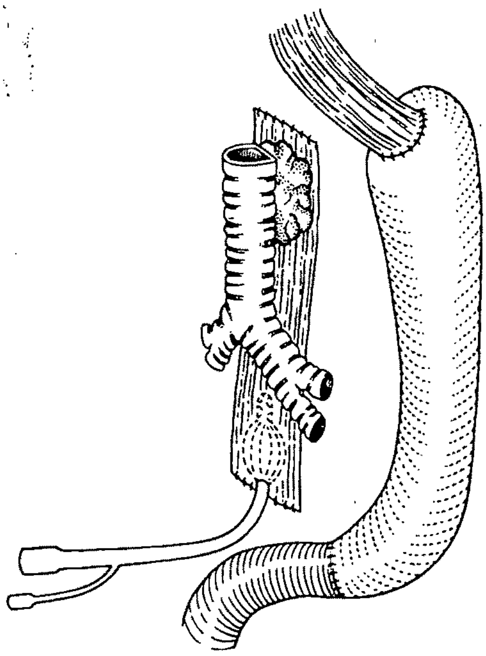

FIG. 1. Palliative esophageal bypass with esophageal exclusion. A fistula is created in the distal esophagus over a Foley catheter.

revealed a massive tumor obstructing the esophagus at the thoracic inlet. Posterior invasion of the trachea was present, with early left recurrent laryngeal nerve involvement, and resection was considered an inappropriate option. Esophageal exclusion was performed with the use of a substernal tunnel to bring the stomach up to the neck, and a cervical esophagogastrostomy was performed just below the proximal esophageal sphincter. A pyloroplasty was also performed. The excluded esophagus was decompressed by use of a #16 Foley catheter, which entered the esophageal lumen through the anterior wall of the esophagus immediately distal to the diaphragmatic hiatus. The catheter was brought out as a directed fistula under the right subcostal margin. The proximal esophagus was closed above the tumor (Fig. 1).

The patient was swallowing normally within a few days of operation, and there was minimal mucus drainage from the esophagus. Eight weeks after the operation, radiologic evaluation of the excluded esophagus was performed through the distal esophagostomy. The radioopaque material revealed multilevel simultaneous contractions in the esophageal body. Extravasation through the tumor and into the mediastinum was documented. After discharge the patient was comfortable for 9 months.

TABLE 1. *Motor Response of the Excluded Esophagus to Voluntary Swallowing*

Number of swallows	40
Resting intra-esophageal pressure	5
Percentage response	40/40
Primary waves	85
Tertiary waves in response to deglutition	15%
Spontaneous tertiary contractions	2.3/minute
Secondary waves	0%
Contraction pressures	
Primary waves	28 mmHg
Tertiary waves in response to deglutition	24 mmHg
Spontaneous tertiary contractions	16 mmHg

Manometric Evaluation

Twelve weeks after the bypass procedure, using the distal esophagostomy to introduce the motility catheter, motor function of the esophagus was evaluated with a standard manometric technique described previously.[14] Each one of the three lumina of the manometry catheter was perfused at a rate of 1.9 mL/min with a Harvard perfusion pump (Harvard Apparatus, Millis, MA). The perfused lumina were connected to three proximal transducers (H.P. Model 1280, Hewlett Packard, Corvallis, OR) and the recording made on a physiograph (H.P. 7754-A, Hewlett Packard). By instilling a 2-mL water bolus into the mouth, 40 voluntary swallows were induced in order to evaluate the function of the excluded esophagus.

Results

Motor function results in the excluded esophagus are shown in Table 1. The resting intra-esophageal pressure remained positive and ranged from 2 to 8 mmHg. All swallows were followed by a motor response in the esophageal body. Eighty-five per cent of the contractions were of the primary type, and 15% were nonpropulsive (Fig. 2). Between swallows, spontaneous tertiary contractions were observed at a rate of 2.5 contractions per minute. Contraction pressures were not high: the mean contraction value of the primary wave was 28 mmHg. Tertiary contractions in response to voluntary swallowing averaged 24 mmHg in amplitude. Mean contraction pressure for the spontaneous tertiary waves was 16 mmHg.

Discussion

If the esophagus is left in its normal position but is excluded from the alimentary tract, it can either be oversewn at both ends, with the reasoning that it will then become an asymptomatic "cyst," or it can be decompressed internally by a Roux-en-Y technique or externally by creation of a tube fistula. Such decompression allows continuous emptying of esophageal secretions and may prevent intraluminal pressure build-up if motor activity is present. There is no consensus on which of these approaches is best. At the beginning of the century, Kirschner advocated the use of a Roux-en-Y internal decompression.[5,14] More recently, Akiyama and Kiyama reported the cases of 11 such patients, and internal or external decompression was always added to the bypass procedure. No significant complications occurred.[15] Steiger et al.[16] presented 30 cases where the esophagus was excluded and decompressed by use of a Foley catheter. Mannell, in presenting her initial 10 cases, stated that five patients had total esophageal exclusion without decompression.[1] When compared with five other patients who had a Roux-en-Y internal drainage, no difference was observed between the two groups. More recently, Mannell and Epstein reported 51 patients with total esophageal exclusion without decompression.[2] Seventeen per cent of the patients had proximal esophageal disruption, and one patient had a distal esophageal leak. Twenty of 38 patients evaluated by computed tomography scanning had an esophageal mucocele develop. This was usually asymptomatic and not progressive. Orringer and Sloan reported their initial experience with 10 patients who had advanced carcinoma where the esophagus was excluded by simply closing it at both ends.[3] Their updated experience with this approach reveals 17% of distal esophageal disruption.[4]

Experimentally, after removing the esophageal muscularis externa, Meltzer showed that primary peristalsis was not interrupted.[9] Surgical transection and re-anastomosis was studied by Carveth et al., who similarly showed that this operation did not stop the progression of the primary esophageal waves.[8] Greenwood performed short intestinal interpositions and short prosthetic interposition at midesophageal level and showed that primary peristalsis "jumped" these interposed segments to continue into the distal portion of the esophagus.[17]

In a different set of experiments in animals, Longhi and Jordan[12] diverted the esophagus at the cervical level and reported that no deglutitive contractions occurred below the level of bolus deviation. Janssens et al.[10,11,13] created a cervical esophageal diversion and a midthoracic esophageal diversion and took electromyographic recordings of both the proximal and distal segments. They reported that when the esophagus was diverted in the neck, deglutition with a bolus elicited a normal response in the esophageal segment above the transection, but there was no peristaltic sequence seen in the thoracic esophagus below the transection. When the diversion was at the midesophageal level, electromyographic activity was recorded in both the proximal and distal half of the esophagus. These investigators suggested that when there were no afferent impulses from the bolus, the central regulating mechanism was not sufficiently coordinated to guarantee peristaltic contractions. Their main conclusion was that primary peristalsis is entirely bolus dependent in its course through the cervical esophagus.

However, despite diversion of the esophagus at the cervical level immediately distal to the upper esophageal sphincter in our patient, the 40 swallows invariably produced a motor responses in the totally excluded esophageal body. Eighty-five per cent of these responses were peristaltic. Local factors such as the presence of carcinoma in the cervical esophagus, the irradiation to the tumor area, and operation followed by proximal mediastinal infection may have accounted for the 15% tertiary contractions that were observed after voluntary swallows. Similarly, the high incidence of spontaneous tertiary activity between deglutitions may have resulted from similar local factors. The small perfusion volume (1.9 mL/min/lumen) used for the manometric recording may have been an additional factor. The implication of these observations is that when the esophagus is totally excluded and left in place, intact organized motor function persists in the esophageal body. It is highly likely that this activity was coordinated *via* the vagi,[18] which were left intact in our patient.

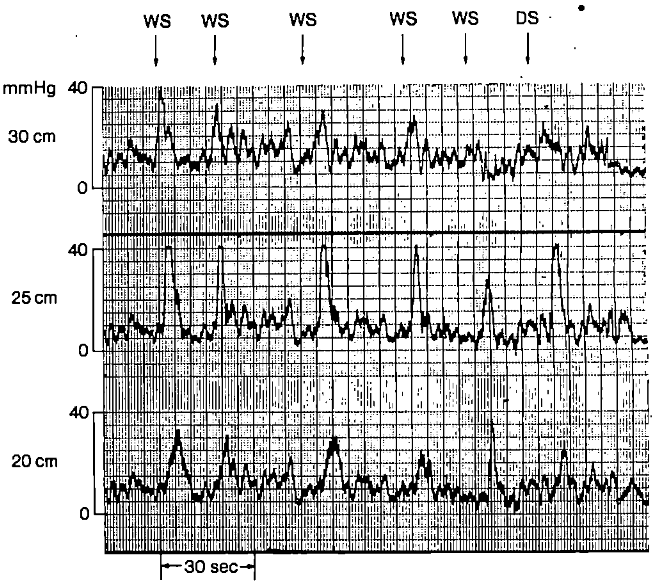

FIG. 2. Primary and tertiary contractions in the excluded esophagus in response to voluntary swallowing (WS = wet swallow). The distances are measured from the skin orifice of the fistula.

Complications do not result in all patients when the esophagus is closed at both ends. This may relate to the strength of esophageal contractions that occur, because it has been reported that an obstructed esophagus can lose its peristaltic activity.[19,20] However, the fact that peristaltic activity may be retained suggests that it is probably safer to use esophageal decompression to prevent disruption of a proximal or distal esophageal closure line.

In conclusion, it appears that when total esophageal diversion is performed in the neck, the excluded esophagus may retain its motor activity. Decompression of the excluded esophagus should be performed in order to prevent complications resulting from this retained activity.

Efficacy of Cefazolin, Cefamandole, and Gentamicin as Prophylactic Agents in Cardiac Surgery

Results of a Prospective, Randomized, Double-blind Trial in 1030 Patients

ALLEN B. KAISER, M.D., MICHAEL R. PETRACEK, M.D., JOHN W. LEA IV, M.D., DOUGLAS S. KERNODLE, M.D.,

In an effort to develop an improved regimen of antibiotic prophylaxis in cardiac surgery, 1030 patients who were to have elective cardiothoracic surgery involving a median sternotomy were selected at random to receive cefamandole or cefazolin, with or without gentamicin, in a prospective double-blind study. Cefazolin was significantly less effective than cefamandole at both the sternal (1.8% *vs.* 0.4%, respectively, $p < 0.05$) and donor sites (1.3% *vs.* 0%, respectively, $p < 0.02$). Seven *Staphylococcus aureus* infections occurred among cefazolin recipients as compared with no such infections among the patients receiving cefamandole ($p < 0.01$). All five wound infections yielding fungi or gentamicin-resistant gram-negative rods occurred in patients who had received gentamicin as a second prophylactic agent. These data suggest that gentamicin has no role as a prophylactic antibiotic in cardiac surgery and that, compared with cefamandole, cefazolin offers unreliable prophylaxis against deep infection at both the sternal and donor sites.

From the Departments of Medicine and Surgery, Saint Thomas Hospital, and Department of Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee

PROPHYLACTIC ANTIBIOTICS have proven effective in lowering wound infection rates after cardiac surgery,[1,2] and most cardiovascular surgeons routinely use one or more antibiotics during the perioperative period. However, despite administration of prophylactic antibiotics, infections in both the sternal and donor sites continue to occur in 1–5% of patients, and controversy exists regarding the optimal prophylactic regimen.[3–6]

Since 1978, more than 1000 median sternotomies have been performed each year at Saint Thomas Hospital. Perioperative cefazolin has been the mainstay of prophylaxis. The deep sternal wound and donor site infection rates have each averaged approximately 2% for the last 5 years. The pathogen spectrum has remained relatively constant over this period of time. *Staphylococcus aureus* has accounted for approximately 40% of pathogens in sternal wounds and coagulase-negative staphylococcus, 25%. Enteric gram-negative rods, fungi, and mixed pathogens have accounted for the remainder of the identifiable pathogens.

Since the early 1980s, several studies had indicated that cefamandole was the most active cephalosporin against coagulase-negative staphylococci *in vitro.*[7–9] The clinical relevance of this finding remains unknown. Because coagulase-negative staphylococci were known to be a common pathogen in sternal wound sites in our hospital, a prospective, randomized, blinded study comparing cefamandole with the most commonly used prophylactic antibiotic, cefazolin, was instituted in November 1984. Because cephalosporin-resistant pathogens accounted for approximately one-fifth of such infections, gentamicin was also included in this trial.

Materials and Methods

Antibiotic Regimens

Using block randomization, patients were assigned to one of four prophylactic regimens. Regimen A consisted of cefazolin, 2 g intravenously (I.V.) at induction of anesthesia, 1 g every 4 hours during operation, and 1 g every 6 hours after operation for 72 hours. Regimen B included cefazolin as outlined above, plus gentamicin

Submitted for publication: April 9, 1987.

1.5 mg/kg given I.V. at the induction of anesthesia. Regimen C was cefamandole, 2 g I.V. at induction of anesthesia, 1 g every 2 hours during operation, and 1 g every 4 hours after operation for 72 hours. Regimen D included cefamandole as above, except that gentamicin 1.5 mg/kg was given I.V. at the induction of anesthesia. No dose adjustments were made for renal failure. Placebo doses were not included. All randomization was performed by one investigator (A.C.R.). Drugs were dispensed in minibags labeled "Mancef" and marked with time for infusion.

Definition of Infection

Wounds were considered infected if (1) purulence was present; and (2) deep subcutaneous tissue (Class II infection), sternum (Class III infection), or posterior mediastinum (Class IV infection) was involved. Class I or superficial infections of the subcutaneous tissue of the sternum or donor site were not included. By definition, such infections appeared trivial upon inspection, and neither prolonged hospitalization nor altered outpatient management was required. Class I sternal infections were tabulated prospectively, however. When the code was broken at the close of the study, the Class I infections were noted to be evenly distributed among the four prophylactic regimens. One Class I infection occurred among regimen A recipients, three among regimen B recipients, two among regimen C recipients, and three among regimen D recipients.

At 3-month intervals, the attending surgeon, at least one other cardiac surgeon investigator, and one nonsurgeon member of the investigative team (A.B.K.) reviewed the clinical course of all patients with wounds exhibiting inflammation and/or drainage. An agreement was reached as to the presence or absence of infection and the depth of infection. Care was also taken at this time to exclude patients with secondary infections in the sternal area that may have developed as a complication of ischemic necrosis of the underlying tissue. One such patient, who was eventually identified as a regimen B recipient, met this criterion and was excluded. She was a 63-year-old patient with long-standing Raynaud's disease and was receiving steroid therapy; she experienced necrosis of the entire hemisternum associated with the use of the ipsilateral internal mammary artery for implantation. According to protocol design, after approximately 1000 patients had been studied, antibiotic regimens associated with infections were identified with a letter code by the pharmacist. At that time, in January 1986, a significant difference in treatment categories was noted. The code was subsequently broken, and the study ended.

Patient Selection

The study design was approved by the Saint Thomas Hospital Institutional Review Board. Written informed consent was obtained from all participants. All adult patients scheduled for elective median sternotomy incision who were free of infection and not receiving any therapeutic antibiotics were considered eligible for inclusion in the study. To remain in the study, patients had to adhere to the antibiotic protocol for at least 24 hours.

All patients showered or bathed with an antiseptic-containing soap the evening before operation. Shaving of the operative site(s) was performed in the holding area immediately before operation. The mediastinum was routinely irrigated with a kanamycin solution (1 g/L of saline) before closure.

Drug Levels

Early in the course of this study, an average of seven plasma specimens per patient were obtained from 25 patients during the operative period. Specimens were frozen at −20 C and shipped to Eli Lilly Laboratories for analysis. Gentamicin levels were analyzed by radioimmunoassay techniques. Cefamandole and cefazolin plasma levels were measured by bioassay. Antibiotic levels were plotted against time on semilog paper and the best straight line determined. The lowest intraoperative serum concentration of antibiotic (usually occurring immediately before antibiotic redosing) was estimated from this plot.

Cost Analysis

Seven of 11 patients with sternal wound infection and five of the six patients with donor site infection had evidence of infection develop after discharge and were re-admitted to Saint Thomas Hospital specifically for management of the infections. All re-admission hospital charges for these 12 patients were considered to be direct costs of infection. For the patients whose wound infections developed before discharge, the charges were considered to be secondary to infection only during the portion of the hospital stay that was clearly prolonged as a result of infection.

Risk Analysis

Demographic data on patients who had cardiac surgery at Saint Thomas Hospital are maintained by an in-office minicomputer. Host risk factors and intra-operative and postoperative complications are identified on work sheets by physician assistants. All such infor-

‡ Difference in infection rates is significant at $p < 0.05$, Fisher's exact test.

mation is obtained at the time of hospitalization and entered prospectively into the computer program. These data were available for analysis for patients entered into the study. Age and the presence of diabetes mellitus, obesity, hypertension, use of internal mammary arteries in coronary artery bypass, perfusion time, and cross-clamp time were tabulated. All statistical tests for association of frequencies (contingency table analysis) were performed by chi square analysis or by Fisher's exact test when expected frequencies were less than five.

Results

Patient Demographics and Risk Factors

Of 1446 patients who had median sternotomy at Saint Thomas Hospital from November 1984 through January 1986, 1057 (73%) were entered into the study. Operations were subsequently canceled for 11 patients, and nine patients were removed from the study for failure to adhere to the antibiotic regimen for the first 24 hours. Seven patients scheduled for thoracic surgery not involving a median sternotomy were inadvertently entered into the study and were later removed. The 27 patients excluded from the study after entry were evenly distributed among the four prophylactic regimen groups.

A total of 1030 patients were therefore available for evaluation. Of these patients, 57 had median sternotomy for valve replacement only, 44 for valve replacement and coronary artery bypass, 919 for coronary artery bypass alone, and 10 for other cardiac surgical procedures. During this period of time, 389 patients had median sternotomy but were not considered for the study. Nine sternal wound infections determined retrospectively by routine nosocomial surveillance occurred among the patients who were not from the study, for an infection rate of 2.2%. Cefazolin was usually given as a prophylactic agent in these patients who were not from the study, although cefamandole and vancomycin, with or without gentamicin, were also used occasionally.

An analysis of infections by the seven participating surgeons demonstrated no significant difference in surgeon-specific infection rates. All risk factors were homogeneously distributed among the four treatment regimens, between patients receiving cefazolin *versus* cefamandole, and between patients receiving gentamicin *versus* no gentamicin. There were no cases of prosthetic valve endocarditis among the 101 patients who had valve replacement.

Efficacy of Prophylaxis

Sternal wound infections developed in 11 of the 1030 patients who had elective median sternotomy (Table 1). Donor site infections developed in six of 963 patients requiring a donor site incision. Patients receiving cefamandole–gentamicin had a significantly lower sternal wound infection rate than those receiving cefazolin–gentamicin (0% and 2.4%, respectively; $p < 0.02$). When infection rates for the regimens that included gentamicin are compared with rates for those that did not, the results are virtually identical (1.2% *vs.* 1.0%). When the results were analyzed by individual cephalosporins, patients receiving cefamandole with or without gentamicin had a significantly lower infection rate than patients receiving cefazolin with or without gentamicin at both the sternal (0.4% *vs.* 1.8%, $p < 0.05$) and donor sites (0% *vs.* 1.3%, $p < 0.02$).

TABLE 2. *Pathogens, Class of Infection, and Prophylaxis Regimen*

	Sternal Infections		Donor Site Infections	
Antibiotic Regimen	Patient No.*/ Class of Infection	Pathogen(s)†	Patient No./Class of Infection	Pathogen(s)
Cefazolin	1/III	*Staphylococcus aureus* (M, K)	12/II	*S. aureus;* CNS; enterococci
	2/III	*S. aureus*	13/II	*Escherichia coli;* enterococci
	3/II	CNS (M, K, G)	14/II	*S. aureus*
			15/II	*S. aureus; Proteus mirabilis*
Cefazolin/gentamicin	4/II	*S. aureus*	16/II	Pseudomonas (K, G); Proteus
	5/III	*S. aureus* Citrobacter (K, G)		Klebsiella
	6/II	CNS (M, K, G) Pseudomonas (K)	17/II	Pseudomonas (K, G)
	7/III	Pseudallesheria		
	8/IV	*Candida tropicalis*		
	9/II	*E. coli*		
Cefamandole	10/II	CNS (M, K, G)		
	11/II	(No growth)		

* All patients had coronary artery bypass surgery (CAB) except patients 5 (ventricular aneurysmectomy) and 7 (CAB plus aortic valve replacement).

† Resistance (if present) to cefazolin/cefamandole (K) is noted within parentheses. Coagulase-negative staphylococci (CNS) and *S. aureus* were also tested for resistance to methicillin (M); and gram-negative rods were tested to resistance to gentamicin (G). All *S. aureus* infections were resistant to penicillin. Susceptibility testing was performed by standard Kirby-Bauer sensitivity testing.

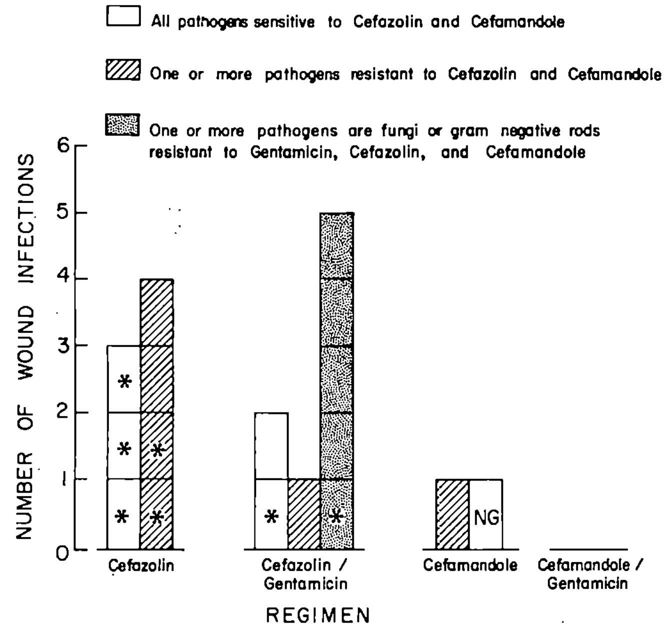

FIG. 1. Correlation of prophylactic antibiotics and antimicrobial resistance of pathogens. One infection in a cefamandole recipient yielded no growth (NG) on culture. All infections yielding *S. aureus* (denoted by an asterisk) occurred among cefazolin or cefazolin–gentamicin recipients. Resistance of fungi and gram-negative rods to cefazolin–cefamandole and gentamicin occurred only in cefazolin–gentamicin recipients. No infections occurred among cefamandole–gentamicin recipients.

Infecting Organism

All seven wound infections yielding *S. aureus* (four sternal and three donor sites) occurred in patients receiving cefazolin as a prophylactic agent (seven of 508 cefazolin recipients *vs.* none of 522 cefamandole recipients, $p < 0.01$). Coagulase-negative staphylococci as a single or co-infecting pathogen were identified in three sternal wound sites and one donor site. Three of these infections occurred in patients receiving cefazolin (Table 2). In five wound infections, all pathogens isolated were susceptible to both cefazolin and cefamandole (Fig. 1). All of these infections occurred in recipients of cefazolin or cefazolin–gentamicin (five of 508 cefazolin recipients *vs.* none of 522 cefamandole recipients, $p < 0.05$). Of five wound infections yielding gram-negative bacilli resistant to gentamicin (3) or fungi (2), all occurred in patients who had received gentamicin in addition to cefazolin as a prophylactic agent.

Pharmacokinetics

Intra-operative antibiotic levels were measured in 12 patients receiving cefazolin, 13 receiving cefamandole, and 14 receiving gentamicin. The mean trough levels of antibiotics during the bypass procedure averaged 39 μg/mL for cefazolin, 21 μg/mL for cefamandole, and 1.5 μg/mL for gentamicin. However, the trough levels ranged widely among patients. For cefazolin recipients, the lowest trough plasma concentration was 22 μg/mL. For the cefamandole recipients, the lowest trough concentration was 11 μg/mL, and for the gentamicin recipients, 0.7 μg/mL. By the close of the surgical procedure, gentamicin levels in gentamicin recipients were negligible.

Infection Complications and Costs

The excess costs of hospitalization attributable to infection are outlined in Table 3. Among the six patients with Class II infections of the sternal wound, two infections resulted in prolongation of hospitalization and three in re-admission to Saint Thomas Hospital. One patient was managed by repeated incision and drainage of the infection in the physician's office. All Class III and Class IV infections at the sternal site occurred among cefazolin or cefazolin–gentamicin recipients. Three patients with Class III infections of the sternum required re-admission to the hospital; the fourth patient's primary hospitalization was prolonged extensively. A Class IV infection developed in one patient during the initial hospitalization. This patient eventually died of multiple complications. Five of the six deep (Class II) infections occurring at the donor sites resulted in rehospitalization. The average cost of donor site infections was $8500, an amount similar to the $9000 cost of Class II infection at the sternal incision site. Physician fees and office charges related to both sternal and donor site infections were not determined.

TABLE 3. *Excess Cost of Hospitalization Attributable to Infection*

Depth of Infection (No. Patients)	Total Excess Costs ($)	Mean Excess Cost ($)
Sternal site		
Class II (6)*	53,500	8,900
Class III (4)	160,200	40,000
Class IV (1)	73,300	73,300
All sternal sites (11)	287,000	26,000
Donor site		
Class II (6)	51,000	8,500
All sites (17)	338,000	19,882

* Both infections associated with cefamandole prophylaxis were Class II infections.

Discussion

A primary goal of the design of this study was to evaluate the relative efficacy of cefamandole *versus* cefazolin in preventing infection resulting from coagulase-negative staphylococci. Although three of the four infections yielding coagulase-negative staphylococci occurred in cefazolin recipients, infections resulting from coagulase-negative staphylococci were too infrequent to allow conclusions to be drawn regarding the relative efficacy of these two cephalosporins. One can only speculate as to whether a significant advantage of cefamandole *versus* cefazolin could be demonstrated in a setting where coagulase-negative staphylococci were a more frequent cause of postsurgical wound infection.

Of great interest, however, was the finding that infections resulting from *S. aureus* were significantly less likely to occur among the cefamandole recipients. Even if the one infection resulting from a methicillin-resistant *S. aureus* in a cefazolin recipient is not included in the analysis, significantly more *S. aureus* infections occurred among cefazolin recipients than among cefamandole recipients ($p < 0.02$). Slama et al. also recently noted that cefazolin tended to be less effective in preventing *S. aureus* infection after cardiac surgery than either cefamandole or cefuroxime.[6] *In vitro* studies are not currently available that directly explain why cefamandole should prevent *S. aureus* infection more effectively than cefazolin. As early as 1973, however, failures of cefazolin in treating infection resulting from *S. aureus* have been reported.[10,11] Although the precise cause of this phenomenon remains unexplained, a number of investigators have noted that cefazolin appeared to be more vulnerable to hydrolysis by the beta-lactamase of certain *S. aureus* strains than either cefamandole or cephalothin.[12–16] Cefamandole has also been shown experimentally to produce higher concentrations than either cefazolin or cephalothin in fibrin clots.[17,18] Clinically, prophylactic use of cefamandole has been shown to result in high concentrations of antibiotic in atrial muscle and cardiac valve tissues.[19] Whether the inferior performance of cefazolin is related to its vulnerability to *S. aureus* beta-lactamase, to inferior tissue levels, or to other factors is unknown. Whatever the reason(s), data are accumulating to suggest that cefazolin may not be as reliable as other cephalosporins in prophylaxis of wound infection in cardiac surgery.

One conclusion of our study was that gentamicin, when given as a single preoperative dose, offered no protection from infection resulting from cephalosporin–resistant pathogens. Although gentamicin combined with cefamandole was the most effective of the four prophylactic regimens, an analysis of infection rates of the various antibiotic combinations (Table 2) suggests that it was the use of cefamandole *per se*, not cefamandole plus gentamicin, that best explained the observed differences in infection rates. Another interpretation of the apparent lack of gentamicin effectiveness may be related to the use of kanamycin irrigation in all patients. Although there are inadequate data to settle the issue, topical kanamycin may, in fact, be as efficacious as systemically administered gentamicin, thereby blunting any possible demonstration of the latter's efficacy.

However, it was of considerable interest to note that all infections resulting from cephalosporin-resistant (Patient 6) or cephalosporin and gentamicin-resistant (Patients 5, 16, and 17) gram-negative enteric pathogens occurred in patients receiving gentamicin as a second prophylactic agent. Moreover, both fungal infections occurred in gentamicin recipients (Patients 7 and 8). This failure/adverse effect of gentamicin was disappointing but not completely unexpected. Gentamicin has yet to be proven effective as a prophylactic agent in prospective clinical trials in clean surgery.[20] Furthermore, a previous study in cardiac surgery suggested that the routine use of gentamicin prophylaxis can be associated with a marked increase in gentamicin resistance within the hospital environment.[21] Given the fact that plasma levels were uniformly low in all patients at the close of operation, an observation noted previously,[22] it may be that prophylactic efficacy cannot be realized unless frequent doses of this agent are given. The threat of ototoxicity or nephrotoxicity associated with repeated doses must, however, serve as a caution, if not a deterrent, in designing prospective clinical trials involving frequent doses of gentamicin.

Because failure of prophylaxis in cardiothoracic surgery has been related to inadequate serum levels at the close of prolonged procedures,[4,23] we administered intraoperative doses of cefamandole and cefazolin so that adequate levels of these cephalosporins would be maintained throughout the surgical procedure. The results of our cephalosporin serum assays obtained during cardiopulmonary bypass were consistent with the findings of others.[24–27] Based upon these data, cefazolin dosing intervals might safely be lengthened to 6 or 8 hours. However, pending collection of additional data, frequent doses of cefamandole (every 2 hours) should be used during bypass if predictably high levels are to be achieved throughout the surgical procedure.

In May 1986, cardiac surgeons at Saint Thomas Hospital changed from the predominant use of cefazolin to cefamandole. Subsequent to this change, only eight deep sternal wound infections have developed among 1131 patients (infection rate, 0.7%). Five deep donor site infections have also occurred during this time. *S. aureus* has been isolated from four of these 13 infections. These follow-up data suggest that cefamandole continues to be preferred to cefazolin for prophylaxis of cardiac surgery in our hospital.

In view of these results, single-dose gentamicin, as an adjunct to cephalosporin prophylaxis, probably has no place in routine prophylaxis in cardiac surgery. Efficacy has not been demonstrated, and there is a suggestion that the use of gentamicin prophylactically may encourage the emergence of resistant organisms. Whether multiple dosing of gentamicin or the use of other broad-spectrum antibiotics would be effective in preventing gram-negative rod infection is unknown. The apparent failure of cefazolin in preventing wound infection, especially infection resulting from *S. aureus,* has important implications in view of the widespread current use of this antibiotic. Cefazolin has clearly demonstrated its effectiveness as a prophylactic agent in a wide variety of clean and clean-contaminated surgical procedures.[20] Nevertheless, this study and the recent study by Slama et al.[6] have now demonstrated its inferiority to other cephalosporins in prophylaxis of wound infections in cardiac surgery.

The standard coronary ligation model for experimental myocardial infarction results in variable areas and patterns of necrosis; therefore, the healing of such infarctions is also variable. The authors developed an experimental myocardial injury model using simple cryoinjury, which allows standardization of the size, depth, and location of the wound. Thirty-eight left ventricular cryolesions were created in 19 dogs, which were then killed from 3 to 35 days after injury. A consistent decrease in the depth of scar ($p < 0.005$) and accumulation of collagen ($p < 0.0001$) over time characterized this healing myocardial wound. Histologic examination revealed that the cellular pattern of healing myocardial cryolesions is similar to that of a healing myocardial infarction but with less variability. The authors advocate the use of cardiac cryolesions as a model of experimental myocardial wound healing.

DESCRIPTIONS of the histopathologic evolution of myocardial infarction attribute little active role to the pericardium. In a study of 192 autopsies, Fishbein et al.[1] mentioned some endocardial and pericardial fibrosis adjacent to the infarcted myocardium. Cardiac surgeons frequently encounter pericardial adhesions in patients with healed myocardial infarctions and those who have had previous cardiac surgical procedures. In fact, recent enthusiasm has arisen for using artificial pericardial substitutes to minimize adhesion formation in an attempt to facilitate reoperation.[2] The role of the pericardium in myocardial wound healing, however, remains incompletely characterized.

One of the difficulties in studying myocardial wound healing is the variability induced in creation of the wound. Experimental myocardial infarction is usually produced by ligation of coronary arteries, with or without injecting the vessel with foreign substances.[3] Unfortunately, the extent of infarction produced depends on the coronary arterial anatomy supplying this region of the ventricle (which is variable) and the (equally variable) collateral arterial supply. Another limitation of this technique is the 20–40% early attrition associated with creation of the infarct,[4] usually resulting from ventricular tachyarrhythmias.

Cardiac cryolesions were first described by Hass in 1948[5] and have recently been used as an ablative technique in the surgical treatment of arrhythmias.[6] Cryolesions reportedly heal into a firm scar with little disruption of surrounding myocardial anatomy; furthermore, arrhythmias are rare after creation of cryolesions, and abnormal degrees of ventricular ectopy are not present a week after freezing.[7] Because cryolesions should represent reproducible, nonarrhythmogenic areas of myocardial necrosis, we studied such cryolesions as an experimental model of myocardial wound healing.

Methods

Nineteen adult mongrel dogs of both sexes (14–31 kg) were anesthetized with intravenous pentobarbital (30 mg/kg), intubated, and placed on a Harvard ventilator. Electrocardiograms were continuously monitored. The heart was exposed through a right thoracotomy performed through the fifth intercostal space. The pericardium was opened longitudinally, and the heart was de-

livered from the pericardial sac. All animals received humane care in compliance with "Principles of Laboratory Animal Care," formulated by the National Society for Medical Research, and the "Guide for the Care and Use of Laboratory Animals," prepared by the National Academy of Science and published by the National Institutes of Health (NIH Publication 80-23, revised 1978); this protocol was approved by the Palo Alto Veterans Administration Medical Center Animal Research Committee.

Cryolesions were produced by cooling a pure copper rod (15 mm in diameter and 175 mm in length) in a bath of dry ice and acetone. When the rod ceased to produce bubbles in the dry ice/acetone bath, it was manually held on the surface of the left ventricular myocardium for 2 minutes. The area of frozen myocardium thawed over a period of 5 minutes, assuming a cyanotic color and contracting less vigorously. When the cryolesion had thawed, the copper rod was again used to freeze the same area of myocardium for an additional 2 minutes. A second area of myocardium, at least 2 cm from the first, was then injured with the same "double-freeze" technique. Two lesions were made on each left ventricle. During the period of thawing, arterial bleeding was occasionally observed, but it spontaneously ceased after several minutes.

A sterile surgical glove (latex rubber) was rinsed in normal saline and then cut into circular pieces (3 cm diameter). A piece of latex was then sutured around one of the cryolesions (chosen at random) with the use of a continuous 4–0 polypropylene suture, and the heart was replaced in the pericardial sac. The pericardium was closed with the use of continuous 3–0 chromic suture. Chest tubes were placed and the incision closed in standard fashion.

Animals were killed at 3 days and 1, 2, 3, and 5 weeks. Hearts were removed *en bloc* with the surrounding pericardium. The degree and extent of attachment of the pericardium to the exposed (bare) cryolesions and those covered by the latex rubber patches were recorded as the pericardium was dissected free from the myocardium. The physical dimensions of the healing lesions were recorded. A full-thickness sample of myocardium containing the cryolesions was removed with a cuff of normal myocardium and placed in 10% formalin. After fixation, a 1-mm (True-Cut) needle biopsy was performed through the center of each cryolesion for hydroxyproline analysis, and a transverse, transmural section of the cryolesion was processed, embedded in paraffin, and stained with hematoxylin and eosin or Masson's trichrome.

The transmural biopsy specimens were heated at 60 C for 48 hours, weighed, and then hydrolyzed for 18 hours in 6 N HCl at 110 C. The specimens were then dried and resuspended in a known volume of water. Total hydroxyproline was measured with the Technicon Auto Analyzer.[11] Standards of known collagen content were routinely run with this assay. Statistical analysis was performed by use of the two-way analysis of variance (ANOVA), followed by appropriate paired and unpaired t-tests.

Results

Creation of cryolesions did not result in prolonged arrhythmias, but touching the ventricle with the cold copper rod precipitated transient sinus tachycardia (which resolved after rod removal) in several dogs. The dogs were continuously monitored for 2 hours after creation of the lesions; only occasional premature ventricular beats were noted. All animals survived creation of the myocardial cryolesion and the intended postoperative follow-up interval. Ventricular fibrillation developed in one additional animal before myocardial freezing, and the dog was excluded from the study.

The pericardium was not attached to the exposed cryolesion or to the latex patch in any of the dogs killed at 3 days. By 7 days, the pericardium had become attached to most of the exposed cryolesions and to the myocardium surrounding the latex patch in two of the four dogs in this group. Interestingly, in these two dogs without adherence to the area surrounding the latex rubber patches, the pericardium was also not adherent to the exposed cryolesions. In dogs killed after 14 days, the pericardium was adherent to both the exposed cryolesions and the myocardium surrounding the latex patches in all dogs. In one of the four dogs killed at 21 days, the pericardium was not adherent to either lesion. The pericardium in both dogs killed at 5 weeks was adherent to the surgically created wounds.

The dimensions of the cryolesions were analyzed according to treatment group (latex rubber patch *vs.* no patch), but no significant differences were found between groups. The depth of the exposed cryolesions decreased from 5.5 ± 0.4 mm (mean ± standard error of the mean [SEM]) on day 3 to 0.9 ± 0.1 mm on day 35, whereas the depth of the patched cryolesions decreased from 6.2 ± 0.3 to 0.9 ± 0.1 during the same period. Because the depth of lesion was not dependent on the presence or absence of the pericardium, the data from both groups were combined. Analyzed together, the depth of the cryolesions was inversely related to postoperative time ($r = -0.91$, $p < 0.0001$, SEE = 0.746 [Fig. 1]).

The collagen content (as assessed by transmural biopsy hydroxyproline levels) of the cryolesions exposed to the pericardium increased from 35.5 ± 8.0 μg/mg dry weight at 3 days to 212 ± 20 μg/mg at 35 days. The

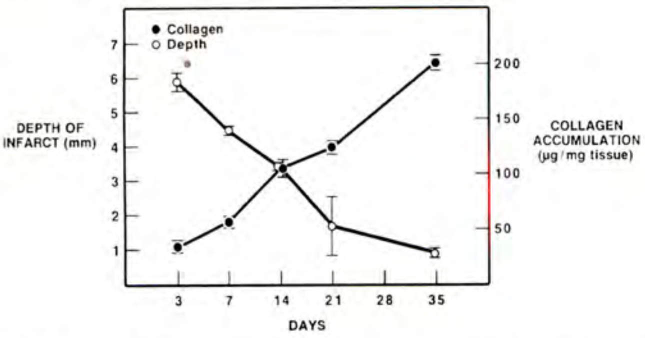

FIG. 1. Depth of cryoinjury "scar" decreased while collagen accumulation increased during 5 weeks of observation. Variability expressed as plus or minus 1 standard error of the mean.

collagen content of the cryolesions that were patched with latex ranged from 32 ± 8 to 190 ± 7 during the same period. Because collagen accumulation in the cryolesions did not differ significantly between the two groups, these data were also combined. When all cryolesions were analyzed, collagen accumulation in healing cryolesions correlated strongly with time ($r = 0.89$, $p < 0.0001$, SEE = 19.22 [Fig. 1]).

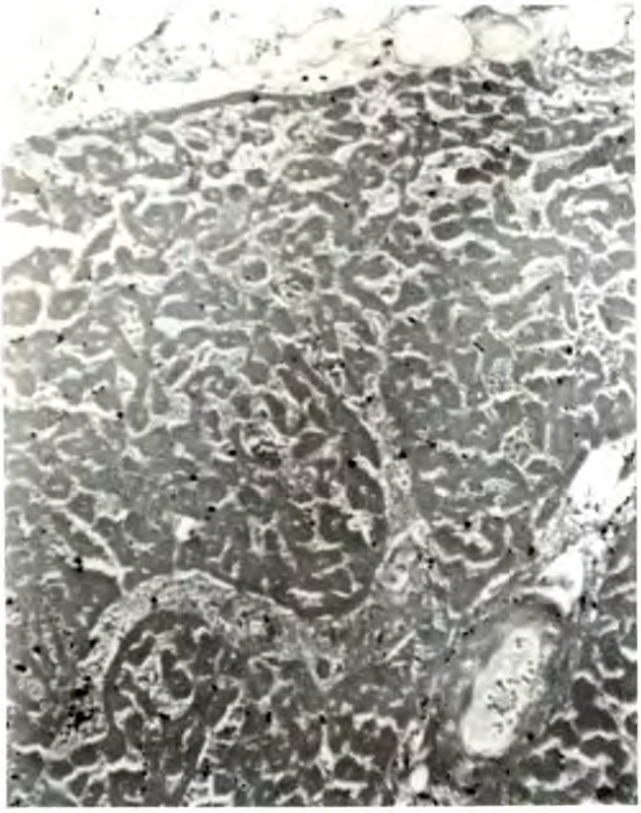

FIG. 2. Canine left ventricle 3 days after cryoinjury. Note epicardium above and coagulative necrosis of underlying myocardium (hematoxylin and eosin, original magnification ×200).

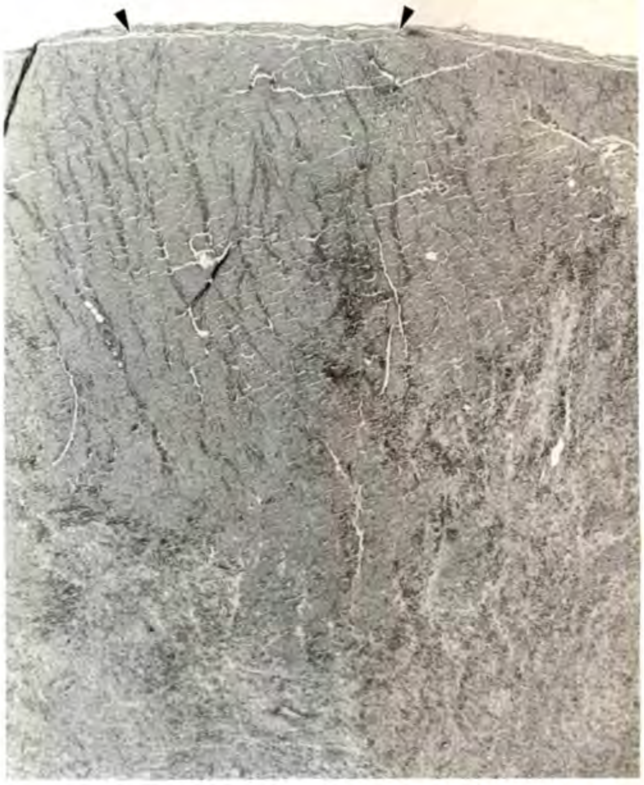

FIG. 3. Canine left ventricle 14 days after cryoinjury showing replacement of muscle by granulation tissue at perimeter of the lesion (arrows indicate epicardium) (hematoxylin and eosin, original magnification ×20).

Early microscopic examination of the healing cryolesions revealed hemorrhage and extensive coagulation necrosis with loss of nuclear staining (Fig. 2). Necrosis and granulation tissue persisted in the 14-day specimens (Fig. 3) but was absent in the lesions after 21 and 35 days (Figs. 4–6). Polymorphonuclear leukocytes were present in substantial numbers only in the early lesions. Macrophages, in contrast, were present in the cryolesions harvested between 1 and 3 weeks. Endothelial cell proliferation with new capillary formation (neovascularization) was not evident at 3 days but was markedly present after 7 and 14 days (Figs. 4 and 5). Fibroplasia had started by the 7th day and was most prominent after 14 days (Figs. 3 and 4); this fibroplastic response had started to regress in the 21-day specimens and was absent after 35 days (Figs. 5 and 6). Histologically, collagen deposition was evident in the 7-day specimens and steadily increased thereafter throughout the entire sampling period, as illustrated in Figures 3–6. This pattern was consistent with the quantitative hydroxyproline data [Fig. 1]). No substantial qualitative histologic differences were found between the cryolesions patched with latex rubber and those that were exposed to the pericardium, as summarized in Table 1.

Discussion

The presence of pericardial adhesions surrounding areas of old myocardial infarction has been interpreted to suggest that the pericardium attaches to the myocardium when inflammation is present, perhaps reinforcing the structural integrity of the necrotic tissue or contributing additional blood supply. Historically, surgeons have tried to enhance this process in an attempt to revascularize ischemic myocardium; Beck surgically joined areas of experimental myocardial infarction to the pericardium, greater omentum, and other tissues in hopes of inducing collateral circulation to the heart in 1935.[8] Yamazaki et al. reported fewer arrhythmias, decreased left atrial pressure, and higher left ventricular ejection fractions in dogs after surgical treatment with a synthetic "on lay" patch[9] that covered the infarction and constricted its size by 25%.

The experiments reported herein were designed to demonstrate if more rapid and/or complete healing of a standardized myocardial injury occurred if the pericardium was directly attached to the area of infarction. No difference was seen in the rate at which the patched and the exposed myocardial cryolesions healed. The change in wound depth, furthermore, was uniform over time, with or without the adherent pericardium. No qualitative differences were demonstrated histologically, and no significant quantitative difference in hydroxyproline accumulation was demonstrated between the two groups in this experimental model.

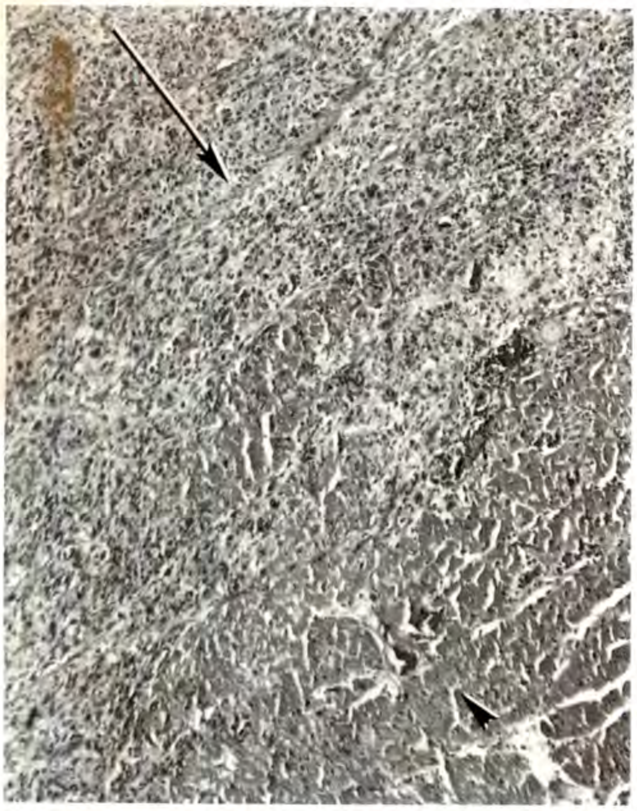

FIG. 4. Left ventricular myocardium from the same heart as shown in Figure 3. Granulation tissue is present (arrow), with viable myocytes below (arrowhead) (hematoxylin and eosin, original magnification ×100).

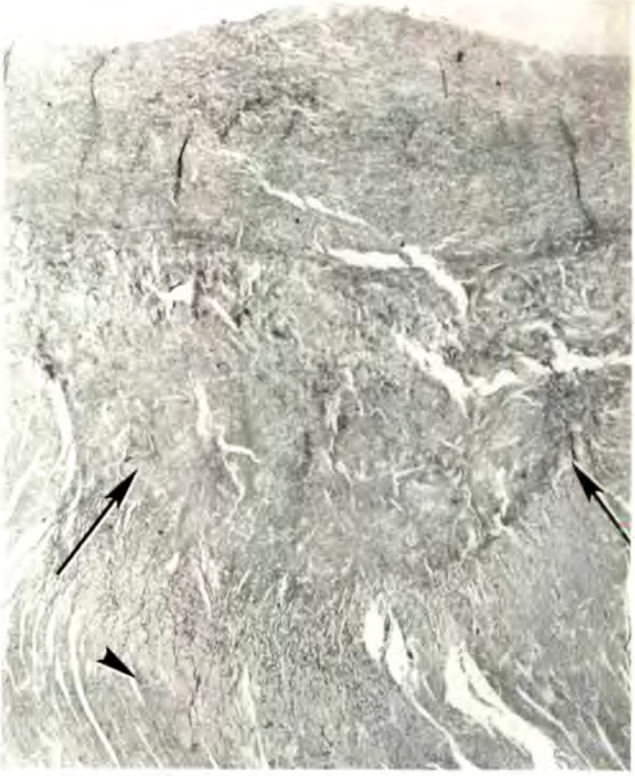

FIG. 5. Canine left ventricle 35 days after cryoinjury, illustrating sharply demarcated scar (arrow). Intact myocardium is present below this scar (arrowhead) (hematoxylin and eosin, original magnification ×15).

We cannot conclude, however, that the pericardium does not protect acutely infarcted human myocardium from ventricular rupture or possibly contributes an element of supplemental blood supply. The lesions in this experiment were not transmural; furthermore, the cryolesions were created in well-perfused and otherwise healthy, uncompromised regions of normal canine myocardium, which has exuberant collateral vascular supply. Therefore, the question as to the role of the pericardium in the healing of human myocardial wounds and infarcts remains unresolved.

These observations did demonstrate that cardiac cryolesions provide a reliable and reproducible experimental model for the investigation of myocardial

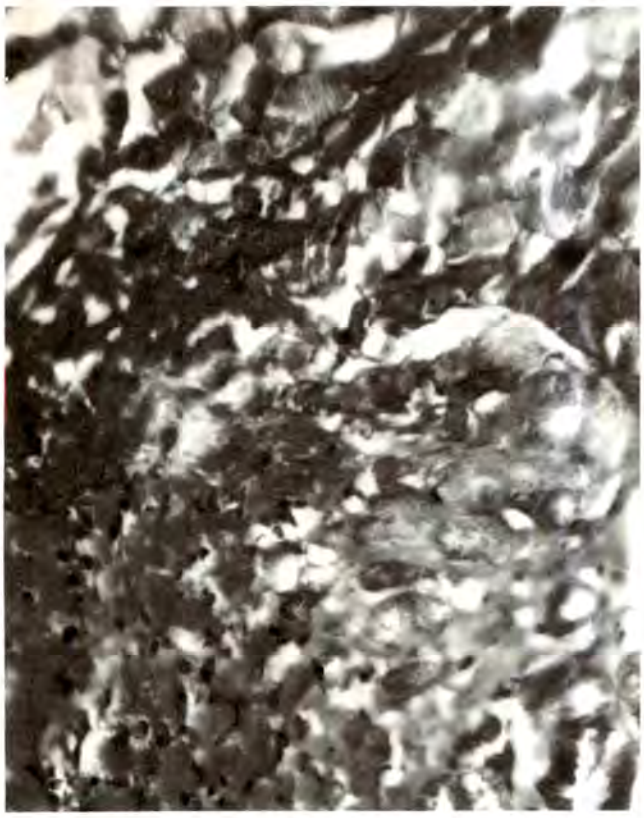

FIG. 6. Same heart as in Figure 5, demonstrating densely collagenous scar with a paucity of cells in the region of the cryolesion (hematoxylin and eosin, original magnification ×200).

wound healing. Unlike the standard technique of coronary ligation, which generates a variable extent and pattern of myocardial necrosis, cryolesions produce a uniform, highly reproducible area of necrosis. The shape of the lesions can be controlled easily by altering the geometry of the cryoprobe. Because the pattern of necrosis extends radially, depth relates to the size of the epicardial lesion. The depth of the injury may also be augmented by increasing the duration of freezing, decreasing the temperature of the probe, and, probably, by applying multiple freezes.[7] It appears that the most reliable way to create transmural lesions is to introduce a trocar cryoprobe through the myocardium.[7]

TABLE 1. *Histologic Observations in the Myocardial Cryolesions at Different Times After Operation**

Histologic Findings	Severity of Histopathologic Changes by Age of Infarct (Days)†					
	3	7	14	21	35	Control
Hemorrhage	3	2	1	0	0	0
Necrosis	3	2	1	0	0	0
Leukocytes	2	1	0	0	0	0
Lymphocytes	0	2	1	0	0	0
Macrophages	0	3	2	1	0	0
Endothelial cells	0	3	3	1	0	0
Fibroblasts	0	1	3	1	0	0
Collagen	0	1	2	3	3	0

* Lesions from both groups were combined in this analysis because there appeared to be no qualitative difference between the two groups.

† Relative severity of histopathologic changes was graded as follows: 0 = absent; 1 = mild; 2 = moderate; or 3 = severe.

Cardiac cryolesions differ from clinical myocardial infarction primarily in the mechanism of injury. Cryogenic injury results in coagulative necrosis, whereas myocardial infarction results from venous hemorrhage after arterial occlusion. Both mechanisms produce necrosis, which heals by interacting with cellular elements of the surrounding myocardium. The histologic studies done in this study reveal that the cellular pattern of healing cryolesions corresponds closely to that seen in healing myocardial infarctions. Granulocytes appear first in the injured area and are later replaced by macrophages. Fibroblasts and endothelial cells migrate to the wound edge; the fibroblasts then produce collagen, within which the endothelial cells form small vessels. This pattern essentially follows that described by Mallory et al.[10] in their classic description of the healing process of myocardial infarction.

One histologic difference between the healing of a myocardial infarction and a cardiac cryolesion was the absence of necrotic tissue after 14 days. Macrophages were not seen in the (cryolesion) wounds after 21 days. This difference probably relates little to the healing process but rather to the size of the original injury or ongoing myocardial ischemia. Because size has not been quantitated precisely in experimental studies of healing myocardial infarction, necrosis and inflamation may persist because of the size and/or shape of the lesion or other factors.

One objection to this model for investigation of myocardial wound healing is the plentiful amount of blood flow in the myocardium surrounding the cryolesion, which may have minimized the potential effect of the pericardium in terms of contributing collateral blood supply. This theoretic problem, however, could be solved by the creation of cryolesions in an area of ischemic (coronary occlusion) myocardium. Coronary artery branches could be ligated distally, where such would not result in a large infarction, thereby possibly reducing the attendant arrhythmias.

An advantage of cryolesions for the investigation of myocardial wound healing is the remarkable consistency of healing; the depth of the lesions decreased and the collagen content of the wounds increased as a function of time. Additionally, the use of cryolesions rather than coronary ligation offers a distinct advantage in terms of early animal attrition. None of the animals died before the date they were to be killed; however, had this method been used to produce larger ares of necrosis or transmural necrosis, the mortality rate might have been greater. This difference probably rests entirely in the relative absence of ventricular arrhythmias.

Long-term Results with Autogenous Tissue Repair of Traumatic Extremity Vascular Injuries

ROBERT A. McCREADY, M.D., NANCY M. LOGAN, B.A., MICHAEL E. DAUGHERTY, M.D.,* SALLY S. MATTINGLY, M.D., CHERYL CROCKER, R.N., R.V.T., and GORDON L. HYDE, M.D.

From the University of Kentucky Medical Center, Lexington, Kentucky

With extensive vascular injuries in which a vascular conduit is required, there is controversy as to whether an autogenous or prosthetic graft is preferable. The authors reviewed their experience with 91 extremity arterial injuries in which autogenous tissue was used to repair vascular injuries of the extremities. Twenty-two patients also had concomitant repair of associated venous injuries with autogenous vein grafts. Ten patients required amputations, despite patent grafts in five patients, because of severe muscle necrosis. Two patients had thrombosis of their vein grafts develop in the early postoperative period but did not require amputation. The authors identified only one late vein graft failure in a patient in whom an infected pseudoaneurysm developed. Three patients with extensive soft tissue injuries had infection develop in vein grafts, with subsequent massive bleeding that ultimately required arterial ligation. Among the 22 patients with repair of their venous injuries, occlusion of popliteal vein repairs was documented in two patients and suspected in three others. The remainder of patients had satisfactory results. The excellent results obtained in the vast majority of the authors' patients with extremity vascular injuries reinforces their preference for using autogenous tissue whenever a vascular conduit is required. Exceptions include patients with extensive soft tissue loss precluding adequate graft coverage, the repair of large vessels, and life-threatening emergencies when there is insufficient time to harvest and prepare a vein.

RECENT CLINICAL and experimental studies suggest that prosthetic grafts are satisfactory conduits for the repair of traumatic injuries even in contaminated wounds.[1-11] Our preference has been to avoid the use of prosthetic grafts because of the risk of subsequent graft infection. In addition, prosthetic grafts have inferior patency rates compared with autogenous grafts in elective lower extremity revascularization, which is an important consideration in young patients with long life expectancies.[12] The purpose of this study was to review our results with autogenous veins used in the repair of traumatic vascular injuries with particular reference to late follow-up.

Materials and Methods

We reviewed the records of 91 patients in whom autogenous veins were used to repair extremity arterial injuries at the University of Kentucky Medical Center from 1963 through July 1985. Patients in whom prosthetic grafts were used or in whom primary vascular repair was feasible were excluded. In 22 of these 91 patients, autogenous veins were used to repair associated venous injuries.

Seventy-nine per cent of the patients were male and 21% were female. The mean age was 30.1 years, with a range of 12–74 years. The injuries were caused by blunt trauma in 29% and penetrating trauma in 71%, most of which were secondary to gunshot wounds. There were five deaths, all of which occurred in patients in profound shock on admission from multiple injuries. Thirty-three per cent of the patients had associated bone fractures, 37% had direct nerve injuries, and 19% had extensive soft tissue injuries.

Follow-up data were obtained by chart review, contact with personal physicians, or follow-up examination. Graft patency was determined by physical examination, noninvasive vascular laboratory studies, and, in selected instances, by angiographic or venographic studies. Ten patients were lost to follow-up. The mean length of follow-up among the surviving patients was 33.5 months (range: 1–207 months).

TABLE 1. *Results of Autogenous Tissue Repair of Traumatic Extremity Vascular Injuries*

Artery (Number of Patients)	Autogenous Graft			Results of Arterial Repair			Causes of Graft Failure			Associated Venous Injuries	Postoperative Amputations
	SV	CV	BV	Excellent	Early Failure	Late Failure	Infection	Technical	Outflow		
Axillo–subclavian (14)	14			13		1				7	
Brachial (28)	23	2	3	24	4		2	1		9	3
Common femoral, superficial femoral, or popliteal (40)	49			43	4		1	1	2	29	6

SV = saphenous vein; CV = cephalic vein; BV = basilic vein.

Results

The location of the arterial injuries, types of autogenous grafts used, and results are listed in Table 1.

Axillo–Subclavian Arterial Injuries

Among the seven patients with associated venous injuries, four veins were repaired with interposition saphenous vein grafts and one with a saphenous vein patch. The subclavian vein was ligated in two patients with no subsequent edema. All venous repairs appeared to be patent.

Among the 14 arterial repairs, the single late vein graft failure was the development of an infected pseudoaneurysm (*Staphylococcus aureus*) 8 months after operation, which was treated by ligation. The patient has a viable upper extremity. Several patients continue to have significant functional impairment from their associated neurologic injuries.

Brachial Artery Injuries

Of the four early graft failures, one graft thrombosed because of compression from a muscle flap that was rotated to cover a large soft tissue defect. Another graft thrombosed because of extensive distal thrombosis. There had been a several-hour delay between injury and subsequent revascularization in this patient. Both patients have mildly ischemic extremities but did not require amputation.

In the two patients whose autogenous vein grafts became infected, there was massive soft tissue loss that had precluded adequate soft tissue coverage of the grafts. The wounds subsequently became infected with multiple organisms, and both grafts bled massively several days after operation. At re-exploration, the bleeding sites were in the mid-portions of the vein grafts, and it appeared that a portion of the vein wall had become necrotic. A second saphenous vein graft was placed in one patient, but it subsequently became infected, with recurrent massive hemorrhage. Both patients ultimately required ligation of the brachial artery, which resulted in mildly ischemic extremities.

The venous injuries were ligated in all patients, and none of the patients had edema develop. Three patients required amputations early after operation because of extensive muscle necrosis. All three patients had severely ischemic extremities on admission because of a long delay between injury and restoration of circulation.

Common Femoral, Superficial Femoral, or Popliteal Artery Injuries

Among the 29 patients with concomitant venous injuries, interposition saphenous vein grafts were used in 14 patients and saphenous vein patch grafts were used in two. The venous injuries were repaired primarily in 11 patients. The popliteal vein was ligated in two patients, both of whom required amputation.

Six amputations were required in the early postoperative period because of extensive muscle necrosis, despite patent grafts in two patients. Once again, there had been a long delay between injury and revascularization in these two patients.

There were four early graft failures, all of which resulted in amputation. Technical error appeared to be the cause of graft failure in one patient. Venous outflow occlusion was the likely cause of graft failure in another patient in whom the popliteal vein was ligated when exploration was performed initially at another institution, and it was not possible to restore patency of the popliteal vein. In addition, the saphenous vein that was used for the interposition graft was harvested from the injured extremity, which likely increased his venous hypertension. Another graft failure occurred in an elderly patient in whom all three tibial arteries were severely atherosclerotic. The long delay between injury and revascularization in this patient resulted in extensive distal thrombosis.

The fourth graft failure occurred in a patient with a large soft tissue defect precluding adequate coverage of the graft. The wound became infected with multiple gram-positive and gram-negative organisms, with subsequent profuse bleeding from the vein graft. Another saphenous vein graft was placed, but recurrent hemorrhage developed and a third interposition vein graft was placed. Several weeks later, a large infected pseudoaneurysm developed, and the patient required an above-knee amputation. Pathologic examination of the vein graft demonstrated aneurysmal dilatation and necrosis in the vein wall.

Among the 14 interposition vein grafts used to repair associated venous injuries, there were two failures documented by venographic studies. Three patients require support stockings to control mild edema, but no venographic studies were done to determine patency of the venous repairs.

Discussion

In treating traumatic vascular injuries, primary repair of the damaged vessels is the preferred method of treatment. However, extensive damage to the vessels precludes primary repair and necessitates either ligation of the vessel or use of a vascular conduit. Because ligation of critical arteries such as the popliteal artery results in a prohibitively high amputation rate, surgeons have been aggressive in attempting to repair major vascular injuries.

When primary vascular repair is not feasible, there are three options. The first is to use autogenous tissue, most commonly saphenous vein. The second option is to employ prosthetic material, usually Dacron or polytetrafluoroethylene (PTFE). Prosthetic grafts are often required in the repair of major intrathoracic or intra-abdominal arteries because of their large size. A third option is to perform an extra-anatomic bypass with either a prosthetic or autogenous graft, thus avoiding a potentially contaminated area. The advantages of this approach in the treatment of popliteal artery injuries were outlined in a previous report from this institution.[13]

There are conflicting results reported with prosthetic grafts used to repair traumatic vascular injuries. In their report on the military experience in Vietnam, Rich and Hughes noted a prohibitively high incidence of prosthetic graft failure among patients with traumatic vascular injuries who had contaminated wounds.[14] Infection and thrombosis were the most common causes of graft failure. Massive life-threatening hemorrhage often accompanied the infection. In distinct contrast to these poor results, there are a number of reports from major civilian trauma centers describing very satisfactory results with prosthetic grafts, usually PTFE, used to repair vascular injuries both in the arterial and venous systems.[2-5,11] However, one series reported a 29% late occlusion rate among PTFE grafts used to repair arterial injuries and a 100% occlusion rate among the PTFE grafts used for the repair of venous injuries.[11] Certainly such a high occlusion rate argues the routine use of prosthetic grafts in vascular trauma, particularly when the vast majority of patients are young.

One would intuitively expect a high incidence of infection among prosthetic grafts that are placed in contaminated wounds. However, several clinical and experimental studies suggest that prosthetic grafts may be superior to autogenous tissue grafts in contaminated wounds.[1-10] In one series of patients with traumatic vascular injuries for which interposition grafts were required, 12 perigraft infections developed, five of which occurred in patients with Dacron grafts, and seven patients had infection develop in saphenous vein grafts. In five of the seven vein graft infections, the vein graft subsequently disrupted with profuse hemorrhage in all five patients. In contrast, among the patients with infected Dacron grafts, three patients had intermittent anastomotic bleeding with pseudoaneurysm formation, but there were no episodes of gross hemorrhage. Among those with infected Dacron prostheses, there were "sentinel" bleeding episodes that heralded the anastomotic breakdown, but there were no episodes of profuse hemorrhage. Because these "sentinel" bleeding episodes allowed time for corrective measures such as graft removal or extra-anatomic bypass, the authors felt that Dacron was preferable to autogenous vein in potentially contaminated vascular injuries when extra-anatomic bypass with autogenous tissue was not feasible. In addition, there are a number of antecdotal reports of patients exsanguinating as a result of dissolution of an infected saphenous graft that had been used to repair traumatic vascular injuries.[7,15-17] A common factor in all of the patients with infected vein grafts and massive bleeding has been a massive soft tissue defect and a contaminated wound.

Experimentally, prosthetic grafts appear to tolerate infection better than autogenous grafts.[6-10] In a study comparing infected PTFE and vein grafts in canine femoral arteries, transmural necrosis with exsanguinating hemorrhage occurred in six or seven infected vein grafts where only two of seven infected PTFE grafts bled.[9] The bleeding in the two animals with infected PTFE grafts resulted from necrosis of the host artery at the anastomotic site. Other experimental studies have confirmed the tendency of autogenous vein grafts to undergo transmural necrosis when infected.[6,8,10] In contrast, the bleeding seen with infected prostheses results from host artery necrosis at the anastomosis, and exsanguinating hemorrhage is rare.

Once a vein graft becomes infected and bleeds, the native artery should be ligated proximal and distal to the point of infection. In two of our three patients with infected vein grafts that bled, multiple attempts at revascularization with fresh saphenous vein grafts were made, but profuse, recurrent hemorrhage occurred in both. Similar disastrous results with multiple attempts at revascularization in the presence of gross infection were reported by Rich et al. from Vietnam, and we completely agree with their opinion that multiple attempts at revascularization in the presence of infection are ill-advised.

The critical factor that seems to predispose autogenous or prosthetic grafts to infection appears to be a lack of adequate soft tissue coverage.[2,11,15–17] In our study, all three patients with infected vein grafts had massive soft tissue loss. It has been postulated that bacterial infection prevents contact between the vein graft and host tissues by its inflammatory action and also introduces an element of collagenase activity that can lead to transmural necrosis and disruption of vein grafts.[2]

In an effort to provide coverage of exposed vein grafts, Ledgerwood and Lucas used porcine grafts as temporary biologic dressings with good results.[18] Major soft tissue reconstruction has been attempted at the time of the initial vascular repair, but the results have been disappointing.[17]

When there is massive soft tissue loss precluding adequate soft tissue coverage, or if there is gross contamination of the wound, we believe that there is a definite role for prosthetic grafts if an extra-anatomic bypass with an autogenous or prosthetic graft through undamaged tissue planes cannot be performed. Our preference would be to use a PTFE graft as a temporizing measure until wound sepsis has been controlled and the wound is ready for major soft tissue reconstruction. At the time of definitive soft tissue reconstruction, consideration should be given to replacing the prosthetic graft with an autogenous vein graft because of the superior patency rates with autogenous vein grafts in lower extremity revascularization.[23]

The patency rates with autogenous vein grafts in our study were excellent, because we identified no late graft occlusions. Because several of our patients were lost to long-term follow-up and follow-up arteriograms were performed on only a few patients, it is certainly possible that our incidence of late graft failure might have been considerably higher had we been able to obtain long-term follow-up information on all patients. Graft occlusion could have occurred in some of these patients, with the patients remaining asymptomatic because of excellent collateral circulation. In the Vietnam military experience, Rich et al. noted that 24 of 34 patients with thrombosed arterial repairs did not require operative intervention, attesting to both the ability of collateral circulation to provide adequate circulation as well as to the fact that these patients are often limited in their activities by their associated neurologic deficits.[22] However, we believe that our low incidence of graft infection is accurate because these patients would have undoubtedly returned to this institution for treatment of any graft infection.

Our satisfactory long-term results with autogenous tissue have encouraged us to advocate its use in the vast majority of traumatic vascular injuries in which primary repair is not feasible. However, there are situations in which the use of prosthetic grafts is preferable, if not mandatory, such as in the repair of large intrathoracic or intra-abdominal arteries, when the large size of the vessels necessitates the use of a prosthetic graft. Patients with multiple associated injuries or those who are hemodynamically unstable may also be better served with a prosthetic graft rather than by additional time being taken to harvest a vein graft. Should subsequent reconstruction be required in these patients because of thrombosis or infection of the prosthetic graft, elective revascularization with autogenous vein grafts can be performed.

In patients with large soft tissue defects and potentially contaminated wounds, we believe that an extra-anatomic bypass with either an autogenous or prosthetic graft through noninfected tissue planes should be considered. When this is not feasible, consideration should be given to use of a prosthetic graft such as PTFE because it appears to tolerate subsequent infection better than autogenous tissue and the reported short-term patency rates are satisfactory.

Editorial

A Future for Surgical Critical Care?

JOHN A. WEIGELT, M.D., F.A.C.S.

From the Department of Surgery, University of Texas Health Science Center, Dallas, Texas

CRITICAL CARE MEDICINE is an exciting new medical specialty to some and a bad dream to others. Attempts by the Society of Critical Care Medicine to mold a consortium of specialties into one have been unsuccessful, but, despite this failure, the need for appropriate critical care has not disappeared.[1] The surgical intensive care unit is vital to surgical patients requiring supportive care before and after an ever-widening range of complex procedures. How will surgeons meet the needs of their patients in the intensive care unit? In particular, can academic surgical centers establish surgical critical care as a medical specialty in an educational environment?

Surgical patients are placed in a surgical intensive care unit for many reasons, but, in broad terms, their needs are reduced to organ monitoring, fluid resuscitation, and cardiopulmonary support. Providing immediate care for these patients is often difficult because surgeons are required to spend more time in the operating room performing increasingly difficult, intricate, and time-consuming procedures. One answer to this scenario is to relinquish care of the surgical patient to an intensivist.[2] This option is not acceptable to a surgical education program and is questionably appropriate for excellent surgical care. The converse solution is to have each surgeon care for his or her patients. Unfortunately, time commitments, training, and experience of all surgeons do not make this an attractive solution either. A final choice is to manage these patients with a medical committee, which has already been criticized as self-serving, inefficient, and costly. This dilemma in surgical care will not go away, and we must find a solution within our resources.

The American Board of Surgery is attempting to resolve this problem by establishing a specialty certificate based on training and experience requirements. This is a beginning but cannot be considered an answer. This beginning implies that surgical intensive care should be provided to surgical patients by surgeons. The advantages of surgical involvement include the following: (1) surgical diseases are already known by the critical care consultant; (2) basic surgical principles are similar among operating and critical care surgeons; (3) educational programs can be developed for better surgical education within the basic residency and surgical critical care programs; and (4) surgical patients benefit from a knowledgeable and available provider of critical care.

However, where are these surgeons? At the present only a handful of surgeons practice critical care. This is not surprising because the club is usually entered by doing a critical care fellowship that is commonly designed without operative experience and surgical mentors. This approach is hardly a way to attract young surgeons to a discipline and a poor way to instill faith in a trainee's capability with other surgeons. Our credibility must be established among surgical peers, so that we are viewed as operative surgeons who are active in surgical critical care.[3]

The major disadvantage of having surgeons provide critical care is its similarity to our first option of using

intensivists, to whom the operative surgeon relinquishes his or her patient's care. Although it is similar, it is not the same. Surgeons speaking to surgeons have a better chance of communicating about their patients' problems because of their common backgrounds. Furthermore, the operative surgeon must remain the patient's primary physician and have the final say regarding patient care. The organizational plan is a cooperative team effort with one captain, the operative surgeon. The team players have mutual respect and confidence for one another as they achieve their goal of excellence in surgical critical care. Furthermore, educational programs will benefit because surgical trainees will become familiar with all types of surgical patients requiring critical care.

Can this solution be applied in nonacademic environments? It certainly is possible, but variations of this organizational scheme will be more realistic and will possibly include nonsurgeons as providers of surgical critical care. However, the design of these variations will most certainly be helped if surgical trainees have an organized and favorable experience in surgical critical care provided by their surgical professors.[4]

Unless we begin to develop surgical critical care, the surgeon's role will predictably decrease, despite our vociferous good intentions. Our efforts must be united to avoid internal disputes among specialties fighting for their turf in the surgical intensive care unit.[5] Already an attitude exists that critical care is different among surgical specialties and competency should be controlled by each surgical specialty. This is truly fragmentation of surgery at its best, or worst, and can only serve to guide surgical critical care down a narrow and winding path leading to mediocrity and self-destruction.

Critical care must be embraced as a branch of the tree of surgical knowledge that is practiced by fellow surgeons with an appropriate fund of information. These efforts must be supported by all surgeons and surgical disciplines so that the expertise in perioperative care the surgical critical care specialists possess complements our operative expertise while primary surgeon–patient relationships are respected. This is a tall order but one that can be accomplished if a cooperative approach to surgical critical care is accepted by all surgical disciplines. We must acknowledge surgical critical care as a necessary surgical discipline and establish guidelines to teach surgical critical care within our training programs. Without this recognition, cooperation, and planning it is likely this branch will never bear fruit.

Editorial Review on "A Future for Surgical Critical Care?"

GEORGE F. SHELDON, M.D., F.A.C.S.,* and WARD O. GRIFFEN, JR., M.D., F.A.C.S.†

THE ARTICLE by John A. Weigelt, M.D., "A Future for Surgical Critical Care?", usefully highlights some of the problems and the promise of the Certificate of Added Qualifications in Critical Care. Dr. Weigelt addresses several points of concern now that surgical critical care has evolved into an area of special interest recognized by the American Board of Surgery through a Certificate of Added Qualifications.

Weigelt correctly dismisses as improper the prac- of surgeons relinquishing the postoperative care of their patients to nonsurgeons, even though it is the *modus operandi* in many academic and community medical centers. However, he is concerned about the paucity of surgeons who could properly be called "intensivists." He notes that credibility in critical care by surgeons must be established among surgical and medical peers. A "surgical intensivist" must also be respected as an operative surgeon. A surgeon who has administrative and clinical capabilities in intensive care must have competence equivalent to critical care peers in other disciplines, for example, anesthesiology, internal medicine, and others.

The evolution of intensive care as a specialty has a complex history. Although recovery rooms have become prevalent only in the last 25 years, in 1863 Florence Nightingale observed "it is not uncommon in small country hospitals to have a recess or a small room leading from the operating theater in which the patients remain until they have recovered or at least recovered from the immediate effects of the operation."[1]

In 1923 W. E. Dandy developed the concept at Johns Hopkins of a neurosurgical intensive care unit (ICU). A combined recovery room and ICU was common in some German universities as early as the 1930s. In North America, the first coronary care units were established in 1962. The evolution of cardiac surgery has led to the further development of this concept and further specialization.[2]

In Scandinavia, the mortality rate from respiratory paralysis associated with polio was high in the 1940s. The development of many ventilators evolved because of polio epidemics. The development of dialysis and burn units, as well as other labor-intensive patient care organizations, has logically resulted in people having special expertise.[3-6]

Equally important to skill in intensive care is availability of facilities and number of staff members. Other issues such as cost containment, administrative expertise, and others must be considered in the management of the modern ICU, and, to this end, a National Institute of Health consensus group recently developed standards for ICUs and recommended four category levels based primarily on nurse:patient ratios.[7-10]

Complex professional concerns relating to specialization and fragmentation are part of the debate regarding further specialty designations. Although specialization is a legitimate and useful application of knowledge benefitting patients with special needs, fragmentation frequently must bear the onus of being self-serving. In contrast to both, the concept of additional credentials is more consistent with the background of specialties such as internal medicine, pediatrics, and anesthesia with shorter core training programs than surgery. Nevertheless, today almost 60% of the people finishing residency education in general surgery, which has a 5-year minimal requirement for Board eligibility, opt for additional education. This tends to produce a core of people who wish formal recognition, be it in cardiothoracic surgery, colon and rectal surgery, plastic surgery, surgical critical care, or other specialties. Unfortunately, Added Qualifications are interpreted as essential for issuing credentials by many hospital boards. It is not uncommon for the

† Executive Director, American Board of Surgery.

American Board of Surgery to receive inquiries requesting verification of a Diplomate's education in a special area such as vascular surgery, such inquiry being directed toward making a ruling about privileges in that area and probably requiring the additional certification for these privileges.

As pointed out by Walt, "the central question for surgeons is whether the patient in the surgical intensive care unit is better served by a surgeon or a non-surgeon as the responsible physician and the administrator of the SICU."[1] Unfortunately, available data describing the surgeon's role in the ICU are not extensive. Machiedo (1980) surveyed academic surgical departments in the United States and found the following: (1) 61% had surgeons as surgical intensive care unit (SICU) directors, and 93% were pleased with that arrangement; (2) 84% felt that involvement in the ICU did not detract from a surgeon's central role as an operator; (3) paradoxically, rotations of surgical residents through the ICU were available in only 55% of the programs and usually for only 1 or 2 months while they were junior residents; (4) Fellowships in Critical Care were minimally available; (5) Canadian surgeons, who may have more experience with ICUs than American surgeons, have become comfortable, as have surgeons in the United Kingdom, with anesthesiologists dominating the ICU scene; and (6) most people surveyed felt that Fellowships should, and could, be incorporated into a 5-year surgical residency, and only a minority favored the establishment of a special certificate.[8]

In 1983 the Pre- and Postoperative Care Committee of the American College of Surgeons conducted a broader survey and found out that SICUs were under the direction of surgeons in only 39–61% of the institutions polled. The lower representation was found in not-for-profit private hospitals. This survey suggested that surgeons were delegating the care of patients in the ICU to others, perhaps to other specialists. The survey resulted in additional conclusions: (1) 54% of the respondents agreed that "surgeons are abandoning ICU patients to non-surgical specialists"; and (2) in 50% of the SICUs, residents other than surgery residents might write orders.[14]

The Society for Critical Care Medicine, which includes a surgical section, has continued to be interested in a special certificate.[12,13] A Joint Committee for Critical Care Medicine, composed of representatives from the American Boards of Anesthesiology, Internal Medicine, Pediatrics, and Surgery, was first formed in 1979 to address the issue of additional certification in critical care. The Committee's deliberations over several years identified preliminary requirements and a method of application and even produced a number of questions to be used on a written examination. However, in 1983 the American Board of Internal Medicine withdrew from the joint committee, followed shortly by the withdrawal of the American Board of Pediatrics. The committee collapsed. The individual Boards then considered applying to the American Board of Medical Specialties separately for permission to award an additional certificate in critical care.

At the American Board of Surgery, the discussions were pointed and often heated and revolved around two opinions: (1) critical care and general surgery are synonymous and therefore no critical care certificate was needed; and (2) if other Boards were going to award a critical care certificate, the Diplomates of the American Board of Surgery should have access to a similar certificate. The latter opinion received the majority vote at the June 1984 meeting. In 1985, the four previously mentioned specialty Boards were granted permission to award a Certificate of Special Qualifications in Critical Care. This was subsequently changed by the American Board of Surgery to a Certificate of Added Qualifications in Surgical Critical Care. It is important to note that in all four proposals regarding critical care certification, the American Board of Medical Specialties insisted on a statement that the person who is the patient's primary physician must remain so, regardless of who is caring for certain features of the patient's care or where the care is rendered.

There are multiple objectives associated with the decision by the American Board of Surgery to award a Certificate of Added Qualifications in Surgical Critical Care. One is to assure the level of preparation of the surgeon in order to continue to care for the "sick patient." Moreover, we must maintain our ability to care for our patients in all locations, with the same capabilities that will be available from other specialists. One beneficial feature of the decision to offer a Certificate of Added Qualifications in Critical Care will be the renewed involvement of surgeons in critical care as an educational process.

The Residency Review Committee for Surgery has focused attention on education in critical care. With the rapid growth of group practice, more cross-coverage and team care is occurring in the practice of surgery. Many group practices have people within the group who bring different special contributions to a practice. Expertise in critical care is an appropriate additional dimension. Research in the arena of critical care has long been a focus of activities of surgical investigators. Our understanding of shock, resuscitation, infection, nutrition, fluid and electrolytes, immunology, and other areas are greatly enhanced and stimulated by the "living laboratory" of the ICU.

Again, citing Walt, "The task of caring for the critically ill is not one for the amateur, for the unavailable, for the narrow-minded, and probably not for the imperious or ignorant. To the extent that we do not fit these categories, we are assured of our place in the surgical intensive care unit unless we resign it by default. If we were to be displaced from the surgical intensive care unit by cognitive gurus, this would feed and confirm the prejudice of those who wish to promote the picture of the surgeon as a technician."[1]

In this day of the "arms race" of Added Qualifications and Special Certificates, the best approach to the issue of critical care certification is to work toward enhanced education in the ICU setting for general surgery residents. However, a segment of our surgical residents should be encouraged to follow a pathway beyond first certification leading to Added Qualifications in Surgical Critical Care. To do less would be to abandon an essential feature of the care of patients with life-threatening illness.[15]

Book Reviews

William P. Longmire, Jr., M.D.
Advisor for Editorial Board
Los Angeles, California

H. Kim Lyerly, M.D.
Advisor for Residents in Surgery
Durham, North Carolina

Cardiac Surgery, 2nd Edition, in the series **Cardiovascular Clinics.** Dwight C. McGoon. 446 pp. Philadelphia: F. A. Davis Co. 1987. $75.00.

THIS BOOK admirably reflects the unique credentials and qualifications of the editor. The 22 chapters arranged in six sections are written by surgeons who, like Dwight McGoon, have immense practical experience, a scholarly appreciation of cardiac surgical science, and a capability for clear and concise exposition. The result is a volume of genuine merit that provides a highly readable synopsis of current cardiac surgical capability across the entire breadth of the discipline.

The prologue and epilogue by Dr. McGoon provide parameters of historic evolution and visions of the future from his perspective as a practitioner, innovator, author, and editor. The section on coronary heart disease contains eight chapters. Remaining sections are dedicated to valvular disease, congenital heart disease, aortic diseases, operative and postoperative developments, and emerging advances consisting of two to four chapters each.

There is some variation in style between chapters but none in quality. Reference lists with each chapter are well selected and remarkably complete without being tediously long. Illustrations are of excellent quality and sufficiently numerous to adequately elucidate many recent advances in technique, although the book is not designed to be an atlas.

The particular strength of this book is the achievement of a concise summary of a broad range of topics covering the entire field of cardiac surgery without being either incomplete or superficial. With 423 pages it is of manageable size for a briefcase.

This book is ideal for the practicing cardiologist or cardiology fellow wishing to grasp the essence of modern cardiac surgery. For experienced cardiac surgeons it will provide a painless review because the authors took the time to be brief. For cardiac surgical residents, registrars, and fellows it represents a rare opportunity to gain a knowledge of practice and perspective in the most rapidly progressing surgical specialty, which has yet emerged in medical practice.

JOHN J. COLLINS, JR., M.D.
Boston, Massachusetts

Surgical Treatment of Congenital Heart Disease, 3rd Edition. Grady L. Hallman, Denton A. Cooley, Howard P. Gutgesell. 235 pp. Philadelphia: Lea & Febiger. 1987. $45.00.

THIS POPULAR TEXT by Drs. Denton A. Cooley and Grady L. Hallman (1st Edition, 1966) has been revised and published as a 3rd Edition. This new volume includes a third author, Dr. Howard P. Gutgesell, a pediatric cardiologist who has substantially expanded the sections on diagnosis, in particular echocardiography and cardiac catheterization. Another important addition is the excellent chapter on the surgical treatment of cardiac dysrhythmias. Throughout the book, the reproductions of the x-rays, cine angiograms, and echocardiograms are of the highest quality; the drawings of the various surgical techniques are lucid and focus on the most important steps of the operations.

Although the authors in the preface to the latest edition recognize the trend towards early primary intracardiac correction of congenital cardiac defects in the very young, including the neonate, the text reflects, however, a more conservative attitude. Two-stage approach, *i.e.,* palliative operation early in life followed by a later repair, is advocated for a number of defects causing critical disease in infancy, such as tetralogy of Fallot, transposition of the great arteries (with or without VSD), truncus arteriosus, and others. Repair of transposition of the great arteries by Mustard operation, for example, is recommended at 12 months of age after initial palliation with either a balloon atrial septostomy or, if necessary, by blade septostomy in contrast to the current trend to repair in infancy, preferably by arterial switch.

Certainly, for a few remaining lesions such as single ventricle, hypoplastic left heart syndrome, with or without aortic atresia, pulmonary atresia with intact ventricular septum, and tricuspid atresia, a two-stage approach remains the only option at this time. Unfortunately, these challenging surgical problems were either not included at all in this text or were dealt with in a very abbreviated fashion under the common rubric of miscellaneous anomalies.

Another important trend in the management of congenital heart disease to which the authors do not allude, is the treatment in many centers of some of the simple lesions, *i.e.,* patent ductus arteriosus, pulmonary and aortic valve stenosis, by enterprising pediatric cardiologists rather than surgeons. Invasive catheterization techniques, such as balloon catheter dilation of stenotic aortic and pulmonary valves and also of stenosis of pulmonary or systemic arteries have proven very effective. Our pediatric cardiology colleagues are also very successful in manipulating umbrella-like devices to obliterate patent ducti (except in the premature neonate) and in implanting various types of coils to occlude aortopulmonary collaterals or other residual (including surgical) shunts.

Dr. Cooley and his associates have accumulated a very large experience with cardiac transplantation. It is therefore surprising and regretable that the authors did not include a chapter on heart and heart-lung transplantation in the pediatric age group.

Finally, it would have been useful for the reader to be offered a breakdown of the operative and late mortality statistics. Obviously, the overall results reflect the pioneering effort of this world-renowned institution in the development of surgery for congenital heart disease. Consequently, a higher operative mortality is to be expected. However, much has improved over the ensuing years, including the early and late surgical mortality for most congenital heart defects. By presenting the global mortality, the reader cannot appreciate the historic evolution of improved surgical results nor can one gain insight into present day expectations and standards of care.

According to this distinguished group of authors, *Surgical Treatment of Congenital Heart Disease* was not meant to offer an exhaustive review of every aspect of congenital heart disease, but was meant to describe the techniques that are in daily use for the management of the more common lesions treated at the Texas Heart Institute. Within this context, this superbly illustrated and well-documented atlas fulfills its goal.

ALDO R. CASTANEDA, M.D.
Boston, Massachusetts

The Soft Tissue Sarcomas. Frederick R. Eilber, Donald L. Morton, Vernon K. Sondak, James S. Economou. 316 pp. Orlando: Grune & Stratton, Inc. 1987. $69.50.

THIS TOME of 22 chapters represents a comprehensive treatise of soft tissue sarcomas edited by recognized oncologic authorities from UCLA. The editors have organized the first comprehensive volume that addresses the clinicopathologic features and management for soft tissue sarcomas of various organ sites.

The Soft Tissue Sarcomas provides a descriptive, highly readable, well-organized approach to the epidemiology, staging, and clinical considerations for management of these rare neoplasms. These highly complex lesions are classified with pathologic descriptions offered for the various tissue types. Authors address the considerations of history (*e.g.*, site, size, growth rates, etc.) as an important overall assessment of disease. Approaches to obtain appropriate pathologic tissues with needle-biopsy/aspiration cytology techniques *versus* open biopsy are described with regard to operative planning. All photomicrographs are black and white but provide adequate depiction of salient histology. A section reviews staining characteristics, immunopathology, and electron microscopy that differentiate sarcoma variants and correlates these parameters with light microscopy. A summary of the clinicopathologic features of the principle soft tissue sarcomas represents a major feature of the text and should be of considerable value to the pathologist and the surgeon.

A chapter devoted to radiologic diagnostic modalities for sarcomas includes: conventional radiography of the chest, tomography, xeroradiography, and ultrasonography. Representative illustrations of these modalities are excellent and enhance the text. Separate sections consider computed tomography, magnetic resonance imaging, angiography, and lymphangiography. Although brief and descriptive, these state-of-the-art modalities enhance the diagnostic capability to allow operative planning and place in perspective the role of comprehensive evaluation *before* surgical intervention.

The authors consider conventional and investigational chemotherapy for these tumors and the results for available single agents. Chemotherapy protocols recommended for the management of low-grade spindle, high-grade spindle cell, small cell, and pleomorphic sarcomas are reviewed. Additionally, a section comprehensively discusses radiation therapy and radiobiology for the various cell types. Authors develop the concept of dose-response curves and the effectiveness of radiation to control subclinical disease. The overall advantages of radiation therapy alone *versus* its combination with surgery is objectively reviewed in the preoperative and postoperative setting. This section briefly enumerates response rates of chemotherapy given as an adjuvant before operation.

The student of this disease will appreciate the comprehensive discussion of sarcomas for various anatomic sites (nervous system, head and neck, lung, chest wall and trunk, breast, cardiac, gastrointestinal tract, hepatobiliary, genitourinary, gynecologic, retroperitoneum, and extremities). Review of each of these organ-specific sarcomas includes the diverse clinical presentations, diagnosis, staging, and clinical management. Most sections are thorough and well supported with illustrations and a comprehensive bibliography. Authoritative approaches for the therapy of pulmonary metastases and the management of pediatric sarcomas are included. Such difficult challenges are considered in a concise, articulate, and scholarly manner. Potential application of immunotherapy is presented from a historic and therapeutic standpoint.

Overall the text is carefully organized and structured to provide the clinician and pathologist involved with the care of soft part sarcomas a well-referenced, contemporary approach to the diagnosis and management of this neoplasm. It is recommended to the surgeon as the definitive textbook on soft tissue sarcomas.

KIRBY I. BLAND, M.D.
Gainesville, Florida

Manual of Critical Care. Frank B. Cerra. 802 pp. St. Louis: C. V. Mosby Co. 1987. $24.95.

THIS BOOK'S preface states that the care of the critically ill patient has produced a multidisciplinary fund of knowledge and experience. A stated goal of the book is to begin the dissemination of this common knowledge to the student, resident, fellow in training, and surgical practitioner. This goal is achieved.

The book is divided into four parts: (1) general principles of physiology and metabolism of ICU patients; (2) organ dysfunction; (3) systemic dysfunction; and (4) therapeutics. An outline style is used, although some chapters are more completely outlined than others. The metabolic, arrhythmia, cardiac pacing, renal dysfunction, and hepatic dysfunction chapters are examples of complete outlines. The remaining chapters are good, although the pulmonary dysfunction and central nervous system chapters are not as detailed as the rest. The outline form is easy to read and should allow the book to be used as a quick reference. In some areas, further reading will be necessary, but the text does give an adequate reference list at the end of each chapter.

The content is generally excellent. Many diverse facts and figures are now obtainable in this simple compact text. When appropriate, such as in the airway chapter, the reader is instructed in the basic principles of how, what, why, and where. At other times the content is dedicated to difficult problems with diagnosis or therapy such as in the discussion of different modes of ventilation and weaning the difficult patient. The multiple charts outlining common problems, their causes, and ideas for correction is another strong area.

Some therapeutic content might be questioned as local habit of the individual authors. Problem areas include the discussion of pneumatic antishock garments, use of platelets, and use of fresh frozen plasma. However, these criticisms are small compared to the vast areas of knowledge the book covers.

I believe this book will be invaluable to the surgical trainee involved with critically ill patients and it will give the surgical practitioner a glimpse of a rapidly developing new field in surgery. I believe it will be a valuable addition to your practical surgical library.

JOHN A. WEIGELT, M.D.
Dallas, Texas

Notice to Contributors and Subscribers

ANNALS OF SURGERY is a monthly journal which considers for publication original articles in the field of surgery. It is the oldest continuously published journal in the English language solely devoted to the surgical sciences. The Editorial Board considers only papers judged to offer significant contributions to the advancement of surgical knowledge.

CONTRIBUTIONS. Four typed copies of the manuscript and four copies of the illustrations should be sent prepaid to the Chairman of the Editorial Board of Annals of Surgery.

David C. Sabiston, Jr., M.D.
Annals of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina 27710

Annals of Surgery has joined a number of other leading Medical Journals which endorse the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." These Requirements were established by an agreement among a number of Editors of Clinical Journals in the United States, Canada and the United Kingdom. The Criteria for preparation of manuscripts are as follows:

SUMMARY OF REQUIREMENTS

Type manuscript double spaced, including title page, abstract, text, acknowledgments, references, tables, and legends.

Each manuscript component should begin on a new page, in this sequence:

Title page
Abstract and key words
Text
Acknowledgments
References
Tables: each table, complete with title and footnotes, on a separate page
Legends for illustrations

Illustrations must be good quality, unmounted glossy prints usually 12.7 by 17.3 cm (5 by 7 in.) but no larger than 20.3 by 25.4 cm (8 by 10 in.).

Submit the required number of copies of manuscript and figures (*see* journal's instructions) in heavy-paper envelope. Submitted manuscript should be accompanied by covering letter, as described under "Submission of Manuscripts," and permissions to reproduce previously published materials or to use illustrations that may identify subjects.

Follow journal's instructions for transfer of copyright.

Authors should keep copies of everything submitted.

PREPARATION OF MANUSCRIPT

Type manuscript on white bond paper, 20.3 by 26.7 cm or 21.6 by 27.9 cm (8 by 10½ in. or 8½ by 11 in.) or ISO A4 (212 by 297 mm) with margins of at least 2.5 cm (1 in.). Use double spacing throughout, including title page, abstract, text, acknowledgments, references, tables, and legends for illustrations. Begin each of the following sections on separate pages: title page, abstract and key words, text, acknowledgments, references, individual tables, and legends. Number pages consecutively, beginning with the title page. Type the page number in the upper right-hand corner of each page.

Manuscripts will be reviewed for possible publication with the understanding that they are being submitted to one journal at a time and have not been published, simultaneously submitted, or already accepted for publication elsewhere. This does not preclude consideration of a manuscript that has been rejected by another journal or of a complete report that follows publication of preliminary findings elsewhere, usually in the form of an abstract. Copies of any possibly duplicative published material should be submitted with the manuscript that is being sent for consideration.

TITLE PAGE

The title page should contain [1] the title of the article, which should be concise but informative; [2] a short running head or footline of no more than 40 characters (count letters and spaces) placed at the foot of the title page and identified; [3] first name, middle initial, and last name of each author, with highest academic degree(s); [4] name of department(s) and institution(s) to which the work should be attributed; [5] disclaimers, if any; [6] name and address of author responsible for correspondence about the manuscript; [7] name and address of author to whom requests for reprints should be addressed, or statement that reprints will not be available from the author; [8] the source(s) of support in the form of grants, equipment, drugs, or all of these.

ABSTRACT AND KEY WORDS

The second page should carry an abstract of not more than 150 words. The abstract should state the purposes of the study or investigation, basic procedures (study subjects or experimental animals and observational and analytic methods), main findings (give specific data and their statistical significance, if possible), and the principal conclusions. Emphasize new and important aspects of the study or observations. Use only approved abbreviations (*see* list of Commonly Used Approved Abbreviations elsewhere in this document).

Key (indexing) terms: Below the abstract, provide and identify as such, three to 10 key words or short phrases that will assist indexers in cross-indexing your article and that may be published with the abstract. Use terms from the Medical Subject Headings list from *Index Medicus* whenever possible.

TEXT

The text of observational and experimental articles is usually—but not necessarily—divided into sections with the headings Introduction, Methods, Results, and Discussion. Long articles may need subheadings within some sections to clarify their content, especially the Results and Discussion sections. Other types of articles such as case reports, reviews, and editorials are likely to need other formats, and authors should consult individual journals for further guidance.

Introduction: Clearly state the *purpose* of the article. Summarize the rationale for the study or observation. Give only strictly pertinent references, and do not review the subject extensively.

STATEMENT OF OWNERSHIP, MANAGEMENT AND CIRCULATION
(Required by 39 U.S.C. 3685)

Date of Filing—October 1, 1987

Title of Publication—Annals of Surgery

Publication No. 026260

Frequency of Issue—Twelve Issues Per Year—Monthly

Subscription Price—$53.00

Location of Known Office of Publication—2350 Virginia Ave., Hagerstown, MD 21740

Location of the Headquarters of General Business Offices of the Publisher—East Washington Square, Philadelphia, PA 19105

Publisher—J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105

Editor—David C. Sabiston, Jr., M.D., Dept. of Surgery, Duke University Medical Center, Durham, NC 27710

Managing Editor—Ann S. Kishbaugh, East Washington Square, Philadelphia, PA 19105

Owner—J. B. Lippincott Company, East Washington Square, Philadelphia, PA 19105

Known Bondholders, Mortgagees and other security holders owning or holding 1 per cent or more of total amount of bonds, mortgages or other securities: Harper & Row Publishers, Inc., 10 East 53rd St., New York, NY 10022

	Average No. Copies Each Issue during Preceding 12 Months	Actual No. of Copies of Single Issues Published Nearest to Filing Date
A. Total no. copies printed (*net press run*)	20,025	19,200
B. Paid circulation		
1. Sales through dealers and carriers, street vendors and counter sales	—	—
2. Mail subscriptions	18,081	17,844
C. Total paid circulation	18,081	17,844
D. Free distribution by mail, carrier or other means. Samples, complimentary, and other free copies.	524	462
E. Total distribution (*sum of C and D*)	18,605	18,306
F. Copies not distributed		
1. Office use, leftover, unaccounted, spoiled after printing	1,420	894
2. Returns from news agents	—	—
G. Total (*sum of E & F—should equal net press run shown in A*)	20,025	19,200

Subject Index to Volume 206 (July–December 1987)

A

Abdominal wall defects, expanded PTFE patch in, 765
Abdominoperineal resection, compared to sphincter-saving procedure in rectal carcinoma (*Letters*), 224
Adipocyte lipolysis, adrenergic control of, 744
Adrenergic control of adipocyte lipolysis, 744
Aging, and survival after trauma, 738
Albumin in cardiopulmonary pump prime solution, substitute for, 210
Ammonia production, intestinal, after blood meals, 5
Anastomosis
  coloanal, in rectal disease, 600
  colonic, blood flow in, 335
  femoral, false aneurysms in, 168
  gastrointestinal, complications of, 138
  ileal pouch–anal, in ulcerative colitis, 504
  straight ileoanal, with endorectal pullthrough, 595
Aneurysm, false, femoral anastomotic, reoperation for, 168
Angioplasty
  percutaneous
    of dialysis fistulas, 777
    transluminal, results of, 403
  vein patch, during carotid endarterectomy, 628
Animal studies
  assessment of endorectal pullthrough procedures, 586
  cellular immunity in cholestasis, 578
  cyclosporine nephrotoxicity, 655
  dose-responsive model of smoke inhalation injury, 89
  lymphocyte participation in wound healing, 25
  magnetic resonance imaging of muscle flaps and jejunal grafts, 624
  pulmonary hypertension and leukosequestration, 642
  pulmonary leukosequestration in hind limb ischemia, 162
  small intestine role in ammonia production, 5
  thyroid hormone affecting muscle metabolism in sepsis, 18
  vascular allograft rejection, 757
Antibiotics, prophylactic
  in cardiac surgery, 791
  and prothrombin response to warfarin, 155
Anticoagulants, and antibiotics affecting prothrombin response to warfarin, 155
Antilymphocyte serum in cyclosporine-treated renal allograft recipients, 649
Aorta, ascending, origin of right pulmonary artery from, 102
Aortic valvotomy in congenital aortic stenosis, 496
Aspirin, esophageal stricture from, 173
Atherosclerosis, and effects of intravenous anticholesterol solution, 296
ATP-magnesium chloride in cyclosporine nephrotoxicity, 655
Autoimmune disease, upper extremity ischemia in, 521

B

Bacteria
  adherence to vascular graft materials, 612
  and formation of pigment gallstones, 242
  phagocytosis of, fibrin affecting (*Letters*), 681
Bactericidal activity of neutrophils affected by burn blister fluid, 340
Bile gastritis, duodenal switch procedure in, 414
Bile vomiting, and enterogastric reflux (*Letters*), 233
Biliary tract
  cellular immunity in cholestasis, 578
  cholelithiasis in cirrhotic patients (*Letters*), 683
  detection of choledocholithiasis with intraoperative ultrasonography or cholangiography, 53
  operative choledochoscopy in acute cholangitis, 142
Billroth anastomoses in pancreatoduodenectomy, and postoperative cholecystokinin levels, 148
Biopsy of liver, ultrasonography-guided, 728
Blood flow in colonic anastomoses, 335
Bone marrow transplantation in neuroblastoma, 514
Book reviews, 114, 222, 385, 551, 679, 814
Burns
  blister fluid affecting neutrophil function in, 340
  immature T-cell phenotypes in, 564
  lipolysis in, 214

C

Calculi
  choledochal, detection with intraoperative ultrasonography or cholangiography, 53
  cholelithiasis in cirrhotic patients (*Letters*), 683
  and operative choledochoscopy in acute cholangitis, 142
  sepsis in pigment gallstone disease, 242
Calf compression, external pneumatic, 636
Carcinoid tumors, malignant, 115
Cardiopulmonary bypass, pump prime solutions in, 210
Carotid endarterectomy, vein patch angioplasty with, 628
Caterpillar Corporation system for reimbursement of physicians, 349
Cefamandole, prophylactic, in cardiac surgery, 791
Cefazolin, prophylactic, in cardiac surgery, 791
Chemotherapy
  cyclosporine in
    nephrotoxicity of, 655
    for renal allograft recipients, antilymphocyte serum with, 649
  intra-arterial, in recurrent hepatoma, 40
  regional versus systemic 5-fluorodeoxyuridine in liver tumors, 685
Chest injuries, blunt, 200
Cholangiography, intraoperative, compared to ultrasonography in detection of bile duct stones, 53
Cholecystokinin levels, pancreatoduodenectomy affecting, 148
Choledochoscopy, operative, in acute cholangitis, 142
Cholelithiasis
  in cirrhotic patients (*Letters*), 683
  pigment, in sepsis, 242
Cholestasis, cellular immunity in, 578
Cholesterol levels, intravenous anticholesterol solution affecting, 296
Cirrhosis
  carcinoma with, esophagogastrectomy in, 74
  cholelithiasis in (*Letters*), 683
  and emergency portacaval shunt for variceal hemorrhage, 48
  and regeneration of liver after major resection, 30

Colitis, ulcerative
  ileal pouch–anal anastomosis in, 504
  straight endorectal pullthrough in, 595
Collagen type III formation in wounds, 752
Coloanal anastomosis in rectal disease, 600

Cortisol levels, postoperative, indomethacin affecting, 770
Critical care medicine, future of (*Editorial*), 125-A
Cryolesions, cardiac, as model of myocardial wound healing, 798
Cyclosporine
  nephrotoxicity of, 655
  for renal allograft recipients, antilymphocyte serum with, 649

D

Dextran 70 infusions with 7.5% NaCl in severe injuries, 279
Diabetes mellitus
  control with gastric bypass, 316
  and effects of whole pancreas or islet transplants, 324
Dialysis
  and angioplasty of access fistulas, 777
  and PTFE grafts for access, 666
Drainage
  in gastric bypass surgery, 134
  open, in infected pancreatic necrosis, 542
  in pyogenic liver abscess, 699
Drug-induced esophageal strictures, 173
Duodenojejunostomy, proximal end-to-end, in duodenogastric reflux, 414
Duodenum, and pancreatoduodenectomy
  affecting cholecystokinin levels, 148
  gastrobulbar preserving, 717

E

Editorial, 809
Electrocardiogram, and placement of subclavian vein catheter tip (*Letters*), 226; (*Letters*), 682
Embolization in recurrent hepatoma, regional chemotherapy with, 40
Endarterectomy, carotid, with vein patch angioplasty, 628
Endorectal pullthrough
  assessment of four procedures in, 586
  straight ileoanal anastomosis with, 595
Endoscopy
  in colonic volvulus, 1
  colonoscopy in rectal bleeding, 606
  operative choledochoscopy in acute cholangitis, 142
Endothelial removal in vascular allografts, 757
Epinephrine
  and lipolysis in burns, 214
  postoperative excretion affected by indomethacin, 770
Esophagogastrectomy in carcinoma with cirrhosis, 74
Esophagus
  blood supply of, 184
  cancer of, high-dose photoirradiation of, 193
  computerized axial manometry of, 465
  jejunal interposition for benign disease (*Letters*), 682
  palliative exclusion of, motor function in, 787
  replacement by gastric transposition in children, 69
  strictures of, drug-induced, 173
  variceal bleeding in
    emergency portacaval shunt for, 48
    shunts versus sclerotherapy in, 261

F

Fasciitis, necrotizing, treatment of, 661
Fat
  lipolysis in burns, 214
  metabolism in trauma and sepsis, 744
  oxidation affected by biosynthetic growth hormone, 56
Fee schedule, access-oriented negotiated, 349
Femoral anastomotic false aneurysm, reoperation for, 168
Fever, postoperative, indomethacin affecting, 770
Fibrin, and phagocytic killing of Escherichia coli (*Letters*), 681
Fibrinolytic activity affected by external pneumatic calf compression, 636
Fluid administration, and infusions of 7.5% NaCl/dextran 70 in severe injuries, 279
5-Fluorodeoxyuridine infusions, regional versus systemic, in liver tumors, 685

5th Annual International
Breast Cancer Seminar
Presented in Cooperation with the American Cancer Society
MIAMI
March 24 - 26, 1988
HOTEL INTER•CONTINENTAL MIAMI

Join 14 leading specialists from all over the world at this post graduate seminar. They will be discussing the latest developments in the diagnosis and treatment of all forms of breast disease.

Participants include:
JOHN BOSTWICK, III, M.D.
Emory Clinic, Section of Plastic and Reconstructive Surgery, Atlanta, Georgia
DIANA BRINKLEY, M.D.
Consultant in Radiotherapy and Oncology, London
AMAN U. BUZDAR, M.D.
Professor of Medicine, Medical Breast Service, University of Texas, M.D. Anderson Hospital, Houston, Texas
ROBERT CALLAHAN, Ph.D.
Chief, Oncogenetics Section, Laboratory of Tumor Immunology and Biology, National Cancer Institute
GARY M. CLARK, M.D.
University of Texas, Health and Science Center, Department of Medicine/Oncology, San Antonio, Texas
ISAIAH J. FIDLER, D.V.M., Ph.D.
Professor and Chairman, Department of Cell Biology, M.D. Anderson Hospital and Tumor Institute, Houston, Texas
BERNARD FISHER, M.D.
Distinguished Service Professor, Department of Surgery, University of Pittsburgh, School of Medicine
ROBERT L. GOODMAN, M.D.
Professor and Chairman, Department of Radiation Therapy, University of Pennsylvania School of Medicine
FRANK E. GUMP, M.D.
Chief, Breast Service, Columbia-Presbyterian Medical Center, New York
DANIEL KOPANS, M.D.
Director of Breast Imaging, Harvard Medical School
LANCE LIOTTA, M.D.
Pathology Department, National Cancer Institute
SUSAN M. LOVE, M.D.
Director of Breast Clinic, Beth Israel Hospital, Boston
BERNARD PIERQUIN, M.D.
Chief, Dept. Cancerologie, Henri Mondor Hospital, France
LASZLO TABAR, M.D.
Mammography Dept., Central Hospital, Falun, Sweden
Approved for 17 hours of Category I Credit.

THE CLEVELAND CLINIC FOUNDATION

presents

The Seventh International Endoscopy Symposium:
Endoscopic Treatment of Esophageal Varices

A comprehensive and practical discussion of endoscopic approaches to the treatment of esophageal varices.

MARCH 14-17, 1988

Stouffer Orlando Resort Orlando, Florida

Michael V. Sivak, Jr., M.D.
Symposium Director

GUEST FACULTY
John P. Cello, M.D
Jacob Korula, M.D.
K.J. Paquet, M.D.
R.A.J. Spence, M.D., F.R.C.S.
Professor John Terblanche
Walter L. Trudeau, M.D.
Gregory Van Stiegmann, M.D.
David Westaby, M.D.

ONCOLOGY FELLOWSHIPS AT NIH

The National Cancer Institute, National Institutes of Health, Public Health Service, is accepting applications for fellowships in oncology. Positions are available to physicians who have completed at least two years of training in internal medicine, pediatrics, or surgery.

The medical oncology training program offers 3-year fellowships beginning July 1, 1988 and July 1, 1989. This 3-year program consists of one year of primary clinical responsibility on the medical oncology, pediatric oncology, and radiation oncology services of the National Cancer Institute. The second and third years consist of an individualized program of laboratory research and clinical investigations and continued outpatient clinical experience. Fellowships satisfy subspecialty Board requirements for Medical Oncology and Pediatric Hematology-Oncology.

The Surgery Branch offers a two-year surgical oncology fellowship program beginning July 1, 1988 and July 1, 1989. This program consists of 6 months of patient care and 1½ years of laboratory research with the senior staff of the Surgery Branch. A third year of continued laboratory experience is available to selected Fellows.

Emphasis is placed on continuity of patient care, principles of patient management, and design and conduct of clinical trials. Seminars, lectures and conferences deal with a variety of related subjects including biostatistics, immunology, epidemiology, cell biology, cell kinetics, molecular biology, virology, genetics, clinical pharmacology, diagnostic pathology, and radiobiology.

The laboratory aspects of the program are directed at training Fellows to become independent investigators. Topics under study include cell kinetics, endocrine aspects of cancer, clinical pharmacology of antineoplastic agents, tumor immunology, cell biology and molecular biology, viral oncogenesis, hematopoietic differentiation and genetics. In addition, there is ample opportunity for participation in clinical investigations. Medical Staff Fellows will be assigned to civil Service positions with an annual salary of $30,000 and an increase of $2,000 for each additional year up to a maximum of $34,000. Medical Staff Fellows will receive all benefits including health insurance, life insurance options, vacation and sick leave. In addition, moving, travel expenses for the Fellow and Federal health care benefits are available. For further information and application procedures, please contact:

Samuel Broder, M.D., Deputy Clinical Director
National Cancer Institute, National Institutes of Health
Public Health Service, Bldg. 10, Room 12N214
Bethesda, Md. 20892
(301) 496-4251

Deadline for applications is January 15, 1988.

DORNIER
DORNIER MEDICAL SYSTEMS

Dornier Medical Systems recently placed an advertisement in this publication referring to a gallstone lithotripter currently under clinical evaluation by Dornier in Germany. The gallstone lithotripter has not yet begun clinical trials in The United States. The Dornier Gallstone Lithotripter is a Class III Medical Device under The Medical Device Amendments of 1976 to the Federal Food, Drug and Cosmetic Act. The device will become commercially available in the United States only if Pre-market Approval is obtained from the U.S. Food and Drug Administration.

"Absolutely. The Meadox® Woven Double Velour."

Reduces surgical time and preparation. . .

In the world of grafts, there are several advantages only a true hybrid, like the Meadox Woven Double Velour can offer. Easy and controllable *in situ* preparation—we call it *Quick-Prep*—is one. Then there's its low porosity combined with high strength. . . plus a weave so unique you won't think you're handling and suturing a woven graft at all. But that's only half the story.

And improves your patient's prognosis

This versatile graft is, in fact, a unique high strength woven offering true, low profile velour healing properties — such as thorough tissue ingrowth, a well anchored neointima, and excellent long-term patency.[1] All of this is available in a selection of 30 sizes . . . more than enough to make it your first all-around choice.

So try the Meadox Woven Double Velour. It's the only one that lets you opt for healing *plus* convenient preparation . . . *instead of one or the other.* Call us for the details and to arrange for an evaluation.

It's the Meadox Woven Double Velour

Turning the material advantage into a clinical edge
